23 **Running title:** Emotional semantic variant frontotemporal dementia.

24 **Keywords:** Right temporal lobe predominant neurodegeneration; loss of empathy and nonverbal
25 semantics, person-specific knowledge, frontotemporal dementia; FTLT-TDP type C.

26 **Abbreviations:**

27 bvFTD = behavioral variant frontotemporal dementia; esvFTD = emotional semantic variant
28 frontotemporal dementia; FTD = frontotemporal dementia; FTLT = frontotemporal lobar
29 degeneration; rATL = right anterior temporal lobe; lATL = left anterior temporal lobe; sd =
30 standard deviation; svPPA = semantic variant primary progressive aphasia; TDP-43 = transactive
31 response DNA binding protein 43

32 **Abstract:**

33 It has been proposed that focal anterior temporal lobe (ATL) degeneration is a specific, unitary
34 FTLT-DTP-related disease that initially preferentially affects the left or right hemisphere. Patients
35 with early left ATL (LATL) atrophy show severe anomia and verbal semantic deficits and meet
36 criteria for semantic variant primary progressive aphasia (svPPA) and semantic dementia,
37 prompting appropriate neurological care. There is less consensus regarding the symptoms in right
38 ATL (rATL) predominant cases, who most often present with behavioral and emotional changes
39 leading to a misdiagnosis of a psychiatric disorder, and later of behavioral variant frontotemporal
40 dementia (bvFTD). Uncertainties regarding early symptoms and lack of an overarching framework
41 continues to hinder proper diagnosis and care of patients with rATL disease. Here, we present
42 symptom chronology, cognitive and socioemotional profiles of a large, well-characterized,
43 longitudinally followed cohort of patients with rATL-predominant degeneration and propose new
44 criteria and nosology for the syndrome.

45
46 We identified individuals with a clinical diagnosis of bvFTD or svPPA and a structural MRI
47 (n=478). Based on neuroimaging criteria, we identified three groups: patients with rATL-
48 predominant atrophy with relative sparing of the frontal lobes (n=46), patients with frontal-
49 predominant atrophy with relative sparing of the rATL (n=79), and patients with LATL-
50 predominant atrophy with relative sparing of the frontal lobes (n=75). Seventy-eight patients had
51 undergone autopsy. We analyzed patients' clinical, neuropsychological, genetic, anatomical, and
52 pathological profiles.

53
54 In the rATL-predominant group, the earliest symptoms were loss of empathy (27%), person-
55 specific semantic impairment (23%), and complex compulsions and rigid thought process (18%).
56 On testing, this group exhibited greater impairments in emotional theory of mind, identifying
57 famous people from names and face, and facial affect naming (despite preserved face perception)
58 than the LATL- and frontal-predominant groups. The clinical features were highly sensitive (81%)
59 and specific (84%) in differentiating rATL from bvFTD in the first three years of the disease.
60 FTLT-DTP (84%) was the most common pathology.

61
62 Our results suggest that rATL-predominant degeneration is characterized by early loss of empathy
63 and person-specific knowledge, deficits that are caused by progressive loss of semantic memory
64 for concepts of social-emotional relevance. Although this syndrome exists along a clinical,
65 anatomical, and pathological continuum with svPPA, patients present with progressive behavioral
66 changes. To facilitate early identification and care in clinical and research settings, we propose
67 specific diagnostic criteria and the term "emotional semantic variant frontotemporal dementia" to
68 distinguish this syndrome from other forms of frontotemporal dementia.

69

70

71

72

73

74 **Introduction**

75 The term “frontotemporal dementia” (FTD) was introduced to encapsulate the progressive
76 personality changes, social conduct impairment, and language deficits associated with atrophy of
77 the frontal and temporal lobes.¹ Within FTD, behavioral symptoms often localize to frontal,
78 temporal, insular, and striatopallidal regions in the right hemisphere, whereas language deficits
79 typically localize to structures in the left.² Currently, the behavioral syndrome associated with
80 FTD is referred to as “behavioral variant frontotemporal dementia” (bvFTD), and the language
81 syndromes are brought together under the term “primary progressive aphasia” (PPA).

82
83 The syndromes that target the anterior temporal lobe (ATL) are often initially asymmetric, with
84 focal atrophy targeting either the right ATL (rATL) or left ATL (lATL),^{4,5} and thus have distinct
85 early clinical presentations. Patients with lATL-predominant atrophy typically have notable
86 language deficits, which were well-represented in the consensus clinical criteria for semantic
87 dementia and more recently for semantic variant PPA (svPPA).^{6,7} Although these criteria do
88 include semantic deficits for objects and faces, they primarily emphasize verbal semantic deficits
89 that result in anomia, single word comprehension deficits, and object-identification impairments,
90 and do not highlight socioemotional and behavioral deficits and thus overlooking the important
91 symptoms resulting from rATL degeneration.

92
93 Patients with focal atrophy of the rATL, exhibit prominent emotional changes and behavioral
94 symptoms that can be hard to distinguish from those of bvFTD, and may not initially have
95 significant aphasia symptoms.^{4,8–13} Although in the early stages of disease, atrophy may be
96 asymmetric and target the ATL unilaterally, over time the disease spreads to the contralateral
97 hemisphere, and language and behavioral symptoms converge.^{4,13,14} As both lATL- and rATL-
98 predominant degeneration are typically associated with frontotemporal lobar degeneration -
99 transactive response DNA binding protein 43 type C (FTLD-TDP type C) pathology,⁵ lateralized
100 ATL presentations are thought to reflect different manifestations of a single pathological
101 continuum.^{4,15–19} Studies that have investigated the clinical characteristics of rATL-predominant
102 degeneration find that patients show difficulties recognizing familiar people and empathizing with
103 others.^{4,11,20–22} Diminished empathy—which can include lack of emotional responsiveness as well
104 as decreased social connection and compassion—is often remarkable when disease targets the

105 rATL.^{11,23–26} Neuroimaging studies have associated rATL atrophy with deficits in a wide range of
106 socioemotional functions including empathy,²³ nonverbal social cue (e.g., sarcasm) detection,²⁷
107 and facial emotion recognition.^{28,29} Feelings of familiarity that known others typically elicit may
108 also rely preferentially on the rATL,²⁸ which suggests that even friends and family members may
109 lose their affective significance to patients with rATL-predominant dysfunction.

110
111 By integrating information from primary and association sensory and motor cortices, the ATLs are
112 considered amodal hubs that represent all categories of semantic knowledge.^{15,18,30–34} Though there
113 is strong evidence for bilateral ATL contribution to semantic conceptual knowledge, specialization
114 is hypothesized to appear as a result of divergent inputs from right and left hemispheres.^{19,35–38}
115 Whereas the lATL would bind verbal features into semantic conceptual knowledge through strong
116 connections with linguistic networks, the rATL may be more centrally involved in representing
117 nonverbal semantic knowledge through its prominent connections with right-sided socio-
118 emotional networks.^{16,32,39,40} According to this framework, lATL degeneration would disrupt
119 verbal semantic knowledge, such as word comprehension and retrieval, and rATL degeneration
120 would degrade nonverbal, socially-relevant semantic knowledge in individuals with typical
121 hemispheric functional lateralization. Consistent with this hypothesis, nonverbal semantic
122 knowledge tasks, including visual semantic associations;⁴¹ identification of living beings (animals
123 are recognized mainly by their visual features);³⁹ sound recognition;⁴² and tactile,¹⁷ olfactory,⁴³
124 and gustatory stimulus recognition have all been linked to rATL.⁴⁴ Importantly, nonverbal
125 semantic processing is also necessary for the recognition and identification of familiar and famous
126 people from faces and voices.^{28,42} By extension, the rATL is also hypothesized to link emotion
127 concepts with visual associations as well as non-verbal bodily changes (e.g., changes in autonomic
128 nervous system functioning, motor activity, and experience), thus serving as the core hub for
129 socioemotional semantic processing.^{31,45,46} Although patients with rATL-predominant
130 degeneration are often described as having “prosopagnosia,” this term does not fully capture the
131 deficit, because patients cannot recognize familiar people from visual (face), linguistic (name), or
132 auditory cues (voices), indicating a broader semantic deficit for biographical, person-specific
133 semantic knowledge.⁴⁷ This lateralized specialization is observed in individuals known to have
134 left-brain language dominance, non-right-handed patients can present with reverse
135 symptomatology if they have reversed hemispheric dominance.^{25,48}

136

137 Despite these advances in theoretical understanding of right and left ATL functions, studies
138 systematically testing both semantics and socioemotional functions in large well-characterized
139 cohort of patients are still lacking. Furthermore, there is no consensus on a set of diagnostic criteria
140 for the rATL-predominant syndrome, and patient symptomatology has not been clearly linked to
141 theoretical cognitive models. Patients with rATL-predominant atrophy pose a nosologic challenge
142 as they can have symptoms that overlap with the diagnostic criteria for svPPA and semantic
143 dementia,^{6,49} which emphasize verbal semantic deficits, and bvFTD, which focus on behavioral
144 and emotional features.⁵⁰ Lacking formal nomenclature or diagnostic criteria, patients with rATL-
145 predominant degeneration are described with terms such as right temporal svPPA, right temporal
146 semantic dementia, right temporal bvFTD, and right temporal variant FTD.^{4,8-10,47,51-53} Because
147 loss of empathy is often misinterpreted as a psychiatric symptom and because there are no clinical
148 criteria for the rATL-predominant syndrome, these patients are often identified later in the disease
149 course, when severe behavioral impairment often justifies a diagnosis of bvFTD. Furthermore, the
150 current conflation of rATL-predominant and bvFTD syndromes may cause unnecessary confusion
151 about patients' underlying neuropathology, which is much more heterogeneous in bvFTD, and
152 thus will make the selection of a disease-modifying treatment more difficult for clinicians as
153 pathology-specific drugs become common in the near future. Diagnostic criteria that would
154 facilitate the early identification of rATL-predominant patients would also accelerate studies of
155 nonverbal semantics and allow for the development of reliable measures that track these
156 socioemotional changes in neurodegenerative illnesses.

