32 Abstract

Early intervention is now considered the core treatment strategy for autism spectrum disorders 33 (ASD). Thus, it is of significant clinical importance to establish a screening tool for the early 34 detection of ASD in infants. To achieve this goal, in a longitudinal design, we analysed spontaneous 35 bodily movements of 4-month-old infants and assessed their ASD-like behaviours at 18 months of 36 age. Infants at high risk for ASD at 18 months of age exhibited less rhythmic and weaker bodily 37 movement patterns at 4 months of age than low-risk infants. When the observed bodily movement 38 patterns were submitted to a machine learning-based analysis, linear and non-linear classifiers 39 successfully predicted ASD-like behaviour at 18 months of age based on the bodily movement 40 patterns at 4 months of age, at the level acceptable for practical use. This suggests the utility of the 41 proposed method for the early screening of infants at risk for ASD. 42

43

44

45

47 **1. Introduction**

Autism spectrum disorder (ASD) is a developmental disorder, typically characterised by a collection of symptoms, including repetitive behaviours, restricted interests, and poor social communication skills (American Psychiatric Association, 2013). ASD is generally considered to have genetic underpinnings (Anderson, 2015). Recently, the prevalence of ASD has been increasing. This is partly owing to increased public awareness and changes in the ASD diagnostic criteria. However, a significant increase in the prevalence of ASD remains unexplained; hence, there is a pressing need for establishing reliable treatment strategies for ASD.

At this point, there is no definitive cure for ASD, but an increasing number of studies indicate the efficacy of early intervention for children with ASD (Dawson et al., 2010; Green et al., 2015), which is manifested in improved prognosis and social adaptation. Thus, early detection of children at risk for ASD and early intervention are now considered to be a core treatment strategy for ASD (Dawson, 2008).

It is generally accepted that ASD can be diagnosed at around 3 years of age. However, a 60 number of studies have indicated that early signs of ASD can be detected during infancy and 61 toddlerhood (Adrien et al., 1993; Baranek, 1999; Osterling, Dawson & Munson, 2002; Klin et al., 62 2009). For example, a retrospective study by Osetrling et al. (2002) analysed birth-day videos of 63 ASD and typically developed (TD) children, and found that children later diagnosed with ASD 64 showed lower social functioning compared with TD children. Likewise, a prospective study by 65 Elsabbagh et al. (2012) revealed that children with ASD show atypical electrophysiological 66 activation to socially significant facial information (e.g. direct gaze), compared with their siblings 67 without ASD and with TD children as young as 10 months of age. 68

Previous findings pertaining to the early signs of ASD raise the possibility that children at
 risk for ASD can be screened during toddlerhood or, in some cases, during infancy. Early detection

could lead to early intervention, potentially improving the prognosis for children with ASD and/or for those with sub-clinical-level symptoms. However, presently, there are no established tools for early detection of the ASD risk, and screening of children at risk for ASD requires time-consuming assessments and/or observations by teams of multidisciplinary professionals consisting of experienced clinicians and psychologists (Zwaigenbaum et al., 2009).

Atypical motoric function is one of the most frequently reported signs of ASD during early 76 development (Teitelbaum et al., 1998; Ozonoff et al., 2008). Many studies have reported various 77 types of atypical bodily movement patterns, from infancy and toddlerhood, such as unbalanced 78 posture and movement (Esopsito et al., 2009, 2011; Dawson et al., 2018), hypotonia (Adrien et al., 79 1993), spasticity in limb extremities (Dawson et al., 2000) and impairment in manual movement 80 control (Sacrey et al., 2018). These behavioural observations are in line with neuroimaging-based 81 82 findings and histological studies on the brains of humans with ASD, in which atypical patterns have been reported regarding the morphology and function of motor-related neural regions, such as the 83 basal ganglia and cerebellum (Rinehart et al., 2006; Qiu et al., 2010). 84

In studies on motor function during infancy, intensive attention has been paid to 85 spontaneous movements in the supine position, which can be evaluated starting from the neonatal 86 87 period. Neonates and infants exhibit a repertoire of bodily movement patterns in the supine position, which has been termed the general movement (GM). Prechtel et al. investigated the developmental 88 trajectory of GM in TD children and proposed a framework for qualitative assessment of GM that 89 90 can be used for predicting the risk of deficiency in higher-order brain functions, such as cerebral palsy (Einspieler et al., 2016; Burger & Louw, 2009). Although the number is relatively small, 91 92 several studies have also indicated the utility of GM for assessing the risk of psychiatric conditions 93 (Einspieler et al., 2014; Hadders-Algra, Bouwstra & Groen, 2009).

