- 13
- 14 Abstract

Background: Despite rigorous disinfection, fumigation and air treatment, infectious microbial load has been found to circulate and survive for significant durations in health care settings. This raises significant concerns for hospital acquired infections. We have developed a novel, hybrid, trap-and-kill airborne-microbicidal technology called "ZeBox" which is efficient in clearing 99.999% of airborne microbial load under controlled lab conditions. In this study we evaluate the clinical performance of the ZeBox in reducing airborne and surface microbial load in two independent hospital settings.

Methods: The studies were conducted in single bed and multi bed ICU of two hospitals. Airborne and surface microbial loads were collected at pre-determined sampling sites pre- and postdeployment of the ZeBox enabled device. The Normality of data distribution was determined using the Shapiro-Wilk test. Statistical significance was determined using Students' T test and Mann-Whitney's U test. Pathogenic and opportunistic organisms were characterized using 16S rDNA sequencing. Furthermore, the antibiotic sensitivity of the isolated organisms was tested against current treatments of choice across major antibiotic classes.

Results: Post-deployment, we found statistically significant reductions in both airborne and 29 surface microbial load within the operating range of the ZeBox enabled technology. Across the 30 both hospital ICUs, there was 90% reduction of airborne microbial load on average, and 75% 31 reduction of surface microbial load on average, providing a low bioburden zone of roughly 10-15 32 feet diameter around the unit. These reduced microbial levels were maintained during the entire 33 duration of device operation over several weeks. Many of the clinical isolates recovered from one 34 of the hospitals were drug resistant, which highlighted the potential ability of ZeBox to eliminate 35 drug-resistant microbes and thereby reduce the frequency of hospital acquired infections. 36

Conclusions: ZeBox enabled technology can significantly reduce a broad spectrum of microbial
burden in air and on surfaces in clinical settings. It can thereby serve an unmet need in reducing
the incidence of hospital acquired infections.

Background

Human exposure to environmental organisms is associated with infectious disease 2 transmission as well as allergic and non-allergic respiratory illnesses [1]. The most recent 3 airborne Covid-19 pandemic highlights the continuous crisis caused by biological agents on 4 public health. Even before the current pandemic, Healthcare-associated infections (HAIs) 5 were a growing concern for clinical practice worldwide. Close to 2 million patients contract 6 HAIs in the U.S. every year, out of which nearly 100,000 patients die [2]. The overall HAI 7 rate is about three-fold higher in the developing world, with the risk of contracting device 8 9 associated infections being as much as 15-19-fold higher [3]. These infections are often due to multidrug-resistant (MDR) bacteria, which have increasingly few treatment options [3,4]. 10 Additionally, the risk of contracting HAIs increases if the prior bed or room occupant 11 12 suffered from infection; this risk is as much as four-fold higher for an Acinetobacter infection [5]. 13

14

1

Microbial load in indoor environments can have various origins including shedding from 15 occupant's respiratory tract or skin, aerosolization from showers, or similar systems [6-8]. 16 Ouite often, bacteria, viruses, fungi, or fungal spores can also be resuspended from floors 17 and deposited on interior surfaces distant from the source of contamination via airborne 18 dispersion and can be further dispersed via contact with healthcare workers and through 19 20 cross-contamination [9,10]. Pathogenic microorganisms can survive in indoor environments for long periods of time [11] depending on the temperature and humidity, despite regular 21 cleaning protocols instituted by healthcare spaces. The survivability of an organism is 22 strongly dependent on the nature of the surface. For example, SARs-CoV-2 can survive 23 between 2 hours to 28 days depending on the surface, ambient temperature, humidity and 24 exposure to sunshine [12]. Extended contamination of surfaces can lead to the cumulative 25

1	build-up of pathogens over time, particularly those that are resistant to surface or terminal
2	room disinfection and can pose a significant hazard to the next patient [13]. Under typical
3	heating, ventilation and air conditioning (HVAC) found in hospitals, Clostridium difficile
4	spores, Vancomycin resistant Enterococcus (VRE), Methicillin resistant Staphylococcus
5	aureus (MRSA) and Acinetobacter baumannii have been recovered after 4-5 months with
5	surface contamination levels exceeding the number of bacteria or virions necessary for the
7	transmission of infection [14,15]. Causing even more concern for nosocomial spread, it has
3	been found that Pseudomonas can linger on surfaces for as long as 16 months [14].