157

158 The goal of the present study was to examine the clinical, neuropsychological, genetic, anatomical,
159 and pathological characteristics of a large cohort of patients with rATL-predominant atrophy.
160 Patients were studied within a multidisciplinary project on FTD-spectrum disorders that included
161 comprehensive assessments of both language and socioemotional functioning. Based on the
162 results, we propose new diagnostic criteria for a rATL-predominant syndrome that is on a
163 continuum with, but qualitatively and quantitatively distinct from, both bvFTD and lATL-
164 dominant svPPA syndromes as currently defined. To evaluate the validity of these criteria, we
165 compared these rATL patients to those with frontal-predominant bvFTD and lATL-predominant
166 svPPA, as determined by clinical and neuroimaging criteria. We hypothesized that patients with

167 rATL-predominant damage would have a specific pattern of early semantic memory loss for socio-
168 emotionally relevant, non-verbal concepts, such as famous people and emotions, also resulting in
169 typical behavioral symptoms such as loss of empathy. We expected that lack of empathy would be
170 a prominent feature, and that other bvFTD behavioral symptoms (e.g., disinhibition, apathy/inertia,
171 and lack of judgment/dysexecutive symptoms) would be less common. We also anticipated that
172 patients with rATL-predominant degeneration would have some characteristic symptoms of
173 svPPA (e.g., word comprehension and confrontational naming difficulties) but that these would be
174 comparatively mild and would often not meet general PPA diagnostic criteria (i.e., aphasia as the
175 most prominent early clinical feature and the principal cause of functional impairment).

176

177 **Materials and methods**

178 **Participants:**

179 We identified patients who met bvFTD and/or svPPA criteria (see below) and had research visits
180 between 1998 and 2019 (n = 682) at the University of California, San Francisco (UCSF) Memory
181 and Aging Center (MAC). As symptoms were often mild at early research visits, scores on the
182 Clinical Dementia Rating scale (CDR) were not used when determining study inclusion.⁵⁴ Patients
183 who did not have a brain MRI within one year of the first research evaluation were excluded (n =
184 204). From the remaining 478 cases, we used structural neuroimaging measures to identify
185 individuals with predominant rATL atrophy and relative preservation of the frontal lobes (see
186 details below) (n = 46). We also included three other groups for comparison: a group of individuals
187 with lATL-predominant atrophy and relative preservation of the frontal lobes (n = 75), a group of
188 individuals with frontal-predominant atrophy and relative preservation of the rATL (n = 79), and
189 a group of healthy older controls from the MAC Hillblom Healthy Aging Network (n = 59). We
190 used strict clinical and anatomical inclusion criteria to contrast the rATL patients with these three
191 groups and to clarify the distinct cognitive-behavioral phenotype of the rATL-predominant
192 syndrome. Patients or caregivers provided informed consent following procedures aligned with
193 the Declaration of Helsinki, and the study was approved by the UCSF Committee for Human
194 Research.

195

196 **Diagnostic criteria:**

197 Two raters, a behavioral neurologist (KY) and a neuropsychologist (MM), reviewed all available
198 medical data for the rATL-predominant patients to determine whether they met the following
199 diagnostic criteria: 1) Neary-FTD,⁶ 2) Neary-Semantic,⁶ 3) bvFTD,⁵⁰ and 4) svPPA.⁴⁹ We also
200 noted whether patients had semantic variant features (i.e., impaired confrontation naming and
201 single-word comprehension) regardless of meeting PPA general criteria (i.e., aphasia is the most
202 prominent deficit in early disease).⁴⁹ This allowed us to describe verbal semantic deficits in
203 patients who had predominantly behavioral presentations. The two raters determined whether each
204 of these criteria was met at three different time points: 1) within the first three years of disease
205 onset, 2) at the first MAC research evaluation, and 3) in the years subsequent to the first MAC
206 evaluation.

207

208 **Detailed symptom taxonomy and chronology:**

209 All research participants were evaluated by a behavioral neurologist, a neuropsychologist, a speech
210 and language pathologist, and a nurse. A clinical history was obtained from each patient, with
211 corroboration from the caregiver/informant, and began by identifying the nature and onset of the
212 first symptoms. This was followed by a chronological history of how symptoms evolved, and then
213 a detailed inventoried review of the domains of memory, language, executive function,
214 visuospatial abilities, behavior, sleep, sensory processing, and motor function. Patients did not
215 need to present for evaluation at the same stage of the disease in order for the retrospective
216 interview to fully capture the chronology of symptoms.

217

218 We documented each patient's first five symptoms, rather than all symptoms ever noted, because
219 we expected many of the canonical bvFTD symptoms (disinhibition, apathy, loss of empathy,
220 compulsions, hyperorality, and executive deficits) and PPA symptoms (language and semantic
221 impairment) would emerge for most people in the disease's later stages. In an effort to refine our
222 categorization of the behavioral and emotional symptoms, we catalogued symptoms according to
223 the following taxonomy:

- 224 1. Loss of empathy: Difficulty recognizing, understanding, or responding to others' emotions
225 and needs; selfishness; emotional distance from others; reduced or inappropriate emotional
226 expressivity, diminished social interest, interrelatedness, or personal warmth.

- 227 2. Words and object semantic loss: Loss of knowledge about words, facts, concepts, animate
228 or inanimate objects, places, or landmarks. Patients may demonstrate impaired naming,
229 diminished recall, poor identification, or reduced feelings of familiarity for these domains.
- 230 3. Person-specific semantic knowledge loss: Loss of knowledge about known faces, proper
231 names, and people (including biographical information about famous people, close friends,
232 and/or family members). Patients may demonstrate impaired naming, diminished recall,
233 poor recognition, or reduced feelings of familiarity for these domains.
- 234 4. Complex compulsions and rigid thought process: Adhering to fixed schedules or roles,
235 preoccupation with dogmas (e.g., hyper-religiosity) or health (hypochondriasis), restricted
236 preference for certain colors, clothing, or diet, spending hours playing word games and
237 puzzles.
- 238 5. Simple repetitive behaviors, hoarding, or obsessions: repetitive motor (e.g., clicking,
239 tapping, pacing) or verbal stereotypies, hoarding, or preoccupation with objects or people.
- 240 6. Apathy/inertia: Cognitive (reduced planning and voluntary action), behavioral (reduced
241 self-initiated thoughts and behaviors), and affective (reduced social, emotional, behavioral
242 interest) forms of apathy.⁵⁵
- 243 7. Disinhibition: Impulsivity or socially inappropriate behavior, loss of manners or decorum.
- 244 8. Lack of judgment/dysexecutive: Rash or careless actions, judgment mistakes that are out
245 of character. Of note, in the current bvFTD criteria,⁴⁹ lack of judgment is considered as a
246 part of disinhibition, but for this study we separated these two symptoms as they may be
247 subserved by different neuroanatomical systems.⁵⁶
- 248 8. Episodic memory loss: Difficulty remembering recent events and autobiographical
249 information.
- 250 9. Hyperorality or dietary changes: Altered food preferences, binge eating, increased
251 consumption of alcohol or cigarettes, oral exploration, or consumption of inedible objects.
- 252 10. Motor neuron disease signs: Bulbar and limb signs of motor neuron disease.
- 253 11. Other symptoms: Visuospatial difficulties, declined hygiene, loss of sexual desire, dietary
254 changes (increased or decreased eating), weight gain, weight loss, hypersomnia, and
255 insomnia. These symptoms are either common in other neurodegenerative illnesses or not
256 specific for a single neurodegenerative disease.
- 257

258 **Functional, cognitive, and behavioral assessments:**

259 Patients underwent a comprehensive multidisciplinary assessment that included functional,
260 neuropsychological, and socioemotional measures, Table 1 and Table 2, as previously
261 described.^{11,57} A description of the cognitive battery and further details about patients' performance
262 are presented in the Supplementary material. Verbal semantic knowledge was evaluated with the
263 Peabody Picture Vocabulary Test (PPVT; patients were asked to choose the picture that best
264 describes a word),⁵⁸ the abbreviated 15-item Boston Naming Test (BNT; patients were asked to
265 name different drawings),⁵⁹ and semantic verbal fluency (patients generated as many animals as
266 possible in 60 seconds). Nonverbal semantic knowledge was tested with the picture version of the
267 Pyramids and Palm Trees (PPT-P; patients matched semantically associated pictures).⁶⁰