Considering the success of the GM assessment for predicting the risk of neurological and psychiatric conditions, together with the prevalence of atypical motoric development patterns in children with ASD, it seems feasible to establish an early screening method for objectively evaluating the risk of ASD based on the analysis of bodily motion patterns during early development. Several researchers have developed systems for automatic assessment of GM using image analysis techniques (Gao et al., 2019; Marcroft et al., 2015; Støen et al., 2009). However, these studies did not address the possibility of the ASD risk evaluation.

The primary goal of the present study was to examine whether bodily movement patterns 101 during early infancy are predictive of the ASD risk, which becomes evident later in the development 102 in a prospective design. To achieve this goal, we video-recorded spontaneous bodily movements in 103 4-month-old infants and quantified their features using a novel markerless system for infant 104 105 movement evaluation (Osawa et al., 2009; Tsuji et al., 2020; Kinoshita et al., 2020; Kawashima et al., 2020; Tacchino et al., 2021). Classifiers were trained for predicting the ASD risk in 18-month-106 old infants, based on their bodily movement patterns at 4 months of age. The design of the current 107 study is schematically shown in Figure 1. In contrast to some of the other proposed methods of 108 automated infant movement analysis, our system does not require special equipment or attachment 109 110 of sensors to the body surface; thus, it can be easily implemented in clinical settings.

The risk of ASD in 18-month-old infants was evaluated using the Modified Checklist for Autism in Toddlerhood (MCHAT) (Inada et al., 2011; Kamio et al., 2015). The MCHAT is a questionnaire widely used for early screening of the ASD risk, and is reported to be applicable to toddlers as young as 18 months of age. Although the specificity of the MCHAT method is not very high, it captures early signs of atypical development broadly in many domains, such as social communication and sensory processing.

Figure. 1. Schematic representation of infant video recording setting and the flow of informationprocessing.

117

121 **2. Results**

Of the 62 mother-infant pairs who participated in the video-recording sessions at 4 months 122 of age, 58 mothers returned the MCHAT questionnaire at 18 months of age. Among these 58 123 mother-infant pairs, bodily movement analysis was performed for 41 infants. Video recordings 124 from 17 infants were discarded owing to their short length ($\leq 3 \min; n = 13$) and low frequency (I_1 125 < 10%; n = 4) of bodily movement in them. There were no significant differences between these 41 126 mother-infant pairs and 21 pairs whose data were discarded in terms of the days after birth (W =127 1.439, p = 0.156), the weight at birth (W = 1.227, p = 0.227), the gestational age at birth (W = 1.032, 128 p = 0.308), and mother's age at birth (W = -1.6, p = 0.119). The distributions of high-and low-risk 129 children did not differ between 41 mother-infant pairs and 17 mother-infant pairs whose MCHAT 130 131 data were available but were discarded from the final analysis (p = 0.715); this conclusion was reached based on Fisher's exact test. Thus, although the data attrition rate was relatively high, there 132 were no signs of selection bias. 133

Among the 41 infants, seven were evaluated to be at high risk for ASD (the high-risk group).
 The age-in-days on the day of video recording, weights at birth, the gestational ages of the infants,

136 and the mothers' ages, for the high-and low-risk groups, are summarized in Table 1. The Brunner—

137 Munzel test did not reveal significant group differences either in age (W = 0.067, p = 0.95), weight

- 138 at birth (W = -1.400, p = 0.18), gestational age (W = 0.214, p = 0.835), or mother's age at birth (W
- 139 = 1.172, p = 0.265).

rhythm and d) movement of the center of gravity (iCOG movement) in each group.