9

18

Hospitals, dental clinics, nursing homes and long-term care facilities typically see a large 10 burden of pathogenic organisms posing a health risk to all occupants. Microbial 11 contamination in hospital wards is concentrated in hard-to-reach surfaces such as the floor 12 under beds and bed wheels as compared to higher levels of a room. This correlates both with 13 the source of infection (patients in beds) and the fact that air trapped under beds and 14 instruments is not efficiently cycled through wall mounted air purification units. There is a 15 pressing need to design microbial decontamination devices that function near microbial 16 reservoirs. 17

In dental clinics, aerosols generated through drills and scalers can potentially splatter or 19 aerosolise and move within the indoor environment. Body fluids or blood from patients 20 may harbour viruses (such as mumps, measles, rubella, HSV 1 and 2, HIV, HBV, SARS-21 CoV, influenza A H5N1, influenza A H1N1, MERS-CoV or SARs-CoV-2), or bacterial 22 pathogens (such as Mycobacterium tuberculosis or Legionella pneumophilla) some of 23 which can be transmitted through aerosols and water mists [16-22]. Studies in nursing home 24

and long-term care-home residents have shown that infections account for 27% to 63% of hospitalizations in the United States [23].

Reducing the load of pathogenic organisms to below infectious level is thus crucial to mitigate risk of infection, particularly in indoor spaces. The CDC recommends eliminating microbes at the source as they are produced as the first line of defense against the spread of infections [18]. This aspect has come into greater focus more recently with the rapid spread of coronavirus disease across the globe. Indoor air decontamination is an urgent medical need to maintain health and hygiene needs of occupants.

Currently available technologies for decontaminating room air belong to two broad categories: those which merely trap suspended matter in air (inanimate dust particles along with microbes) and those which are microbicidal. Each of these technologies have their merits and demerits, which have been reviewed in considerable detail by others [24-29].

14 We believe that an ideal air decontamination technology must trap and then kill microbes in situ, thus preventing any future growth and dissemination. While trap-and-kill 15 microbicidal technologies are already available-UV irradiated filters, filters made of 16 microbicidal fibers, and filters combined with plasma technology -they suffer from major 17 demerits regarding flow permeability (which determines power consumption) and 18 generation of toxic by-products during operation. We have developed a novel, hybrid, trap-19 and-kill airborne-microbicidal technology called "ZeBox", which exploits the fact that 20 microbes naturally possess net electric charge (characterized by their zeta-potential) and 21 therefore they can be readily manipulated using an electric field. In ZeBox technology, a 22 non-ionizing electric field is applied between electrode-plates on which unique microbicidal 23 substrates are layered. The electric field plays two roles: it attracts the microbes to the 24

microbicidal substrate and potentiates the substrate to instantaneously killing the trapped microbes [30].

In an enclosed test chamber under challenge conditions, ZeBox powered devices achieved 3 6-9-log₁₀ reduction of a broad spectrum of microorganisms (airborne gram positive and 4 gram-negative organisms of ESKAPE group, viruses, vegetative fungi and spores) in 10 5 minutes, a performance that is at least 1000-fold superior to that reported in the literature. 6 In applications, which almost always consist of a space (enclosed or otherwise) with an 7 unceasing flux of people and patients, a continuous and rapid-action microbicidal device is 8 highly desirable. This is why the superior killing rate of ZeBox technology makes it unique 9 for continuous real-time applications. In this paper, we evaluate the clinical performance 10 of a ZeBox technology powered air decontamination device variant in reducing bacterial 11 and fungal load in air and on surfaces in two independent hospital settings. We also 12 delineate the typical pathogenic and opportunistic organisms found in these settings, to 13 characterize the risk of nosocomial transmission to patients and health care staff. 14

A. Experimental Design for Testing Device Efficiency in Hospital ICUs:

a) Single Bed and Multi Bed ICU Set Up:

The studies were conducted in a single bed ICU and multi bed ICU located in two 4 independent hospitals after approval from their Hospital Internal Ethics Committee. Both 5 rooms were mechanically ventilated with filtered and tempered air at 22.6±1.9°C with no 6 humidification. Housekeeping and nursing staff shared routine cleaning duties. Near-patient 7 sites were cleaned by nurses twice daily at 7 am and 7 pm using wipes (Vernacare TuffieTM 8 wipes) and detergent (HospecTM). Terminal cleaning of the bed-space was performed 9 following discharge. Samples were collected at specific locations identified as sampling 10 sites between 2-3 pm, 7-8 hours post-cleaning of near-patient surfaces three or four times a 11 week. In the Single Bed ICU, samples were collected four times a week over 11 weeks for 12 determining baseline levels of contamination. The ZeBox powered air decontamination 13 device was deployed at the end of the 11th week and samples were collected as before for 14 another 10 weeks. 15

In the Multi bed ICU, samples were collected three times a week, over 13 weeks for determining baseline levels of contamination. The ZeBox powered air decontamination device was deployed at the end of the 13th week and samples were collected as before for another 13 weeks.