268 We assessed multiple domains of socioemotional functioning with a battery of task-based
269 measures. Visual face perception was evaluated with the identity-matching subtest of the
270 Comprehensive Affect Testing System (CATS), in which patients determined whether pairs of
271 neutral faces were from the same person or different people.⁶¹ The ability to label emotional facial
272 expressions with words was tested with the CATS emotion identification task, in which patients
273 chose the emotion term that matched the facial expression depicted in a photograph from a list of
274 multiple choice options.⁶² On the abbreviated version of the Emotion Evaluation Test (EET) from
275 The Awareness of Social Inference Test (TASIT), patients identified the target emotion from a list
276 of multiple choice options that were displayed by actors in short video clips. On the TASIT Social
277 Inference–Minimal Test (SIM), patients were asked to detect sarcasm of actors in videos through
278 interpretation of social cues including prosody, facial expression, and gesture. Theory of mind
279 (ToM)—the ability to infer the thoughts, emotions, and intentions of others—was tested in
280 cognitive (i.e., the ability to identify first and second order object knowledge of actors in videos)
281 and emotional modalities (i.e., the ability to identify first and second order emotion knowledge of
282 actors in videos) using the UCSF theory of mind Test.⁶³ Person-specific semantic knowledge was
283 evaluated using the UCSF Famous Faces Naming test (a free response task in which patients
284 named photographs of famous people's faces), Semantic Famous Face Association test (patients
285 matched famous faces based on their professions), Semantic Famous Name Association test
286 (patients matched written names of famous people based on their professions), and Semantic
287 Famous Face Recognition test (patients chose the famous face among four faces)^{11,64} Further
288 socioemotional testing details are found in the Supplementary material.

289
290 Informant-based measures were also obtained to assess patients' socioemotional behavior in
291 everyday life. Informants rated patients' current cognitive empathy (i.e., perspective taking) and
292 emotional empathy (i.e., empathic concern) using the Interpersonal Reactivity Index (IRI).⁶⁵
293 Sensitivity and responsiveness to others' subtle emotional expressions were rated by informants
294 using the Revised Self-Monitoring Scale (RSMS).⁶⁶ Interpersonal coldness, warmth, and
295 dominance, areas of personality known to be affected in FTD, were evaluated with informant
296 ratings on the Interpersonal Adjective Scales (IAS).⁶⁷ Behavioral inhibition (i.e., behaviors
297 associated with response avoidance and sensitivity to threat) and behavioral activation (i.e.,
298 behaviors associated with approach motivation including reward responsiveness, drive, and fun-
299 seeking) systems were evaluated with informant ratings on the Behavioral Inhibition
300 System/Behavioral Activation System (BIS/BAS) questionnaire.⁶⁸

301

302 **Structural neuroimaging analyses:**

303 We processed structural T1-weighted images, as previously described.^{69,70} W-score maps (W-
304 maps) were generated by comparing each patient's gray matter maps to 534 neurologically healthy
305 older controls from the MAC Hillblom Healthy Aging Network (age range 44-99 years, $M \pm SD$:
306 68.7 ± 9.1 ; 220 male/302 female), adjusted for age, sex, total intracranial volume, and magnet field
307 strength. Mean W-score values were extracted for each region of interest (ROI) in the probabilistic
308 Desikan atlas. W-scores have a mean value of 0 and a standard deviation (SD) of 1; values of +1.65
309 and -1.65 correspond to the 95th and 5th percentiles and indicate regions with larger and smaller
310 gray matter volume compared to the normative sample, respectively.

311

312 Patients were included in the rATL-predominant degeneration group if their lowest three W-scores
313 were in right temporal regions, and they had relative preservations of the frontal lobes based on an
314 atrophy index described as follows. For each patient with rATL maximum atrophy, we calculated
315 the mean W-score of all frontal lobe ROIs and the mean W-score of all right temporal ROIs and
316 computed a proportion with the following index: *right temporal index* = *mean whole frontal w-*
317 *score/mean right temporal w-score*. The rATL-predominant degeneration patients who had an
318 index < 0.50 were included in this study (n = 46) (Fig. 2 and Supplementary Table 1). A similar
319 approach was used to select the comparison groups. Patients were included in the frontal-

320 predominant group if their lowest three W-scores were in the frontal regions, and they had relative
321 preservation of the right temporal regions based on an atrophy index (mean frontal W-map score /
322 mean right temporal W-map score > 0.50). Patients were included in the lATL-predominant group
323 if their lowest three W-map scores were in the left temporal regions, and they had relative
324 preservation of the frontal lobes based on atrophy index (mean frontal W-map score / mean left
325 temporal W-map score < 0.50). We implemented this index for the lATL instead of a right / left
326 temporal laterality index in order to match the rATL and lATL patients based on their degree of
327 accompanying frontal involvement.

328
329 Patients were excluded if they did not meet either the predominant atrophy or the atrophy index
330 requirements. Patients were excluded if their lowest W-scores were not in the rATL, frontal lobe,
331 or lATL (n = 164; four cerebellar, 65 mixed (i.e., lowest three W-scores were in different lobes),
332 62 subcortical, and 33 posterior (i.e., parietal or occipital lobes)), or if their greatest atrophy was
333 in the rATL, lATL, or frontal lobes but did not meet the atrophy index inclusion threshold (total n
334 = 114; 41 with maximum atrophy in rATL but frontal / right temporal > 0.5, 29 with maximum
335 atrophy in the frontal lobe but frontal / right temporal < 0.5, and 44 with maximum atrophy in the
336 lATL but frontal / left temporal > 0.5).

337
338 Recognizing that each of the groups included in this study did not show atrophy merely in one
339 isolated brain region (for instance, patients typically have bilateral ATL volume loss by the time
340 they present for imaging evaluation), we qualify our descriptions by using the term “predominant”
341 to refer to the patient group with maximum atrophy in the one region that is out of proportion to
342 the other regions. Thus, we acknowledge that the brain atrophy pattern of our “rATL-predominant”
343 group also includes frontal and left temporal regions to varying degrees, but these patients
344 unequivocally present with maximum atrophy in the rATL. Similarly, the “lATL-predominant”
345 refers to the patient group with maximum atrophy in the lATL that is out of proportion to the
346 frontal and rATL atrophy. The term “frontal-predominant”, likewise, is used to refer to the patient
347 group with maximum atrophy in the frontal lobes that is out of proportion to the ATL atrophy. The
348 atrophy of each group as shown in Figure 2 extends beyond the regions of maximum atrophy and
349 as such symptoms could be due to atrophy in the other regions involved or multiple parts of the
350 connected networks”

351 **Genetic and neuropathological data:**

352 Participants were screened for the following genetic mutations: *PGRN*, *MAPT*, *TARDBP*, *C9orf72*,
353 *APP*, *PSEN1*, *PSEN2*, *FUS*, and *APOE*. In the patients who underwent autopsy, brains were
354 processed and analyzed according to the UCSF Neurodegenerative Disease Brain Bank protocol.⁷¹
355 In short, eight micro-thick formalin-fixed paraffin-embedded tissue sections from 23 tissue blocks
356 were cut to represent 27 regions of interest. All blocks underwent routine hematoxylin and eosin
357 staining, and subsets underwent immunohistochemistry for hyperphosphorylated tau, amyloid- β ,
358 TDP-43, alpha-synuclein, and 3R-tau antibodies. Neuropathological diagnoses were based on
359 consensus criteria.⁷²⁻⁷⁴

360

361 **Statistical analysis:**

362 Tests of normality for all continuous data were conducted with the Shapiro-Wilk test.
363 Homogeneity of variance was tested by Levene's test. Statistical differences in the frequency of
364 categorical variables across groups such as clinical symptoms and APOE genotype were
365 performed with the Chi-Square test. Means of demographic measures (Table 1) were compared
366 across groups with the ANOVA test. Means of functional, neuropsychological, language, and
367 socioemotional measures (Tables 1 and Table 2) were compared with the ANCOVA test correcting
368 for age, sex, and disease severity as measured by the Mini-Mental State Exam (MMSE). Because
369 of the unequal sample sizes and unequal group variances, pairwise post hoc comparisons were
370 done with estimated marginal means and Bonferroni-Sidak adjusted probabilities to correct for
371 multiple comparisons, with $p < 0.05$ set as the threshold for statistical significance. Data analysis
372 was performed with SPSS (version 27, SPSS/IBM, Chicago, IL). Table 1 and Table 2 show
373 estimated marginal means, standard errors, and statistical significance after correcting for age, sex,
374 and disease severity as measured by MMSE. When using ANCOVA and estimated marginal
375 means for post hoc between groups analysis, the individual datapoints cannot be graphically
376 plotted, for visualization purposes we show in Figure 4 the uncorrected datapoints, means, and
377 standard deviations for key socioemotional measures.