As can be seen from Figure 2, infants in the high-risk group exhibited significantly lower 153 movement strength in their lower limbs (^(A6) I_2 ; W = -4.10; p = 0.0023) and lower balance of 154 movement between their upper and lower limbs (^(A5, 6) I_4 ; W = 2.56, p = 0.035). In the domain of 155 movement rhythmicity, infants in the high-risk group exhibited higher central frequencies and 156 larger second moments around the central frequency in the time series of the body centre velocity, 157 and a fluctuation along the left-right axis ($I_{9,v}$, W = 4.94, p < 0.001; $I_{10,v}$, W = 2.89, p = 0.0099; I_{11} . 158 y, W = 4.17, p < 0.001; $I_{12, y}$, W = 4.76, p < 0.001). Examples of the temporal course of body center 159 fluctuation and the distribution of frequency power are shown for low- and high-risk infants in 160 Figure 3. 161

Figure 3. Example data of the temporal course of body center (iCOG) fluctuation (upper panels) 163

and power spectrum of iCOG fluctuation (lower panels). 164

The standard deviation of the body centre velocity and the fluctuation along the y-axis $(I_{13,y}, \text{Stat} = -2.03, p = 0.0501; I_{14,y}, W = -5.59, p < 0.001)$, and the area covered by the trajectory of the body centre excursion $(I_{15}, W = -5.96, p < 0.001)$ were significantly smaller in the high-risk group than in the low-risk group.

There were significant (p < 0.05) and marginally significant (p < 0.10) group differences across the 14 bodily movement features. For each pair out of the 14 features, we computed the correlation coefficient. Correlational coefficients between $I_{9,y}$, $I_{12,y}$, $I_{11, y}$, and between $I_{11, y}$ and $I_{11, y}$ x were above 0.7. Therefore, these four features were averaged into a single feature. The correlation coefficients between $I_{13, x}$ and $I_{13, y}$, $I_{13, x}$ and I_{15} , $I_{13, y}$ and I_{15} , $I_{14, x}$ and I_{15} , $I_{14, y}$, and I_{15} were all above 0.7. Thus, these five features were compressed into a single feature as well. After the compression, none of the absolute values of the pairwise correlation coefficients was above 0.7.

176

177 2-2. Group Classification using Machine Learning Algorithms

Four classifiers were trained using the seven selected features as predictors. The four 178 machine learning algorithms included two linear classifiers, i.e. linear discriminant analysis (LDA) 179 and logistic regression (LR), and two non-linear classifiers, i.e. a multi-layered perceptron (MLP) 180 181 and a log-linearised Gaussian mixture network (LLGMN; Tsuji et al., 1999). The performance of the MLP and LLGMN depends on the initial state of their random weights. Thus, hyperparameter 182 tuning was repeatedly performed using a nested leave-one-out procedure 10 times, for both the 183 184 MLP and LLGMN. After the hyperparameter tuning, the average number of nodes in the hidden layer of the MLP was 11.39 (SD = 2.0), while the average number of components in the LLGMN 185 was 2.59 (SD = 1.43). Below, we describe and discuss the performances of the MLP and LLGMN 186 187 classifiers with the highest F1 score and the highest area under the precision-recall curve (AUC-PR). The confusion matrices generated by the four classifiers are shown in Figure 4. Fisher's exact 188

test on the data revealed significant associations between classifications made by each of the four classifiers and grouping by the MCHAT score (ps < 0.003). Yule's coefficients of the associations were above 0.85. The performance indicators evaluated using the leave-one-out procedure are summarized in Table 3.

194 **Figure 4.** Confusion matrices summarizing the classification results by the four classifiers.

199 Discussion

The present study investigated the relationships between automatically extracted features of spontaneous bodily movements of 4-month-old infants and their MCHAT scores at 18 months of age. Infants at risk for ASD showed atypical characteristics for a variety of bodily movement features at 4 months of age. Further, four classifiers with bodily movement features as predictors succeeded in classifying infants with low and high ASD-like behaviours. Taken together, these findings indicate that bodily movement patterns at 4 months of age can inform about ASD-like behavioural tendencies at 18 months of age.