20

21

22

b) Selection of Sampling Sites:

i. Single Bed ICU

The room had a dimension of 15 x 10 feet (Fig 1a). Indoor air samples were collected at positions S1 (medicine and reporting table) which was 10 feet away and S2 which was 6 feet away from the air decontamination device . Surface samples were collected from

position S1 (medicine and reporting table) which was 10 feet away and position S3 (patient bed rails) which was 4 feet away from the ZeBox technology powered air decontamination device.

ii. Multi bed ICU

The room had a dimension of 30 feet x 90 feet. The sampling sites were chosen in 6 consultation with the ICU staff to ensure the deployed device did not hinder movement and 7 activities within the ICU. Sampling sites were selected such that two sites (positions 1 and 8 2) were proximal to the ZeBox technology powered air decontamination unit and served as 9 sites on which the direct effect of the device could be monitored. Two other sites (positions 10 3 and 4) were distal to the ZeBox technology powered air decontamination uni and served 11 as the control sampling sites (Figure 1b). The deployed unit (marked by a green circle) 12 could effectively serve an area of 150sq. ft. 13

9

B. Sampling of air for viable microbes

A handheld air sampler (SAS Super ISO 100, VWR), which could sample 100 liters of air 10 per minute, was used to collect air samples. A fixed volume of air was sampled using the 11 air-sampler. Tryptic Soy Agar and Sabouraud dextrose agar plates were used to sample 12 bacteria and fungi, respectively, from the air. Plates were placed in and removed from the 13 air-sampler in an aseptic manner. Plates were incubated at $25\pm2^{\circ}$ C (for fungal cultivation) 14 and $37\pm2^{\circ}$ C (for bacterial cultivation) for 48 hours. After incubation, the number of 15 colonies were enumerated and converted to CFU/m³ using statistical conversion provided 16 by the manufacturer. Control plates were used to ensure the sterility of the entire process. 17

18

19

C. Surface sampling

A cotton swab was moistened with sterile phosphate-buffered saline (1X PBS; pH 7.2) solution using aseptic technique to prevent cross-contamination and was used to wipe a surface of 100cm² area as mentioned in CDC Guideline (EMERGENCY RESPONSE RESOURCES <u>https://www.cdc.gov/niosh/topics/emres/unp-envsamp.html</u>). The sampled swab was placed in a sterile conical vial containing 1ml of sterile phosphate-buffered saline

(PBS) solution. The entire 1ml solution was then plated on to Tryptic Soy Agar and Sabouraud dextrose agar plates for quantification of bacteria and fungi, respectively. Plates were incubated at $25\pm2^{\circ}$ C (for fungal cultivation) and $37\pm2^{\circ}$ C (for bacterial cultivation) for 48 hours. Post-incubation, the number of colonies that appeared were enumerated. Control plates were used to ensure the sterility of the entire process.

D. Microbial identification from Multi Bed Hospital ICU using 16S rDNA sequencing:

Bacterial population from air were collected using a handheld air-sampler on a TSA plate 8 and incubated for 48 hours, allowing the collected microbes to grow and form visible 9 colonies. Colonies were first screened based on their morphological characteristics, (viz 10 texture, color, shape, and elevation) and grouped accordingly. Individual isolates from these 11 groups were then picked for 16S rDNA sequencing. The 16S rRNA gene region of bacterial 12 genomic DNA was amplified using universal bacterial primers. Each of the PCR reaction 13 systems contained 2 μ l of Forward primer (0.4 μ M), 5'-AGR GTT TGA TCM TGG CTC 14 AG-3', 2 μ l of Reverse primer (0.4 μ M), 5'-GGY TAC CTT GTT ACG ACT T-3', 5 μ l of 15 PCR Green buffer (1X), 1.5 μ l of MgCl₂ (1.5 mM), 2.5 μ l of dNTP (0.1 mM), 0.2 μ l of Taq 16 DNA Polymerase (1 unit), and approximately 7.5 ng of DNA template. It was followed by 17 the addition of 20 µl of mineral oil on top of each PCR reaction mixture. The E. coli ATTC 18 25922 DNA was used as the positive control and PCR master mix with Milli-Q water was 19 20 used as a negative control. PCR amplicons were sequenced at the The Bangalore Biocluster Next Generation Genomics Facility (TIFR-NCBS, Bangalore, India). The sequence trace 21 files were assembled, trimmed, aligned and manually checked using Bionumerics software 22 6.0 (Applied. Maths. Sint-Martens Latern, Belgium), and the sequences were classified 23 using the Classifier and SeqMath tools [31] at the Ribosomal Database Project (RDP) and 24 BLASTn databases via the online interface at National Center of Biotechnology and 25