378 **Data availability:**

379 The data for this study is available upon request. The sensitive nature of patients' data and the
380 institutional ethics protocols in place at the time these patients gave informed consent do not permit
381 open data sharing. The clinical and neuroimaging data used in the current paper are available from
382 the senior author (MLGT), upon formal request indicating name and affiliation of the researcher
383 as well as a brief description of the use that will be done of the data. All requests will undergo
384 UCSF-regulated procedure thus requiring submission of a Material Transfer Agreement (MTA).
385 No commercial use would be approved.

386

387 **Results**

388 **Demographic features:**

389 Table 1 shows the demographic information. Although the sex distribution was not different
390 between healthy control and the patient groups, the healthy controls were older than all of the
391 patient groups. Patients in all cohorts were highly educated with an average over 15.5 years of
392 education. In the rATL-predominant group, 91% were White and 9% were Asians, a proportion
393 that was not different from other groups. In the rATL cohort (n = 46), the average age of onset
394 (60.2 years and sd = 6.8 years). In the rATL-predominant group, 52% of the patients were men
395 and 15% were non-right-handed. On average, rATL-predominant patients were in the mild to
396 moderate range of disease severity; at the first research visit, the average MMSE score (25.7/30;
397 sd = 5.2) was higher than the other disease groups. The CDR for the rATL group (average score
398 0.9/3; sd = 0.5) was lower than the lATL-predominant group but not different from the frontal-
399 predominant group. We used age, sex, and MMSE as confounds in all later analyses.

400

401 **Diagnostic criteria and clinical symptom chronology:**

402 During the first three years of the illness, only a minority of patients in the rATL-predominant
403 group met diagnostic criteria for Neary-FTD (13%), Neary-semantic dementia (9%), bvFTD
404 (27%), or svPPA (13%). Approximately one third of the group had verbal svPPA features (i.e.,
405 impaired confrontational naming and object knowledge) but did not meet the general criteria for
406 PPA (36%) because aphasia was not the initial and predominant symptom. At the time of the first
407 research evaluation at the MAC (average 5.3 years after disease onset), these percentages were

408 higher: Neary-FTD (52%), Neary- semantic dementia (11%), bvFTD (83%), svPPA (16%), and
409 semantic variant features (78%) (Supplemental Table 2).

410
411 The clinical histories revealed that, when combining all symptoms that emerged during the first
412 three years of the illness, the most common symptoms for patients with rATL-predominant
413 degeneration were loss of empathy (27%), loss of person-specific semantic knowledge (23%),
414 complex compulsions and rigid thought process (18%), and loss of verbal semantic knowledge
415 (13%) (Fig. 3). The sequence of the first two symptoms in rATL-predominant patients is shown in
416 Supplemental table 3.

417
418 Caregiver-reported examples of loss of empathy included decline in the ability to understand and
419 respond to others' emotions and needs (e.g., not consoling a family member who lost a parent or
420 was diagnosed with a terminal illness, making tactless comments in a funeral, asking a crying child
421 why their eyes were watering, and becoming more self-centered). In our experience, often, loss of
422 empathy toward others can be interpreted by caregivers as selfishness. Examples of loss of person-
423 specific semantic knowledge included not recognizing familiar people by the face or voice, not
424 recalling biographical information of a famous person, and not knowing patients' own relationship
425 to familiar people. Examples of complex compulsions and rigid thought process included
426 adherence to rigid time schedules; dogmatism; hypergraphia; hypochondriasis; restricted color,
427 clothing, diet, game, or puzzle preferences. Less commonly, patients exhibited simple repetitive
428 motor or speech behaviors or hoarding behaviors. Examples of loss of verbal semantic knowledge
429 included difficulty understanding word meaning or recognizing objects.

430
431 When rATL-predominant patients had both person-specific and verbal semantic knowledge loss
432 (32 patients [69%]), the person-specific semantic knowledge symptoms were reported to precede
433 the verbal semantic complaints in 24 patients (75%). Five patients (10%) had person-specific
434 semantic knowledge symptoms without verbal semantic complaints, and six patients (14%) had
435 verbal semantic complaints without person-specific semantic knowledge complaints. Only three
436 patients (6%) had neither person-specific nor verbal semantic knowledge complaints.

437

438 While these initial symptoms in the rATL-predominant group emerged within the first three years
439 of disease onset, additional symptoms (fifth, sixth, and beyond) arose as the disease progressed.
440 Four years after disease onset, common symptoms included apathy and disinhibition. For these
441 two symptoms, differences in reporting created ambiguity. Apathy was explicitly documented in
442 the medical history as a clinical complaint of 11 patients, whereas on the NPI (Supplementary
443 Table 5), apathy was noted in 39 patients, indicating a discrepancy between what caregivers report
444 during the interview with the behavioral neurologist and when answering the NPI questions.
445 Interestingly, the item of apathy on the NPI appeared mainly in the context of affective apathy
446 questions rather than cognitive inertia or autoactivation/behavioral apathy and thus these behaviors
447 could also be interpreted as loss of empathy. This potentially explains the discrepancy between
448 clinical history and NPI with regards to apathy reporting and highlights the need for incorporating
449 loss of empathy questions into the NPI. On history, disinhibition was reported in 23 patients,
450 whereas on the NPI it was coded in 36 patients. In the majority of patients, disinhibition appeared
451 as insensitivity to social context rather than as an impulse-control deficit, for instance making
452 funny comments in a funeral rather than approaching strangers or engaging in dangerous activities.
453 By history, episodic memory impairment, executive symptoms, dietary changes, motor neuron
454 disease, and problems navigating were less frequent and happened later in the disease course. With
455 regards to the less commonly reported symptoms in the rATL-predominant group, five patients
456 (11%) had loss of sexual desire, two as an early symptom. Irritability was reported in eight patients
457 (17%) and as an early symptom only in three patients (6%). Increased eating (7 patients, 8%) did
458 not reach the degree of binge eating, oral exploration or consumption of inedible objects. Sleep
459 changes, increased or decreased sleep, happened in five cases (10%), three of which were in the
460 first year of disease onset.

461
462 In comparison, the early symptoms in the frontal-predominant group were lack of
463 judgment/dysexecutive symptoms (24%), apathy (21%), and disinhibition (17%), as shown in Fig
464 3 and Supplementary Table 4. In the lATL-predominant patients, the early symptoms were verbal
465 semantic knowledge loss (36%), person-specific knowledge deficits (16%), and rigid thought
466 process (18%). Loss of empathy occurred significantly more often in rATL- compared to frontal-
467 and lATL-predominant patients ($\chi^2 = 22, p <.001$ and $11.2 p <.001$, respectively). Deficits in
468 person-specific knowledge were significantly more common in rATL- than frontal-predominant

469 patients ($\chi^2 = 56.1, p < .001$) but not lATL-predominant patients ($\chi^2 = 3.32, p < .68$). Similarly,
470 complex compulsions and rigid thought process was significantly more frequent in rATL-
471 compared to frontal-, but not lATL-predominant groups ($\chi^2 = 19.54, p < .001$ and $\chi^2 = 1.03, p =$
472 0.3 , respectively). In contrast apathy, disinhibition, and lack of judgment/dysexecutive symptoms
473 were significantly more common in frontal- than rATL- and lATL-predominant patients ($\chi^2 = 11.5,$
474 $p < .001, \chi^2 = 5.2, p < .02, \chi^2 = 18.8, p < .001$, respectively).

475 **Functional, cognitive, and behavioral results:**

476 Table 1, Table 2, and Figure 4 show the neuropsychological and socioemotional results.
477 Neuropsychological testing demonstrated that, at presentation to the MAC, patients with rATL-
478 predominant degeneration had severe impairment in both verbal semantic knowledge (on the BNT
479 and PPVT) and nonverbal (visual) semantic knowledge (on the PPT-P). They also had deficits in
480 verbal fluency, with more significant impairment in semantic than in lexical fluency, and on tests
481 of executive functioning. Episodic memory was impaired, and visuospatial processing was intact.
482

483 On tests of socioemotional functioning, rATL-predominant degeneration patients had severe
484 deficits in multiple domains. On the CATS, a static face perception test, although they had no
485 difficulty with face identity-matching, their emotion labeling was impaired, suggesting a deficit in
486 emotion recognition. Patients also had difficulty labeling the emotions of others in videos (TASIT-
487 EET) and understanding paralinguistic cues (TASIT-SIM-M). On tests of Theory of Mind, patients
488 had normal cognitive theory of mind scores but impaired emotional theory of mind scores,
489 indicating poor comprehension of others' emotional, but not cognitive, states. On the Famous
490 Faces test, rATL-predominant degeneration patients could not identify the faces, names, or
491 occupations, of famous people, indicating loss of person-specific semantic knowledge rather than
492 prosopagnosia. On informant-based measures, rATL degeneration patients had abnormal scores
493 on multiple measures of behavior and personality. Patients had very low emotional empathy (IRI
494 Empathic Concern), cognitive empathy (IRI Perspective Taking) and socioemotional sensitivity
495 (RSMS). On a personality inventory (IAS), informants rated patients as having low levels of
496 interpersonal warmth and increased interpersonal coldness yet preserved interpersonal dominance.
497