A close look at group differences of bodily movement patterns reveals that the bodily 207 motion patterns of infants with high MCHAT scores are characterised mainly by (i) reduced 208 frequency and strength of lower limb motion, and (ii) lack of rhythmicity in movements. The latter 209 characteristic is reflected in a larger second moment around the central frequency in the time series 210 of the body centre movement for these infants. For low-risk infants, large power was distributed 211 around the central frequency, indicating that these infants moved their body centres periodically 212 within a certain frequency range. Compared with low-risk infants, power was more diffusely 213 distributed for high-risk infants, indicating that their movement patterns lacked notable rhythmic 214 components. 215

It is generally known that children with ASD exhibit atypical patterns of motor control, such as clumsiness, reduced muscle tone, and poor motor coordination (Paquet et al., 2016; Provost et al., 2007; Fournier et al., 2010). These types of motoric atypicality potentially lead to reduced amplitude and frequency of limb motion and poor coordination of limb movements, as observed in the present study. The lack of rhythmicity in bodily motion patterns might indicate the atypicality of the central pattern generator (CPG) that generates a rhythmic pattern of involuntary movements. Because the CPG is responsible for generating rhythmicity in gait patterns, poor rhythmicity in spontaneous movement patterns during infancy might be linked to atypical gait patterns often
observed in children with ASD (Kindregan, Gallagher & Gormley, 2015).

Most items of the MCHAT concern the development of socio-cognitive functions, such as 225 the theory of mind and joint attention. Thus, the present findings nicely dovetail with the 226 observations by Bhat et al. (2012) that motor delay at 6 months of age is associated with delays in 227 social communication at 18 months of age in infants with high risk of ASD. Considering these, one 228 might be tempted to assume that features of spontaneous bodily movement, as quantified in the 229 present study, are linked to later social development. However, it is premature to draw such a 230 conclusion because impairments in motor and socio-cognitive functions might be connected to the 231 atypicality of different sub-regions of identical neural structures in the autistic brain (Qiu et al., 232 2010). 233

Several studies have found that early signs of autistic traits can be detected well before the 234 diagnosis of ASD (Adrien et al., 1993; Baranek, 1999; Osterling, Dawson, & Munson, 2002; Klin 235 et al., 2009; Elsabbagh et al., 2012). Consistent with these observations, we succeeded in 236 discriminating infants with high ASD risk from those with low ASD risk, using linear and non-237 linear classifiers. Overall, the four classifiers exhibited comparable performance, supporting the 238 robustness of our findings that the bodily movement patterns at 4 months of age contain sufficient 239 amount of information for predicting the emergence of ASD-like behaviour at 18 months of age. 240 At the same time, the performance of the two non-linear classifiers was numerically superior to that 241 of the linear classifiers. Astonishingly, the AUC-ROC for the MLP classifier was above 0.9, 242 indicating the possibility that non-linear classification based on bodily movement features can 243 achieve classification performance that is acceptable even in clinical settings. 244

The present findings provide preliminary results that lead to the establishment of objective markers for the early detection of autistic tendencies in children. A recent surge of studies on digital

phenotyping of ASD (Anzulewicz et al., 2016; Dawson et al., 2018; Ardalan et al., 2019) raised the 247 possibility that behavioural features, quantified using low-cost non-invasive sensors, could provide 248 reliable clues for detecting children and adults at risk for ASD. In a closely related study, 249 Anzulewicz et al. (2016) succeeded in classifying children with ASD from their neurotypical 250 counterparts by submitting finger movement patterns captured by touch sensors in tablets to 251 machine learning-based analysis. A similar attempt was also reported by Ardalan et al. (2019) (for 252 a brief review, see Doi, 2020). The current research extends the achievements of these previous 253 studies by raising the possibility that atypicality in bodily movement patterns in infancy could be 254 used for predicting later emergence of ASD-like tendencies during toddlerhood. A series of large-255 scale clinical studies have shown that ASD can be predicted based on the developmental patterns 256 of brain surface structures (Hazlett et al., 2017) and resting state brain activation (Emerson et al., 257 2017) measured using magnetic resonance imaging during toddlerhood. It would be of great interest 258 to determine whether comparable performance on the early diagnosis of ASD can be achieved using 259 the digital phenotyping technique adopted in the present study. 260 The current study had some limitations. First, motor impairment is often observed in other

The current study had some limitations. First, motor impairment is often observed in other neurological and psychiatric conditions. As such, several researchers questioned the specificity of atypical development of motor function as an early sign of ASD (Ozonoff et al., 2008; Provost et al., 2007). Second, we are not fully confident that bodily movement patterns are linked to ASD, or to the emergence of autism-like behaviours on the sub-clinical level. To address these limitations, the usefulness of our system for early screening of children with ASD should be tested in a longterm study with a prospective design that would recruit children genetically at high risk for ASD.