Information (NCBI). Sequenced genes were aligned using Clustal Omega (<u>https://www.ebi.ac.uk/Tools/msa/clustalo/</u>) and taxonomical analysis were carried out simultaneously.

3

E. Antibiotic sensitivity test of microbes collected from Multi Bed HICU

6 Single colony of each strain was grown in M9 medium. All test compound stocks and dilutions were prepared in DMSO. Serial two-fold dilutions of antibiotics were prepared 7 separately, with concentrations ranging from 2 mg/mL to 0.015 mg/mL. To 150 μ l (3– 8 7×10^{5} CFU/ml) of bacterial culture in 96 well microtiter plates, 3 µL compound from each 9 of the dilutions was added into respective wells to obtain final concentrations ranging from 10 40 µg/mL to 0.3 µg/mL of the test compounds. Media control, culture control and 11 appropriate reference drug controls were included. The plates were packed in gas permeable 12 polythene bags and incubated at 37 °C overnight. Growth was monitored by checking 13 absorbance at 600nm (A600). Minimum inhibitory concentration (MIC) was taken as the 14 concentration that resulted in a growth inhibition of $\geq 80\%$. 15

16

F. Statistical Analysis of Data

All data sets were tested for normal distribution using Shapiro-Wilk test (SW test), following which a non-parametric test, the "Mann-Whitney's U test" (MWU test) was conducted. The details are available in the Supplementary material.

4

A. Validation in Single Bed ICU:

a) Airborne microorganisms:

5 The environmental microbial load was monitored in a single bed ICU room when occupied 6 by patients. Air samples for monitoring baseline load were collected over a period of 11 7 weeks to enumerate microbial distribution at two locations within the room. This was 8 followed by ZeBox technology powered air decontamination unit deployment and sample 9 collection over a subsequent period of 10 weeks with the first sample collection within a 10 period of 3 hours after device deployment.

The airborne bacterial load before deployment was more or less similar at both the medicine 11 table and nurse station, and showed roughly a four-fold intra-day variation over the period 12 of 11 weeks (Figure 2, Table 1), ranging from 580-3000 CFU/m³ (average 1168 CFU/m3) 13 at the medicine table (S1) and 80-1910 CFU/m³ (average 1147 CFU/m3) at the nurse station 14 (S2). Similarly, the airborne fungal load before deployment showed roughly a three-fold 15 variation day to day over 11 weeks, but on some days, the CFU counts were as high as four 16 to seven-fold from the average daily counts (Figure 3, Table 1). Airborne fungal counts at 17 the medicine table (S1) ranged from 78-688 CFU/m³ (average 157 CFU/m³) and 72-698 18 CFU/m^3 (average 168 CFU/m^3) at the nurse station (S2) before device deployment. 19

After deployment of the decontamination device, the airborne bacterial load was reduced to 0-470 CFU/m³ at the medicine table (S1) (average 89 CFU/m³), and 0-710 CFU/m³ at the nurse station (average 108 CFU/m³) (Figure 2, Table 1). This accounts for a 92% reduction of airborne bacterial load at the medicine table (S1) and a 91% reduction at the nurse station (S2). The fungal load after deployment reduced to 4-144 CFU/m³ (average 31 CFU/m3) at the medicine table and 4-202 CFU/m³ (average 42 CFU/m³) at the nurse station (Figure 3,

Table 1). This accounts for 80% reduction of fungal load at the medicine table and a 75% reduction at the nurse station. Both airborne bacterial and fungal load dropped significantly within a period of 3 hours post deployment of the device. The device was in continuous operation for the remaining duration of the study.