498 Although emotion processing was disrupted in frontal-, rATL-, and, to a lesser degree, lATL-
499 predominant patients (as measured by IRI-ET, IRI-PT, and RSMS), the groups differed in their

500 specific constellations of social and behavioral deficits. While the frontal-predominant patients
501 were impaired on both cognitive and emotional measures, the rATL- and lATL-predominant
502 patients generally showed prominent deficits on the emotional, but not the cognitive, components
503 of socioemotional tasks. Specifically, rATL- and lATL-predominant patients showed preserved
504 cognitive theory of mind but impaired emotional theory of mind, whereas frontal-predominant
505 patients showed impairment on both cognitive and emotional theory of mind (Figure 4 and Table
506 2). Similarly, rATL-predominant patients scored within normal limits, on the TASIT-Sincere task
507 (a cognitive control task that assesses simple comprehension) but below expectations on the
508 TASIT – EET (an emotion naming task) and the TASIT – Simple Sarcasm subscale (a test of
509 paralinguistic cue detection). In contrast, the frontal-predominant group scored below expectations
510 on all three TASIT subsets, suggesting both emotional and cognitive deficits. On informant-based
511 personality measures, the rATL-predominant patients showed increased coldness but preserved
512 dominance, whereas the frontal-predominant patients showed increased coldness (to a lesser
513 degree than rATL-predominant patients) but reduced dominance. Furthermore, rATL-predominant
514 patients showed reduction in both their activation and inhibition systems on the BIS/BAS. Reduced
515 reward sensitivity was associated with reduced drive and fun-seeking in rATL-predominant
516 patients, whereas in the frontal-predominant patients reduced reward sensitivity was associated
517 with higher drive and fun-seeking (Fig 4, Table 2). This incongruence in the frontal-predominant
518 group is consistent with the higher rates of impulsivity, such as making sexual comments, in this
519 group as shown on the NPI (Supplemental table 5).

520
521 With regard to face processing and person-specific knowledge, while all disease groups had
522 difficulty with Famous Faces Naming, only rATL-predominant patients (and to a lesser degree
523 lATL-predominant patients) had impaired scores on the Famous Faces Familiarity and Semantic
524 Association tests (Figure 4 and Table 2). On the CATS Face and Affect Matching, whereas the
525 frontal-predominant patients were impaired on both tests, the rATL-predominant patients had
526 preserved face matching but impaired affect matching. The lATL-predominant patients, in
527 contrast, had intact scores on the Face and Affect Matching tests (Figure 4 and Table 2). The
528 deficits in the rATL group did not appear to be due to broader deficits in visuospatial functioning
529 as only the frontal-predominant patients demonstrated deficits in this area (Benson Figure Copy
530 and Visual Object and Space Perception).

531
532 With regard to verbal semantics, both rATL- and lATL-predominant patients had greater deficits
533 on the BNT than the frontal-predominant group. On episodic memory testing, rATL- and lATL-
534 predominant patients showed worse verbal and visual memory impairment compared to the
535 frontal-predominant group (Fig 4 and Table 2). On executive function tests, rATL- and lATL-
536 predominant patients showed better executive function performance compared to the frontal-
537 predominant group (Fig 4 and Table 1).

538

539 **Genetic and pathology results:**

540 Pathology and genetic results are presented in Tables 3 and 4. Only two of the rATL-predominant
541 patients had a genetic mutation, (one had a *MAPT* mutation, and one had a possibly pathogenic
542 *TARDBP* mutation). Seventeen of the frontal-predominant patients (14 *C9orf72* and three *GRN*)
543 and five lATL-predominant patients (three *MAPT* and two *C9orf72*) had genetic mutations. *APOE*
544 data were available in 40 of the rATL-predominant patients (55% E3/E3; 22% E3/E4; 18% E2/E3).
545 No differences in *APOE* genotypes were found between subgroups with available *APOE data*
546 (Supplementary table 7).

547 See Table 3 and Supplementary Table 6 for the pathology results. Most of the rATL-predominant
548 patients with available autopsy data had FTLN-TDP type C pathology (68%). When considering
549 all types of FTLN-TDP cases, regardless of the neuropathological subtype, the percentage
550 increased (84%). Three patients had FTLN-tau (two FTLN-tau Pick's type, and one patient had
551 FTLN-tau unclassifiable 4R tauopathy). In the rATL-predominant group with autopsy data, three
552 patients did not have loss of semantic knowledge on either history or testing, and, interestingly,
553 none of these three cases had FTLN-TDP type C (two had FTLN-tau Pick's type, and one had
554 FTLN-TDP type B). In the lATL-predominant group, there was also large proportion of patients
555 with TDP-43 pathology, in general, and TDP-43 type C, specifically. This is in contrast to the
556 frontal-predominant group, which showed more heterogeneity in its underlying pathology (51%
557 tauopathy, 22% FTLN-TDP type B, 12% FTLN-TDP type A, and 2% FTLN-TDP type C) (Table
558 3).

559

560 **Sensitivity and specificity of the proposed diagnostic criteria:**

561 Based on the most common early symptoms in the patients with rATL-predominant degeneration,
562 here we propose a new set of diagnostic criteria for this syndrome (Table 4). To test the sensitivity
563 and specificity of these criteria, we contrasted the rATL- and frontal-predominant patients
564 (Supplementary Table 8), groups that are often difficult to disentangle clinically. To avoid
565 circularity, we did not calculate sensitivity or specificity values based on the neuroimaging data
566 because our groups were anatomically defined.^{31,75} In the first three years of the illness, the criteria
567 differentiated the rATL-predominant from the frontal-predominant group with a sensitivity of
568 81.3% and a specificity of 84.2%. The sensitivity increased to 86.0% at the time of the first clinical
569 visit and to 93.0% when considering symptoms across all visits. The specificity was 82.8% at the
570 first clinical visit and 81.4% when considering all visits. We predict that sensitivity and specificity
571 will increase in prospectively collected samples because of the increased probing of nonverbal
572 socioemotional semantics during patient evaluations, and should improve further with the
573 inclusion of patients' neuroimaging information.

574
575 The differential diagnosis of rATL- from lATL-predominant patients is somewhat less difficult in
576 clinical practice, in part because all lATL patients show early word-finding and word-
577 comprehension deficits instead of early behavioral symptoms, and thus are easily classified as
578 having a PPA syndrome. As the disease progresses and neurodegeneration spreads to the rATL
579 and orbitofrontal regions,^{4,13,14} however, the continuum between the two clinical presentations
580 becomes more obvious, as predicted by the same FTLT-DTP pathology. Consistent with this, the
581 proposed criteria showed 76.0% sensitivity and 87.0% specificity in distinguishing rATL- from
582 lATL-predominant patients in the first two years of symptoms and 81.3% sensitivity and 68.2%
583 specificity by the third year. The decrease in specificity by the third year highlights the overlap in
584 disease progression between rATL and lATL degeneration.

585

586 **Discussion**

587 Here, we present the symptom chronology, neuropsychology, and socioemotional features of a
588 large cohort of well-characterized patients with predominant rATL degeneration. These patients
589 demonstrated early loss of person-specific semantic knowledge (i.e., mainly face-based, nonverbal
590 semantic knowledge) and empathy as well as complex compulsions and rigid thought process,
591 while later they showed loss of verbal semantic knowledge and eventually apathy and

592 disinhibition. Cognitive and anatomical data showed that rATL-predominant degeneration disrupts
593 the neural representations sustaining mainly nonverbal semantic knowledge for socioemotional
594 concepts, resulting in early, prominent deficits in empathy, people recognition, and social
595 behavior. This constellation of symptoms reflects dysfunction in underlying neuroanatomical
596 systems that are anchored to the rATL and that overlap with, but are dissociable from, those
597 involved in frontal-predominant bvFTD and lATL-predominant svPPA.^{76,77} As such, this
598 syndrome necessitates a distinct nomenclature, which herein we refer to as “emotional semantic
599 variant frontotemporal dementia” (esvFTD), a term that reflects the continuum with the semantic
600 variant PPA (and its original semantic dementia), while highlighting socioemotional cognition and
601 behavior, and not aphasia, as the most common first symptom. The neuropathological etiology of
602 this clinico-anatomical syndrome is usually FTLN-TDP disease, and most often FTLN-TDP type
603 C. The intention of using this name is to describe both the behavioral and cognitive symptoms of
604 this syndrome rather than use an anatomical label, such as in “right temporal variant,” which may
605 also be inaccurate in non-right-handed individuals. In these clinical criteria, loss of nonverbal
606 socioemotional semantic knowledge is the central deficit (Table 4). The core features include loss
607 of empathy, difficulty identifying and naming known people, and complex compulsions or rigid
608 thought process. Supportive features include object naming difficulties, spared visuospatial
609 functions, and preserved speech production (motor speech and phonology). A diagnosis of
610 probable esvFTD also requires neuroimaging evidence of disproportionate rATL atrophy or
611 hypometabolism. The novel diagnostic classification proposed here help identify symptoms that
612 are most specifically associated with rATL degeneration. Although the socioemotional evaluations
613 sensitive to FTD can be complicated by the cognitive difficulties,⁷⁸ this study suggests that
614 including certain measures such as Famous Faces, CATS, PPVT, PPT-P, emotional and cognitive
615 Theory of Mind, IAS-Coldness, and TASIT in the assessment of patients presenting with
616 behavioral and language symptoms is useful in diagnosing patients with esvFTD.