268

269 4. Materials and Methods

270 **4.1.** Participants

Sixty-two 4-month-olds and their mothers participated in video recordings of bodily movement 271 patterns in the present study as a part of the birth cohort study, after the caregivers gave their written 272 informed consents. We used all the data available at the point of analysis without determining the 273 sample size *a priori*, because the number of infants evaluated to be at high risk for ASD was 274 predicted to be quite small. The mother-infant pairs were recruited in Nagasaki City, a rural city 275 on Kyushu Island in Japan, through fliers or in-person advertisement in obstetrics and gynaecology 276 clinics. The protocol of this study was reviewed and approved by the ethics committee of the 277 Graduate School of Biomedical Sciences at Nagasaki University (Registration Number: 14050205-278 2) and the Graduate School of Engineering at Hiroshima University (Registration Number: E-1150-279 1). 280

281

282 **4.2.** *Procedure*

Mother-infant pairs participated in the present study at two time points, i.e. 4 and 18 months after birth. At 4 months of age, the subjects visited our laboratory at Nagasaki University. At this point, we video-recorded the bodily movements of infants while lying in the supine position, for later analysis. Meanwhile, mothers completed several questionnaires regarding their mental state and the development of their infants. We sent out questionnaires, including MCHAT, about a week before each infant reached the age of 18 months after birth, and asked the mothers to send back the questionnaires after answering them fully.

290

291 4.2.1. Bodily Movement Recording

Each infant subject was laid on a black mat, in a cream-white wooden crib. The infant's body, except for the head, arms, and limbs, was covered in a white wrap, for increasing the contrast between the infant's body and background. A video camera was affixed to a silver stainless bar arching over the crib, and was directed downward toward the infant, as shown in the leftmost panel of Figure 1. The infant movements were recorded continuously. The average length of the recorded videos was 24,028 frames (SD = 8,425 frames; range = 9,600–50,940 frames). The frame rate f_s and resolution of the video recordings were 30 fps and 720 × 480 pixels, respectively.

299

300 4.2.2. Self-Administered Questionnaires

We asked the mothers to complete self-administered questionnaires at three points. The first 301 batch of questionnaires was administered at the time of enrolment. The questionnaires asked for 302 demographic information regarding her and her husband's age, socio-economic status, and medical 303 history. At 4 months of age, information about the mother's mental state and infant's developmental 304 state was collected at the lab; the results of this analysis will be reported elsewhere. At 18 months 305 of age, we mailed questionnaires, including the MCHAT. The MCHAT included 23 items of 306 Yes/No questions, asking whether a child exhibited developmental delays in socio-cognitive 307 functions. The MCHAT also included items about atypical behaviors often observed in ASD, such 308 as hypersensitivity to sensory stimulation. The cut-off point was three. 309

310

311 **2.3.** Analysis

312 2.3.1. Bodily Movement Analysis

In the initial stage of processing, the recorded videos were divided into video sub-segments by deleting frames that contained the infants' sleep, crying, and accidental occurrence of external stimulation. Videos of continuous bodily movements were first converted into binary images by image thresholding, to extract the image of the infant's body as the foreground. Images of spontaneous bodily motion were then obtained by frame-by-frame subtraction. Motion in each area of the body was extracted from these images. The procedure for segmenting a static image into body areas is as follows. First, the outer circumference of the infant's trunk within each frame was approximated using an ellipsoid. Then, a rectangle was defined such that the rectangle contained an ellipsoid within it with a margin. Thereafter, this rectangle was divided into four sub-regions, each containing the right arm, left arm, right leg, and left leg. Based on the bodily movement data within each quadrant of the entire rectangle, we calculated 26 features of bodily movement, as summarized in Table 2.