6

7

1

2

3

4

5

b) Surface microorganisms:

Surface samples were collected from the medicine storage table and patient bed rail in the 8 single ICU bed cubicle. Bacterial load before deploying the decontamination device ranged 9 from 1500-9400 CFU/m² and 200-10500 CFU/m² on medicine table (S1) and patient bed 10 rails (S3) respectively (Supplementary Figure S1, Table 1). After device deployment, 11 surface bacterial load reduced to 800-`1900 and 200-1900 on medicine table and patient bed 12 rails respectively. This accounts for a 73% reduction of surface bacterial load on the 13 medicine table. However, there was considerable scatter in the bacterial load on the bed rails 14 both before and after device deployment and no significant reduction of surface bacterial 15 load (~45% reduction of the mean surface load). 16

17

Surface Fungal load before deploying the decontamination device ranged from 400-1100 CFU/m² and 0-1300 CFU/m² on medicine table and patient bed rails, respectively. Postdeployment of the decontamination device, the surface fungal load was reduced to 0- 300 CFU/m² on both medicine table and patient bed rails (Supplementary Figure S2, Table 1). This accounts for 84% reduction of airborne bacterial load at the medicine table and a 74% reduction on the bed rails.

B. Validation in a Multi Bed HICU:

1

2

a) Airborne microorganisms:

The environmental microbial load was monitored in a functional multi-bed HICU room 3 occupied by patients with regular movement of hospital personnel. Air samples were 4 collected as mentioned previously and total culturable microbial load was enumerated. 5 Baseline samples were collected over a period of thirteen weeks to understand the microbial 6 distribution at various positions in the room. This was followed by device deployment and 7 sample collection over a period of a further thirteen weeks. Depending on the position 8 sampled, the bacterial and fungal load in the air before deployment showed considerable 9 variability over time. Airborne bacterial load before device deployment ranged from 58-398 10 CFU/m³ while the fungal load ranged from 14-130 CFU/m³ across the four positions (Table 11 2). 12

After deployment of the decontamination device, the airborne microbial load was reduced 13 to 0-210 CFU/m³ and 0-98 CFU/m³ for bacterial and fungal population, respectively, across 14 the four sampling positions. The maximum reduction in bacterial load in air was shown at 15 Position 1 (0-66 CFU/m³) and Position 2 (0-44 CFU/m³), which were 2 and 8 feet away 16 from the ZeBox technology powered air decontamination unit, than at Positions 3 (20-210 17 CFU/m³) and Positions 4 (24-208 CFU/m³), which were 24 and 26 feet away from the 18 device (Figures 4, Table 2). This accounted for a 96-97% reduction in airborne bacterial 19 load at Positions 1 and 2, but only 40-44% reduction in airborne bacterial load at Positions 20 3 and 4. 21

The trend for airborne fungal load also showed a similar pattern. The maximum reduction was shown at Positions 1 and 2 (0-18 CFU/m³) as compared with Positions 3 (0-98 CFU/m³) and Positions 4 (0-58 CFU/m³). This accounted for 93-94% reduction of airborne fungi at Positions 1 and 2, but only 51-53% reduction at Positions 3 and 4 (Figure 5, Table 2).

No reuse allowed without permission.

2	Surface bacterial load before device deployment ranged from 6-620 CFU/cm ² while the
3	fungal load ranged from 0-70 CFU/cm ² across the four positions. After deployment of the
4	decontamination device, the microbial load was reduced to 0-180 CFU/cm^2 and 0-60
5	CFU/cm ² for bacterial and fungal population, respectively, across the four sampling
6	positions. As before, the maximum reduction in surface bacterial load was shown at Position
7	1 (0-34 CFU/cm ²) and Position 2 (0-48 CFU/cm ²), which were 2 and 8 feet away from the
8	device, while a lowered reduction was observed at Positions 3 (2-120 CFU/cm ²) and
9	Positions 4 (2-180 CFU/cm ²), which were 24 and 26 feet away from the device. This
10	accounted for a 78-90% reduction in surface bacterial load at Positions 1 and 2, but only 62-
11	67% reduction in surface bacterial load at Positions 3 and 4. Similarly, the surface fungal
12	load showed maximum reduction at Position 1 (0-13 CFU/cm ²) and Position 2 (0-10
13	CFU/cm ²) and lower reductions at Position 3 (0-60 CFU/cm ²) and Position 4 (0-40
14	CFU/cm ²). This accounted for 82-92% reduction of surface fungal load at Positions 1 and
15	2, and 37-50% reduction in surface fungal load at Positions 3 and 4 (Supplementary Figure
16	03, Table 02).