617
618 As the rATL is a key hub in socioemotional semantic knowledge—the sensorimotor activities,
619 visceral changes, and subjective experiences that are bound into multimodal concepts,^{31,45} we
620 expected that patients with rATL-predominant degeneration would have core deficits in person-
621 specific knowledge. Socioemotional semantic deficits would interfere with their ability to
622 recognize familiar others, attribute meaning to their emotional expressions, and respond

623 appropriately in social contexts.^{4,10,11,13,23} Identification of known people from their face or voice
624 requires person-specific semantic knowledge that incorporates visual and auditory information
625 about what they look and sound like with biographical information about who they are and how
626 they relate to the observer. Consistent with our hypotheses, patients with rATL-predominant
627 degeneration displayed severe impairment on the Famous Faces Naming, Semantic Association,
628 and Familiarity tasks, a pattern consistent with previous reports.²⁰ These deficits differed from
629 classical prosopagnosia, the visual inability to recognize familiar people from their faces only, as
630 the patients with rATL-predominant degeneration were also unable to recognize familiar others
631 from their face, name, voice, biography, or information about their relationship to the patient.^{28,42}

632
633 Loss of empathy was another hallmark feature of patients with rATL-predominant degeneration.
634 Informants who had been close to the patient before disease onset also reported loss of cognitive
635 and emotional empathy, lack of responsiveness to others' emotional expressions, and increased
636 interpersonal coldness (despite preserved interpersonal dominance, a personality profile that
637 distinguished them from the lATL- and frontal-predominant groups). On socioemotional testing,
638 patients with rATL-predominant degeneration had difficulty selecting a label for facial emotional
639 expressions on the CATS emotion identification task, despite preserved face perception on CATS
640 face identity-matching. This pattern differed from the frontal-predominant group who exhibited
641 impaired performance on both subtasks, and the lATL-predominant group who showed no
642 impairment on both subtasks. Understanding others' feelings also requires semantic knowledge
643 about nonverbal stimuli (tone of voice, body position, facial expression) as well as access to
644 autonomic, bodily cues that foster vicarious experience of others' internal states.^{79,80}

645
646 These findings suggest patients with rATL-predominant degeneration have impaired
647 understanding of the semantics of observed facial expressions and are consistent with literature
648 showing disrupted face processing in both lATL- and rATL-predominant patients.⁸¹ Patients with
649 rATL-predominant degeneration also had difficulty labeling emotions in videos of socioemotional
650 scenarios in the TASIT-EET. Although the videos included facial, prosodic, postural, and gestural
651 emotional cues, patients with rATL-predominant degeneration performed poorly on this task,
652 suggesting a multimodal nonverbal loss of emotional cue comprehension. Moreover, patients with
653 rATL-predominant degeneration were impaired at interpreting videos that tested emotional Theory

654 of Mind, despite the fact that the emotions of the characters were explicitly verbally labeled for
655 them throughout the task. Of note is that patients had no trouble interpreting cognitive Theory of
656 Mind videos that relied on perspective-taking focused on physical objects rather than on others'
657 changing emotions. This was in contrast to the frontal-predominant group, who demonstrated
658 impairment on both the cognitive as well as the emotional tasks. Taken together, these findings
659 suggest that rATL-predominant patients' deficits were due to problems understanding emotions,
660 rather than a result of task-specific non-emotional cognitive demands, and showed that their
661 emotion comprehension deficits extend deeper than the retrieval of the name of the emotion.

662
663 rATL- and lATL-predominant atrophy patients commonly exhibited complex, goal-oriented, and
664 time-consuming behaviors and cognitive rigidity. Frontal-predominant patients, however, showed
665 more simple motor repetitive behaviors, hoarding, and obsessions. Compulsive behaviors in
666 bvFTD commonly include aberrant motor behaviors such as tapping and pacing, hoarding,
667 and echolalia and localize to frontal subcortical networks and left lateral temporal lobe.^{82,83}
668 Whereas more complex compulsions such as preoccupation with certain ideas or activities,
669 following fixed schedules, parsimony, and complex rituals were shown to localize to the rATL.⁸⁴
670 Consistently, our rATL patients most commonly exhibited complex, goal-oriented, and time
671 consuming behaviors and rigid thought process.

672
673 In the later phases of disease, patients with rATL- and lATL-predominant degeneration also
674 exhibited apathy and disinhibition, symptoms that are cardinal features of bvFTD. In the frontal-
675 predominant group, conversely, apathy, disinhibition, and poor judgment/dysexecutive symptoms
676 were the most common early symptoms. This suggests that the early symptoms can help
677 distinguish temporal- from frontal-predominant FTD. In FTD, apathy can reflect underlying
678 deficits in cognitive, behavioral, or affective systems that are anchored by the frontal lobes.⁵⁵
679 Disinhibition in FTD can refer to behaviors that reflect a lack of impulse control, imbalanced
680 reward and punishment systems, executive dysfunction, lack of disgust, or difficulty understanding
681 emotional contexts.⁸⁵ The clinical histories of rATL-predominant patients in our cohort suggested
682 that symptoms recorded as apathy and disinhibition differed from typical examples reported in the
683 frontal-predominant group and commonly known for bvFTD. For instance, lack of participation
684 in activities with family or making tactless comments were due to socioemotional semantic deficits

685 rather than apathy or impaired impulse control. By history, the rATL-predominant degeneration
686 patients had early loss of interest in friends and family, were less affectionate, and made tactless
687 comments indicating a disregard for the social context but did not show deficits in impulse control
688 until after year four of illness.

689
690 Early semantic dementia descriptions focused on the prominent verbal semantic deficits resulting
691 primarily from lATL damage,^{6,86,87} the recent use of more comprehensive neuropsychological
692 batteries has yielded data clearly delineating the socioemotional semantic impairments that
693 predominate in the setting of rATL degeneration. The homogeneous pathology in esvFTD patients
694 emphasizes the clinical importance of separating this group from the more pathologically
695 heterogeneous bvFTD, while placing it on a continuum with its svPPA counterpart. esvFTD
696 (behavioral syndrome) and svPPA (language syndrome) are the two extremes of the semantic
697 dementia continuum. Recognizing both the behavioral and linguistic challenges linked to focal
698 ATL atrophy is important to isolate this relatively homogeneous clinico-anatomical-pathological
699 syndrome from the more pathophysiologically heterogeneous frontal presentations. Consistent
700 with studies that showed emotional deficit in svPPA,^{16,88} our findings highlight that socioemotional
701 changes are present in lATL-predominant patients, although they are not the main complaint and
702 are less prominent than in rATL (see Figure 3). Given the common but graded symptomatology
703 between rATL- and lATL-predominant patients, the proposed criteria can be considered an
704 extension of the svPPA definition and refinement of the original semantic dementia description.
705 As disease progresses, the left and right presentations will often merge, and most patients will
706 develop both language and comporment difficulties. The symmetry between lATL and rATL
707 degeneration is likely not a perfect mirror image, however, as one longitudinal study indicated that
708 while lATL patients demonstrated progressive atrophy in the rATL, rATL patients showed further
709 atrophy in right hemisphere regions including orbitofrontal cortex and anterior cingulate cortex.¹³
710 Stronger functional connectivity between the ATL and orbitofrontal regions in the right
711 hemisphere has been found in healthy individuals, which may help to explain these different
712 effects.⁸⁹ While the challenge of mapping the clinical and pathological continua across all FTD-
713 spectrum disorders is well-known and accepted,^{75,90-93} clear diagnostic algorithms are needed to
714 improve early diagnosis, pathological prediction and specialized care and treatment.