325

326 4.3.2. Feature Selection

We first selected the features that are useful for classifying infants into low and high ASD 327 risk groups. In the first stage of feature selection, we tested group differences on 26 features 328 between infants with low and high ASD risk, using the Brunner-Munzel test. Features that showed 329 significant group differences at the 10% significance threshold were retained for further analyses. 330 This lenient threshold was adopted because we wished to retain as many informative features as 331 possible for later classification using machine learning algorithms. In the second stage of feature 332 selection, the correlation coefficients were computed for every pair of retained features. Pairs of 333 features with correlation coefficients ≥ 0.7 were lumped into a single feature. 334

335

336 4.3.3 Group Classification by Machine Learning

We examined whether bodily movements contain sufficient information for discriminating infants with high ASD risk from those with low ASD risk, using machine learning approaches. Four classifiers were trained for predicting whether an infant belonged to the high-risk group based on the selected bodily movement features, using supervised learning. The four machine learning algorithms included two linear classifiers, i.e. the linear discriminant analysis (LDA) and the logistic regression (LR), and two non-linear classifiers, i.e. the multi-layered perceptron (MLP) and

the log-linearised Gaussian mixture network (LLGMN; Tsuji et al., 1999). The MLP included one 343 hidden layer, the activation function of which was a rectified linear unit. The performance of the 344 four classifiers was cross-validated using the leave-one-out procedure. In the leave-one-out 345 approach, the data of one of the participants were treated as unknown test data, while the data of 346 the remaining participants were used for training the corresponding classifier. This cycle was 347 repeated until the data from every participant served as the test data. The MLP and LLGMN each 348 included one hyperparameter, i.e. the number of hidden layers and the number of components, 349 respectively. These hyperparameters were tuned using a nested leave-one-out procedure 350 (Parvandeh et al., 2020). Fisher's exact test was performed for testing associations between the 351 classifications made by each of the classifiers used in this study and grouping by the MCHAT 352 scores. Yule's correlation coefficient (Yule's Q) was also calculated, for confirming the strength of 353 each association. The performances of the classifiers were compared in terms of the sensitivity, the 354 specificity, the F1 score, the area under curve of receiver-operator-characteristic curve (AUC-ROC), 355 and the area under the precision-recall curve (AUC-PR) as performance indicators. 356

530 Appendix

531 **Definitions of Bodily Movement Features**

In the bodily movement analysis, each frame of the s-th video sub-segment was converted into a binary image after segregating the infant body from the background. Based on the rectangle defined around the infant body in each frame, seven bodily regions, A_k (k = 1-7), were defined. $A_{1\sim4}$ represented the upper right, upper left, lower right, and lower left quadrants, respectively. A_5 and A_6 were defined as $A_1 + A_2$ and $A_3 + A_4$, respectively, thus representing the upper and lower body. Finally, the whole body, A_7 , was defined as the sum of A_5 and A_6 .

From the binary image, body posture, ${}^{(A_k)}P_l$, and body movement, ${}^{(A_k)}M_l$, in each area A_k in the *l*-th frame ($l \le L_s$) were extracted, based on the following equations:

540

541
$${}^{(A_k)}P_l = \sum_{w=1}^W \sum_{h=1}^H {}^{(A_k)}O_l(x_w, y_h)$$

542

543
$${}^{(A_k)}M_l = \frac{\sum_{w=1}^W \sum_{h=1}^H {}^{(A_k)}O'_l(x_w, y_h)}{{}^{(A^7)}Pave}$$

544

545

where ${}^{(A_k)}O'_{l_l}(x_w, y_h)$ is the pixel value of the image obtained by the frame-by-frame subtraction represented by a binary number (0 or 1) at pixel coordinates (x_w, y_h) within area A_k . ${}^{(A_k)}O'_1(x_w, y_h)$ is zero. W and H represent the number of pixels along the x-and y-axes within each area, respectively. ${}^{(A_7)}P^{ave}$ is the average of the maximal values of ${}^{(A_7)}P_l$ up to the *E*-th frame of the first L_e ($E \leq L_e$) frames of the first video sub-segment. L_e was set to 30 frames. When ${}^{(A_k)}M_l$ exceeded the threshold value of M_{th} , the *l*-th frame was judged to contain a bodily movement in area A_k . We hereinafter refer to a frame that contains a bodily movement in area A_k as "a frame with a bodily movement" The coordinates of the body centre at the *l*-th frame, $(G_{l,x}, G_{l,y})$, were calculated by the