Table 2: Descriptive statistics for airborne and surface microbial load in a multi bed ICU.The airborne bacterial and fungal loads were measured at four positions. Position 1 and 2were 2 feet and 8 feet away respectively while positions 3 and 4 were 25 feet and 26 feetaway respectively from the decontamination device.

C. Microbial identification from Multi Bed Hospital ICU using 16S rDNA sequencing

Following sequencing, alignment and taxonomical analysis on the sequenced genes, the 3 organisms were identified and classified as pathogenic and non-pathogenic. As shown in Table 3, the pathogenic organisms identified were Bacillus cereus, Acinetobacter 5 baumanii), Acinetobacter lwoffii (potentially opportunistic pathogen), Klebsiella pneumoniae, Brevundimonas sp. (rare case of opportunistic pathogen), Pseudomonas 7 stutzeri (an opportunistic pathogen), Staphylococcus saprophyticus and Staphylococcus haemolyticus, hominis, cohnii (emerging opportunistic pathogens). In addition, over half a dozen non-pathogenic organisms were identified. 10

D. Antibiotic sensitivity test of microbes collected from Multi Bed HICU

The Minimum inhibitory concentration (MIC) of each of seven antibiotics was tested against each isolated organism. The seven antibiotics chosen represent current treatment choices across the various classes of available antibiotics. The sensitivity of the organisms to these antibiotics is tabulated in Table 3. Among the clinical isolates characterized, several strains were resistant to Ceftazidine, Azithromycin and Ampicillin. The isolates were relatively more sensitive to meropenem and linezolid. Most isolates were highly sensitive to Ciprofloxacin and Rifampicin. The *Kytococcus* and *Micrococcus* isolates seemed resistant practically to all antibiotics tested and had a modest sensitivity towards Linezolid. *Brevundimonas* could not be cultured for susceptibility testing.

MIC (µg/ml).

G. Statistical Analysis of Data

Statistical analysis was carried out on the data set after leaving out the transition period, 2 which was one day after turning on the ZeBox powered air decontamination unit when the 3 microbial load should have settled into a new level of equilibrium. The Shapiro-Wilk test (SW 4 test) indicated that except for some data at position S1 (medicine table) and post deployment 5 bacterial load at position S2/S3 (nurse station/ bed rails) in the single bed ICU, most data sets 6 7 were not normally distributed (data available in supplementary material). In the multi bed ICU, only the post deployment surface bacteria at Position 1 and airborne bacterial load at position 8 3 and post deployment airborne bacterial load at position 4 were normally distributed. The 9 results from the t test and the nonparametric "Mann-Whitney's U test" (MWU test) provided 10 similar levels of confidence. Results of the t-test for all the cases are shown in Tables S4 and 11 S5, and that of the MWU test in tables S6 and S7. We see that the reduction brought about by 12 deployment of ZeBox technology powered air decontamination unit is significant in nearly all 13 the cases, except for surface bacteria at position 2 in the single bed ICU and surface fungi at 14 position 4 in the multibed ICU. All details are available in the Supplementary material. 15

19 **Discussion**

20

We carried out two independent studies to determine the efficiency of proprietary ZeBox technology powered air decontamination device in a single bed ICU and a multi bed ICU. Both studies were carried out when the rooms were occupied by patients, there was expected movement of hospital personnel and the hospital was fully functional. Devices underwent electrical safety and emission testing as per IEC60601-1-2 standards before deployment in

clinical environments. Over the sampling interval, the baseline cultures in indoor air showed considerable variation with large standard deviations but less standard deviation in certain locations as evidenced through surface swab samples. Such variations have been previously described in the literature [32].

The robust and reproducible effect of the ZeBox technology powered air decontamination 5 unit was observed on indoor air and frequently touched surfaces by microbial culture. After 6 3 hours of deployment of the unit, upwards of 95% reduction of bacterial load and upwards 7 of 85% reduction of fungal load was observed in indoor air in both single bed ICU and 8 multibed HICUs, so long as the sampling locations were within the effective range of the 9 device. Similar extent of reduction was observed in surface bacterial and fungal loads. We 10 thus showed that air decontamination could substantially and simultaneously reduce the 11 levels of surface deposition in the same setting irrespective of the type of pathogen present, 12 viz bacteria, fungi and their spores. 13