715

716 The high frequency of the first two symptoms in the rATL-predominant cohort (loss of empathy
717 and person-specific semantic knowledge) and the deficits on both facial emotion identification and
718 famous faces suggest that the regions subserving face and emotion processing are interlinked and
719 possibly undergo interdependent development during maturation and concordant decay during
720 neurodegeneration. Neurodevelopmentally, the ability to acquire and respond to social and
721 emotional concepts is shown to be linked to accurate interpretation of emotional expressions
722 during early childhood. In fact, recognition of emotional facial expressions is a fundamental aspect
723 of human behavioral neurodevelopment, as infants prefer to look at faces from a very early age,
724 and regulate their actions based on maternal emotional facial expressions.⁹⁴ Furthermore,
725 impairment in recognizing emotional facial expressions is presumed to be one of the mechanisms
726 underpinning the behavioral symptoms in autism spectrum disorder which involves the rATL.^{95–}
727 ⁹⁸ Recent work proposes that developmental factors might influence vulnerability to specific
728 neurodegenerative illnesses and links to specific phenotypic presentations.^{99,100} In particular,
729 previous studies suggest that non-right-handedness is over-represented in svPPA compared to
730 other PPA variants and to the general population.⁹⁹ In our esvFTD cohort, there was also a
731 relatively high prevalence of non-right handedness (15%) compared to the 10% reported in the
732 general population.¹⁰¹ Furthermore, a previous case report described a behavioral presentation in
733 a non-right-handed patient who had left temporal predominant atrophy.⁴⁸ Taken together, this
734 evidence suggests that handedness, and thus lateralization of language and emotion processing,
735 might influence how linguistic and behavioral symptoms associate with ATL atrophy, contributing
736 to phenotypic variation.^{99,100}

737
738 Although loss of empathy is the most common symptom used by clinicians and caregivers to
739 describe the early stages of rATL-predominant degeneration, a previous study suggested a
740 prodromal phase of irritability, emotional distance, and changes in sleep, appetite, and libido.⁴ In
741 the present study we considered the subtle early emotional changes such as becoming more selfish
742 and emotionally distant as part of loss of empathy as these symptoms are likely the subtle early
743 manifestations of socioemotional semantic loss. Libido changes and irritability happened in the
744 context of loss of empathy. Similarly, appetite changes happened in the context of other complex
745 compulsions. Sleep changes happened as a prodromal symptom only in a minority of patients. It

746 is possible that the prevalence of these symptoms is underestimated and masked by the more
747 pressing symptoms by the time patients present for evaluation.

748
749 A recently proposed diagnostic framework for focal rATL degeneration identified memory
750 symptoms and prosopagnosia as key features but did not distinguish between episodic or semantic
751 memory.¹⁰² Our results suggest the deficits in the rATL-predominant group extend beyond
752 classical prosopagnosia and represent a multimodal semantic loss for person-specific concepts, but
753 it is also possible that some rATL-predominant patients may have selective prosopagnosia
754 (without person-specific knowledge) in the very early stage of their illness.¹⁰³ We believe that our
755 large sample size, and comprehensive language and socioemotional testing battery enabled us to
756 derive a more complete and precise depiction of symptoms, while at the same time highlighting a
757 semantic memory deficit as the common underlying mechanism in both esvFTD and svPPA.
758 Defining the nature of memory loss in these patients as mainly semantic rather than episodic is
759 particularly relevant, because including episodic memory deficits as a core diagnostic criterion for
760 rATL degeneration syndrome is likely to cause diagnostic confusion with clinical AD, particularly
761 in settings where AD biomarkers are unavailable.

762
763 This study has several limitations. Although our cohorts of patients were studied prospectively by
764 a multidisciplinary team that included experts in both language and behavior, the retrospective
765 nature of chart reviews is heavily informed by the clinician writing the original report. Given our
766 reliance on patients' and caregivers' recollections of the symptom chronology, it is possible that
767 recall bias may have influenced our findings (though our large sample size makes this less likely).
768 Although it is difficult to ascertain the natural history of early symptoms in rare diseases such as
769 the ones we study here, future collaborative, prospective cohort studies with shared measures and
770 approaches will be imperative for making strides in this area. Another limitation pertains our
771 imaging-based selection criteria, which focused on identifying rATL-predominant cases and
772 excluded cases that had both concomitant severe frontal or lATL atrophy. Additional studies are
773 needed to phenotype the subset of FTD patients with other patterns of atrophy, such as co-
774 occurring right frontal and bilateral temporal damage. In addition, although the rATL syndrome
775 we describe includes prominent atrophy in this area, these patients also have atrophy in a network
776 of regions (e.g., lATL and right insula) connected to the rATL. The atrophy of each group as shown

777 in Figure 2 extends beyond the regions of maximum atrophy and as such symptoms could be due
778 to atrophy in the other regions involved or multiple parts of the connected networks. Future work
779 is needed to further elucidate how structural and functional damage in the rATL and its associated
780 networks relate to the symptoms we detected in this group. Finally, we acknowledge the serious
781 limitation that patients included in this study are mostly white, highly educated, and native English
782 speakers. Further studies that include more diverse patient populations are needed to shed light on
783 the cultural and environmental variability of socioemotional and linguistic presentations in patients
784 with focal ATL degeneration,¹⁰⁴ and will provide clinical tools necessary to capture culture-
785 specific language and emotional stimuli.

786
787 In conclusion, we show that patients with rATL-predominant degeneration show early loss of
788 empathy and person-specific knowledge in relation to damage to the neural systems responsible
789 for non-verbal, socioemotional semantic knowledge. Progression of disease includes language-
790 based semantic loss, highlighting the continuum with the semantic variant of PPA and the original
791 description of semantic dementia. In an effort to improve precise communication, we propose the
792 term “emotional semantic variant frontotemporal dementia (esvFTD)”, emphasizing the cognitive
793 (semantic) and chief clinical (behavioral) features of this disorder. Specific neuropsychological
794 tests that investigate knowledge of emotions, social concepts, and biographical information for
795 known people are important for capturing early esvFTD symptoms and should be included in
796 standard evaluations. Accurate identification of esvFTD patients will pave the way to better
797 prognostication and therapeutics and will help to advance our understanding of the role of
798 nonverbal semantics in human social behavior.

799

800 **Acknowledgements**

801 The authors thank the research patients and their families for the time and effort they dedicated to
802 research at UCSF's Memory and Aging Center. VBM analyses were performed using the
803 Brainsight system, developed at UCSF by Katherine P. Rankin, Cosmo Mielke, and Paul
804 Sukhanov, and powered by the VLSM script written by Stephen M. Wilson, with funding from the
805 Rainwater Charitable Foundation and the UCSF Chancellors Fund for Precision Medicine. We
806 thank Anna Karydas and Jennifer Yokoyama (UCSF Memory and Aging Center genetics experts)

807 for assistance with genetic data, as well as Dr. John Trojanowski (Department of Pathology and
808 Laboratory Medicine, University of Pennsylvania. Pennsylvania, Philadelphia) for assistance with
809 autopsy data.

1056

1057 Figure legends

1058 **Figure 1: Patient selection.** We searched the University of California, San Francisco Memory

1059 and Aging Center database. The first inclusion criteria was the clinical diagnosis, we included all

1060 participants who received a clinical diagnosis of behavioral variant frontotemporal dementia or

1061 semantic variant primary progressive aphasia. We then excluded all patients who did not have a

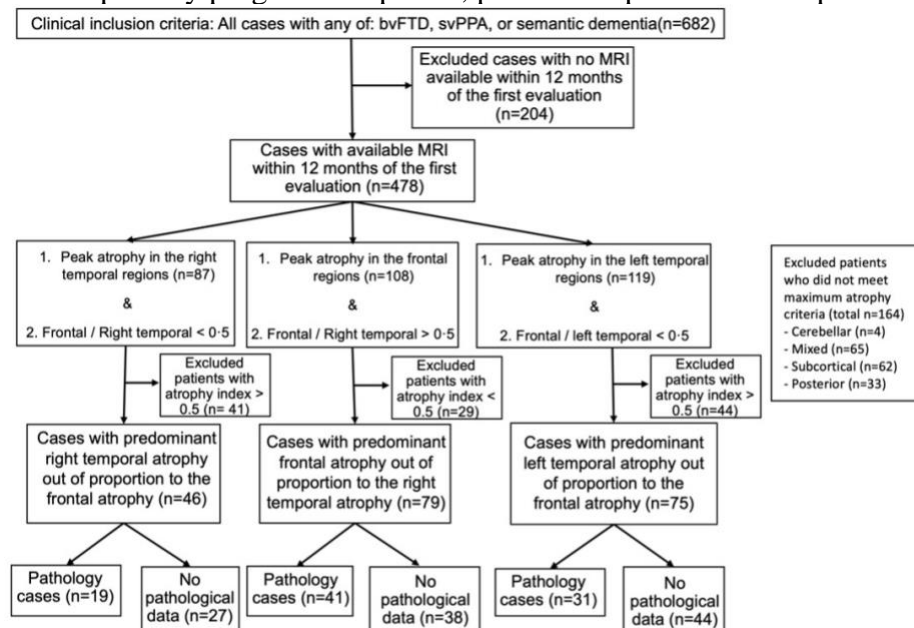

1062 brain MRI within one year of the first research evaluation. Next, we included participants who had

1063 peak atrophy in either the right temporal lobe, frontal lobe, or left temporal lobe on a brain MRI

1064 W-score map and showed predominant atrophy in their respective lobe based on an atrophy index.

1065 bvFTD = behavioral variant frontotemporal dementia spectrum disorders; svPPA = semantic

1066 variant primary progressive aphasia, posterior = parietal or occipital lobes.