555 following equations:

556

557
$$G_{l,x} = \frac{1}{(A_7)} \sum_{w=1}^{W} \sum_{h=1}^{H} x_w {}^{(A_7)} O_l(x_w, y_h)$$

558

559
$$G_{l,y} = \frac{1}{(A_7)} \sum_{w=1}^{W} \sum_{h=1}^{H} y_h^{(A_7)} O_l(x_w, y_h)$$

560

The velocity of the body centre was calculated as the frame-by-frame difference of the body centre coordinates at the *l*-th frame, $(G_{l,x}^{v}, G_{l,y}^{v})$. The fluctuation of the body centre $(G_{l,x}^{d}, G_{l,y}^{d})$ was calculated based on the average of the body centre coordinates, $(G_{x}^{ave}, G_{y}^{ave})$, over the first L_{e} frames of the first video sub-segment, by the following equations:

565

566
$$G_{l,j}^{\nu} = \frac{f_s(G_{l,j} - G_{l-1,j})}{\sqrt{(A_7)P^{ave}}}$$

567

568
$$G_{l,j}^{d} = \frac{G_{l,j} - G_{j}^{ave}}{\sqrt{(A_{7})P^{ave}}}$$

569

570 where *j* is *x* or *y*.
$$G_{1,x}^{\nu} = 0$$
 and $G_{1,y}^{\nu} = 0$.

573 **1. Movement Magnitude**

574 1-1. I1: Movement Frequency

575 Movement frequency was defined as the proportion of the number of frames with bodily 576 movement against the total number of frames *L*, which is the total length of video sub-segments:

577

578
$${}^{(A_k)}I_1 = \frac{100}{L} \sum_{s}^{S} \sum_{l}^{L_s} {}^{(A_k)}\kappa_l$$

579

580
$${}^{(A_k)}\kappa_l = \begin{cases} 1 \ ({}^{(A_k)}M_l \ge M_{th}) \\ 0 \ ({}^{(A_k)}M_l < M_{th}) \end{cases}$$

581 $M_{th} = 0.005$

582

583 1-2. I2: Movement Strength

Movement strength was defined as the average magnitude of movement within frames with a bodily movement. In the following equation, L' represents the total number of frames with bodily movements:

587 ${}^{(A_k)}I_2 = \frac{1}{L'}\sum_{s}^{S}\sum_{l}^{L_s}{}^{(A_k)}v_l$

588

589
$${}^{(A_k)}v_l = \begin{cases} {}^{(A_k)}M_l ({}^{(A_k)}M_l \ge M_{th}) \\ 0 ({}^{(A_k)}M_l < M_{th}) \end{cases}$$

590

592 **1-3.** *I*₃: *Movement Count*

Movement count was defined as the number of temporal segments where continuous bodily movement was detected, divided by the total number of frames *L*. Every frame within each temporal segment met ${}^{(A_k)}M_l \ge M_{th}$. Simultaneously, ${}^{(A_k)}M_l < M_{th}$ was in the frame just before the first frame of the temporal segment and in the frame immediately after the last frame of the temporal segment. The movement count was calculated by the following equation, where ${}^{(A_k)}Q_s$ represents the number of temporal segments within the *s*-th video sub-segment:

599

600 ${}^{(A_k)}I_3 = \frac{1}{L}\sum_{s}^{S}{}^{(A_k)}Q_s$

601

602 **2. Movement Balance**

603 2-1. I4: Ratio of Movement Frequency

604 The ratio of the movement frequency between the bodily regions A_{k1} and A_{k2} was defined 605 by the following equation:

606

607
$$(A_{k1}, A_{k2})I_4 = \frac{(A_{k1})I_1}{(A_{k2})I_1}$$

608

609 2-2. Is: Ratio of Movement Strength

610 The ratio of the movement strength between the bodily regions A_{k1} and A_{k2} was defined

611 by the following equation:

613
$${}^{(A_{k1},A_{k2})}I_5 = \frac{{}^{(A_{k1})}I_2}{{}^{(A_{k2})}I_2}$$

615 **2-3.** *I*₆: *Movement Coordination*

Movement coordination between the bodily regions A_{k1} and A_{k2} was calculated as the correlation coefficient $r_{(A_{k1},A_{k2})}$ between the time-series data of ${}^{(A_{k1})}M_l$ and ${}^{(A_{k2})}M_l$ according to the equation below. Correlation coefficients were computed within sliding temporal windows with a length of L_c . L_c was set to 300 frames. The stride of the sliding window was one frame. Correlation coefficients were then averaged to yield a single index of the movement coordination.