14

1

2

3

4

In the multibed HICU study, at sites distal to the deployed unit, the reduction in airborne 15 bacterial load ranged from 24-45% and airborne fungal load from 35-70%. At the same 16 distal sites, the surface bacterial load reduction ranged from 15-80% and fungal load 17 reduction ranged from 61-73%. At sites proximal to the ZeBox technology powered air 18 decontamination unit, the reduction of both bacterial and fungal load was greater than 95%. 19 This indicates that a low bioburden zone was created with an approximate radius of 10-15 20 feet from the unit, for airborne bacterial and fungal load. These results are in concordance 21 with the results obtained in earlier studies under controlled conditions [30]. 22

To understand if the reduction in the microbial load post-deployment of ZeBox technology powered air decontamination unit was significant, we conducted a statistical analysis of the data (refer supplementary material for details). Since most statistical tests demand that the

data be normally distributed, we first tested the data for normality using the Shapiro-Wilk 1 test. We found that most of the datasets were *not* normally distributed. Therefore, to assess 2 the significance of the reduction in microbial load due to ZeBox powered air 3 decontamination unit, we conducted both a parametric test (Student's t-test) which is 4 applicable to normally distributed data, and a non-parametric test (Mann-Whitney's U test) 5 which is applicable to non-normally distributed data. Despite the different assumptions and 6 theoretical basis underlying the two tests, their conclusions were the same. Except for two 7 cases of surface microbes, one on the bed rail in the single-bed ICU and another at a location 8 9 farthest from the ZeBox technology powered air decontamination unit in the multi-bed ICU, the tests yielded *p*-values significantly less than 0.05. This confirms that there was a 10 significant reduction in the microbial load due to deployment of the ZeBox technology 11 powered air decontamination unit. 12

Data on movement of people was not collected. Previously published studies linking occupancy of ICU to airborne culture numbers required intensive sampling over short time intervals which was not feasible in this study.

Several microbial strains resistant to Ceftazidine, Azithromycin and Ampicillin were found 16 among the clinical isolates characterized. These are typical organisms found in hospital 17 wards, some of which may be responsible for nosocomial or opportunistic infections in 18 immunocompromised patients. The isolates were relatively more sensitive to the newer 19 classes of antibiotics such as meropenem and linezolid. While most isolates were highly 20 sensitive to Ciprofloxacin and Rifampicin, the latter is reserved as first line treatment for 21 drug sensitive Tuberculosis, limiting its use against other infections. The Kytococcus and 22 *Micrococcus* isolates which are resistant practically to all antibiotics tested except Linezolid 23 would be expected to be particularly difficult to treat with available antibiotics, posing a 24 challenge to infections in immunocompromised patients. Thus, an indoor environment 25

equipped with an air decontamination unit which ideally eliminates microbes at source and provides near-sterile circulating air would be the desired way to prevent nosocomial infections.

5 Our study demonstrates that the innovative ZeBox technology can provide an effective trap 6 and kill mechanism to eliminate a broad spectrum of airborne pathogens under clinical 7 conditions. This in turn prevents re-settling of bacterial and fungal microorganisms on 8 surfaces. Continuous operation of the ZeBox powered air decontamination unit can lead to 9 ongoing reductions of pathogens in air and on environmental surfaces.

10

2

3

4

11 Conclusion

12 Effective decontamination technology that aids infection control in healthcare spaces must13 do the following:

14 1. kill pathogenic or contaminating microbes instead of merely trapping

15 2. operate continuously and safely in human presence

3. and require near-zero manual intervention while operating close to the source of infection
or contamination.

No other technology being evaluated globally meets all these requirements. While filtration 18 technologies fail to meet the first criterion, UV and ionization-based technologies fail to 19 20 meet the last two. The unique, extremely effective, energy-efficient technology, ZeBox satisfies all these attributes. The devices powered by the proprietary ZeBox technology 21 effectively eliminate airborne microorganisms like Staphylococcus aureus, Pseudomonas 22 aeruginosa, Candida albicans, Aspergillus fumigatus spores, Mycobacterium smegmatis 23 [30] and Mycobacterium tuberculosis, bacteriophages such as MS2 phage and Phi X 174 24 (data not shown). Devices were previously shown to reduce $5\log_{10}$ to $9\log_{10}$ or 99.999-25