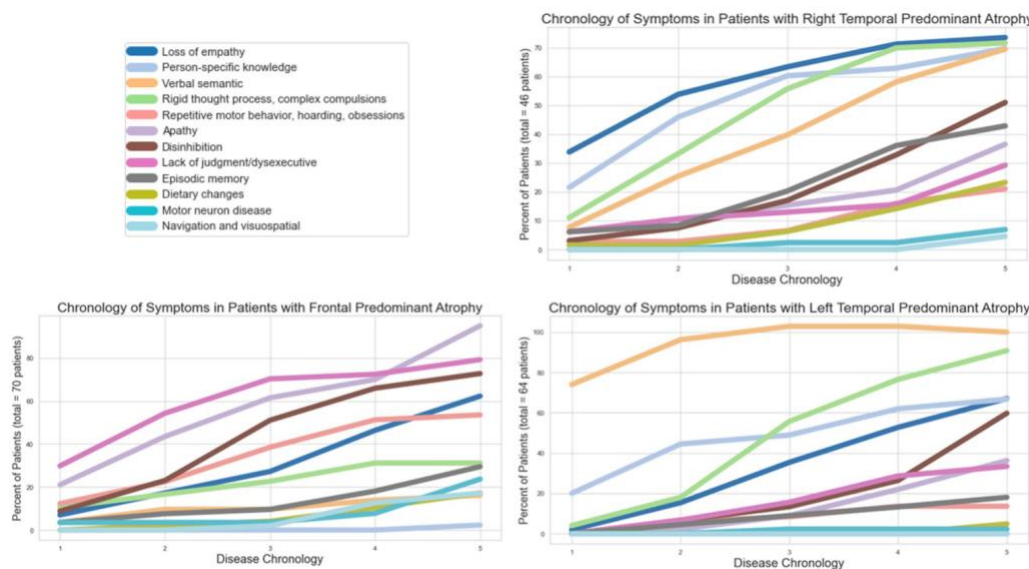

1067
1068

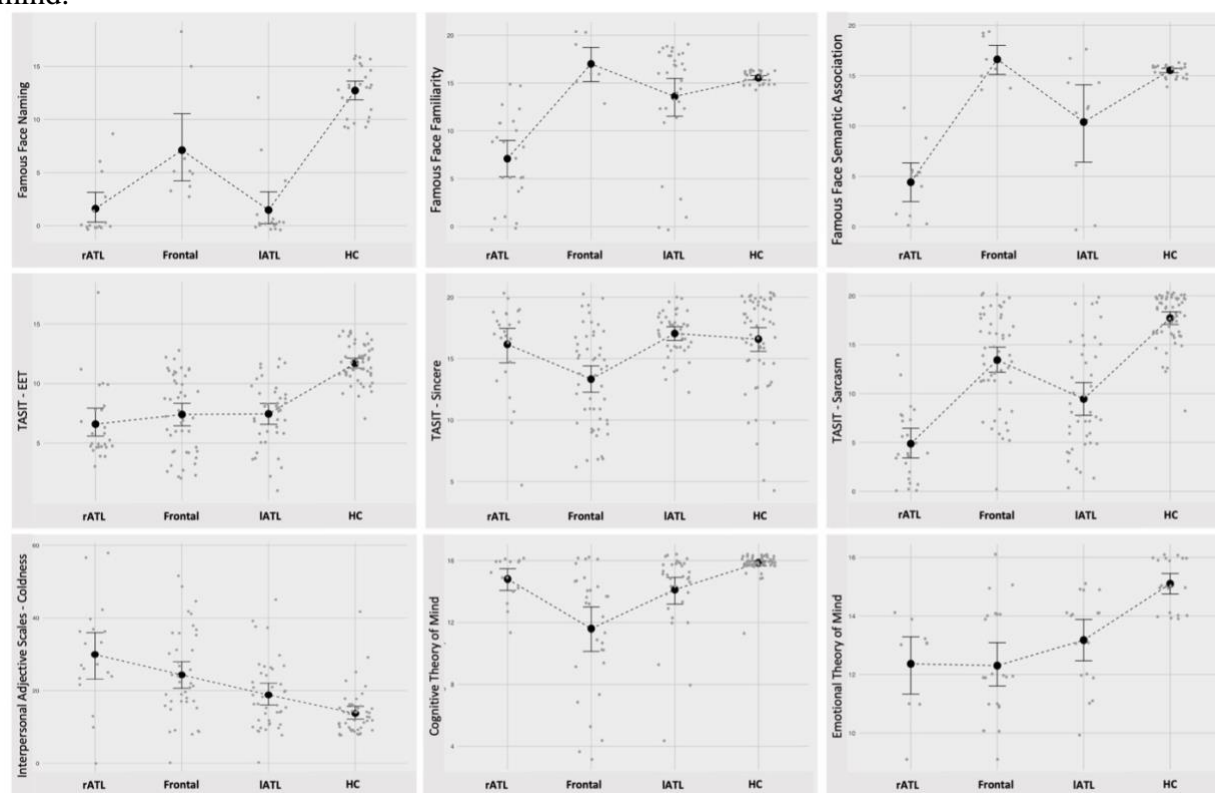

1069 **Figure 2: Neuroimaging in right temporal-, left temporal-, and frontal-predominant**
 1070 **neurodegeneration.** Lateral and mesial views. Predominant right temporal, left temporal, or
 1071 frontal atrophy was used as part of the inclusion criteria based on a data-driven neuroimaging
 1072 approach. The right temporal predominant group exhibited maximum atrophy in the right temporal
 1073 lobe more than the left anterior temporal lobe with involvement of the right more than left insula,
 1074 right caudate, and right more than left subgenual anterior cingulate cortex. Notably there is sparing
 1075 of the frontal, parietal, and occipital lobes. The left temporal predominant group shows maximum
 1076 atrophy in the left temporal lobe more than the right anterior temporal lobe with involvement of
 1077 the left more than right insula, left caudate, and left subgenual anterior cingulate cortex. Further,
 1078 there is sparing of the frontal, parietal, and occipital lobes. The frontal group shows bilateral lateral
 1079 and mesial frontal and left temporal volume loss but relative sparing of the right temporal lobe.

1080 **Figure 3: Chronology of symptoms.** Left upper corner shows the symptom legend. Right upper
 1081 corner shows symptoms chronology in the right temporal-predominant group; the most common
 1082 early symptoms in this group are loss of empathy, loss of person-specific knowledge, and rigid
 1083 thought process and complex compulsion. The left lower corner shows symptom chronology in
 1084 the frontal-predominant group; the most common early symptoms in this group are lack of
 1085 judgment/dysexecutive symptoms, apathy, and disinhibition. The right lower corner shows
 1086 symptom chronology in the left temporal-predominant group; the most common early symptoms
 1087 in this group are verbal semantic loss, loss of person-specific knowledge, and rigid thought process
 1088 and complex compulsion.
 1089

1091
 1092 **Figure 4: Socioemotional and Neuropsychological characteristics.** The figure shows the results
 1093 of the main socioemotional tests that can help distinguish right temporal- from frontal-predominant
 1094 patients. More details can be found in Table 2. Although all disease groups had difficulties with
 1095 famous faces naming, only right temporal, and a lesser degree left temporal-predominant patients,
 1096 had difficulties on Famous Face Familiarity and Semantic Association. Although all disease
 1097 groups showed impaired simple and complex social cues recognition on the TASIT-EET and
 1098 TASIT-Sarcasm, only the frontal predominant group showed impairment on the control cognitive
 1099 task, TASIT-Sincere. Right temporal-predominant patients showed significantly worse
 1100 performance on the complex social cue, TASIT-Sarcasm, compared to the frontal predominant
 1101 group. The right temporal-predominant group showed increased coldness compared to the frontal
 1102 predominant group. The right and left temporal-predominant groups had difficulty with the
 1103 emotional theory of mind but not with the cognitive theory of mind task. In contrast to the frontal-
 1104 predominant group which demonstrated impairment in both cognitive and emotional theory of
 1105 mind.

1106
 1107
 1108
 1109 **Table 1: Demographics, functional, and cognitive scores.**

	Right Temporal	Frontal	Left Temporal	Healthy Control
Epidemiology and Functional Scales				
Handedness, (right, left, ambidextrous)	39, 6, 1	72, 3, 3	68, 6, 1	54, 5, 0

Table 4: Proposed diagnostic criteria for emotional semantic variant frontotemporal dementia (esvFTD)

I. Patient shows gradually progressive deterioration by history and/or testing
II. Possible esvFTD: Patient must have two out of the core features A-C and one out of the supportive features D-F
CORE FEATURES A. Loss of empathy (difficulty understanding emotions) B. Difficulty naming and identifying known people C. Complex compulsions or rigid thought process
SUPPORTIVE FEATURES D. Object naming difficulties E. Spared visuospatial functions including preserved perceptual matching and drawing reproduction F. Spared motor speech and phonology
III. Probable esvFTD: All the following must be present: A. Meets criteria for possible esvFTD B. Imaging results consistent with esvFTD: 1 - Right anterior temporal lobe volume loss and relative sparing of the frontal cortex on MRI or CT or 2 - Right anterior temporal lobe hypometabolism and relative sparing of the frontal cortex on FDG-PET