99.9999999% of viable microbial load based on the starting concentration under challenge 1 conditions. In this study, we demonstrate that the ZeBox technology effectively eliminates 2 the microbial population present in normally functioning hospital environments with 3 efficiency over 95%, from the air and close to 85% from high contact surfaces like patient 4 bed rails. Reducing the environmental microbial load will reduce the occurrence of 5 nosocomial infections in healthcare environments. Although this study demonstrates the 6 device's capability in eliminating bacterial and fungal load from the environment, further 7 study is required to assess impact on viruses under clinical settings, especially respiratory 8 viruses. Nevertheless, this study successfully evaluates a novel decontamination technology 9 that can be used not only in hospitals ICUs but also in other areas such as burns units and 10 around immunocompromised patients, where the maintenance of low bioburden is critical 11 12 to maintaining good health and preventing difficult to treat infections.

Figure S4: Surface Fungal load in Multi bed ICU. Positions 1(a) and 2 (b) were 2 feet and
8 feet away, respectively, from the ZeBox. Positions 3 (c) and 4 (d) were 25 feet and 26 feet
away from the ZeBox. The ZeBox was deployed on day 89 and the first sample was taken
within 3 hours of deployment. The microbial count for that time point is depicted by a
square.

1 Statistical analysis of data

2

Statistical tests were used to determine the significance of the reduction in microbial load due to ZeBox. We divide the time series of measured microbial load into pre-deployment and postdeployment periods. After turning on ZeBox, there is a finite period of transition until the microbial load settles to a new (lower) equilibrium level. The post-deployment period was reckoned to begin at the end of the transition period, assumed to be 1 day after turning on ZeBox.

Most statistical tests applicable to our case make two major assumptions: (1) The data in the pre-9 and post-deployment periods are statistically steady (or stationary); this implies that the statistics 10 of the microbial load within a given period does not change progressively over time, and (2) The 11 data is sampled from a normal (or, Gaussian) distribution. The first assumption is valid because 12 we have left out the transition period from consideration. Whether the second assumption is valid 13 was determined by testing the data for normality using Shapiro-Wilk test (SW test). The null 14 hypothesis for the SW test is that the dataset is sampled from a normal distribution. Table S1 and 15 Table S2 show the results of the SW test; each entry is a pair of the SW-statistic and the 16 corresponding p-value. All the statistical tests were done using the **scipy**-statistics package in 17 **python**. The cases with p-value > 0.05, marked in green, indicate that the corresponding datasets 18 are indeed sampled from a normal distribution. We see that most datasets are in fact not sampled 19 20 from a normal distribution.

SW test, Single	Position 1		Position 2	
Bed ICU	Pre-deployment	Post-deployment	Pre-deployment	Post-deployment
Airborne bacteria	0.82, <0.001	0.96, 0.20	0.94, 0.026	0.98, 0.64

Airborne fungi	0.59, <0.001	0.75, <0.001	0.66, 0.75, <0.001	0.72, 0.75, <0.001
Surface bacteria	0.90, 0.079	0.90, 0.13	0.46, 0.75, <0.001	0.97, 0.91
Surface fungi	0.95, 0.47	0.90, 0.12	0.89, 0.092	0.85, 0.031

5 Table S2. SW test for multi bed data. Each entry is a pair of SW-statistic and the corresponding p-

6 value.

1	If pre- and post-deployment datasets are both normally distributed then, to assess the
2	significance of the reduction in microbial load post-deployment of ZeBox, we may use a
3	parametric test such as the "two sample, left tailed t-test", otherwise a non-parametric test such as
4	the "Mann-Whitney's U test" (MWU test) is appropriate [1]. For the t-test, the null hypothesis is
5	that the mean microbial load in pre- and post-deployment periods are the same, and the alternative
6	hypothesis is that the ZeBox brings about a reduction in the mean microbial load (which therefore
7	requires a left-sided test). For the MWU test, the null hypothesis is that the pre- and post-
8	deployment datasets are sampled from the same probability distribution, while the alternative
9	hypothesis is that they are sampled from different distributions and that the ZeBox brings about a
10	reduction in the microbial load (which therefore requires a left-sided test).
11	Results of the t-test for all the cases are shown in tables S3 and S4, and that of the MWU test in
12	tables S5 and S6. We see that the reduction brought about by deployment of ZeBox is significant
13	in nearly all the cases, except for surface bacteria at position 2 in the single bed ICU and surface
14	fungi at position 4 in the multi bed ICU

15

t-test, Single Bed	Position 1	Position 2
ICU		
Airborne bacteria	14.4, <0.001	14.4, <0.001