621
$$r_{(A_{k1},A_{k2})} = \frac{\sigma\left({}^{(A_{k1})}M_l,{}^{(A_{k2})}M_l\right)}{\sigma({}^{(A_{k1})}M_l,\sigma({}^{(A_{k2})}M_l,\sigma)}$$

622

623 **3. Movement Rhythm**

624 3-1. Central Frequency (I₇) and Second Moment around Central Frequency (I₈) of Movement

The time-series data of M_l of each video sub-segment were analysed in the frequency 625 domain. Within each video sub-segment, the time-series data within a sliding window with the 626 length of L_f were subjected to the fast Fourier transformation. L_f was set to 128 frames. The stride 627 of the moving window was one frame. Then, the average power spectrum density (PSD), P(f), 628 was computed by grand-averaging PSDs across all the sliding widows in all the video sub-segments. 629 Based on P(f), central frequency (F_{cntr}) and second moment around the central frequency (D_{cntr}) 630 were computed according to the following equations, where f_{max} is the maximal frequency range 631 for analysis. f_{max} was 15 Hz. F_{cntr} and D_{cntr} , computed on the basis of P(f), correspond to I_7 and 632 I_8 , respectively: 633

635
$$F_{cntr} = \frac{\sum_{0}^{f_{max}} fP(f)}{\sum_{0}^{f_{max}} P(f)}$$

637
$$D_{cntr} = \frac{\sum_{0}^{f_{max}} (f - F_{cntr})^2 P(f)}{\sum_{0}^{f_{max}} P(f)}$$

638

639 **3-2.** Central Frequency $(I_{9,x}, I_{9,y})$ and Second Moment around Central Frequency $(I_{10,x}, I_{10,y})$

640 *I*_{10,y}) of Body Centre Velocity

The time-series data of the body centre velocity along the x- (top-bottom) and y- (left-right) axes were subjected to the fast Fourier transformation. Based on the resulting PSD, the central frequency and the second moment around the central frequency were computed in essentially the same manner as described in *Section 3-1*.

645

646 **3-3.** Central Frequency $(I_{11,x}, I_{11,y})$ and Second Moment around Central Frequency $(I_{12,x}, I_{12,y})$

647 **I**_{12,v}) of Body Centre Fluctuation

The time-series data of body centre fluctuation along the x- (top-bottom) and y- (left-right) axes were subjected to the fast Fourier transformation. Based on the resulting PSD, the central frequency and the second moment around the central frequency were computed in essentially the same manner as described in *Section 3-1*.

652

653 **4. Movement of the Body Centre**

654 4-1. I13: Mean Absolute Body Centre Velocity

655 The average absolute values of the body centre velocity along the x- $(G_{l,x}^{\nu})$ and y-axes $(G_{l,y}^{\nu})$ 656 were computed using the following equations:

658
$$(I_{13,x}, I_{13,y}) = \left(\frac{1}{L}\sum_{s}^{s}\sum_{l}^{L_{s}}|G_{l,x}^{v}|, \frac{1}{L}\sum_{s}^{s}\sum_{l}^{L_{s}}|G_{l,y}^{v}|\right)$$

660 4-2. I14: Standard Deviation of Body Centre Fluctuation

The mean standard deviations of the body centre fluctuations along the x- $(G_{l,x}^d)$ and y- axis ($G_{l,y}^d$), $\sigma_{x,y}$, within each video sub-segment were computed by averaging the standard deviations in the sliding temporal windows of length L_g , calculated following the equation below. L_g was set to 300 frames. The stride of the sliding window was one frame:

665

666
$$\sigma_j = \sqrt{\frac{1}{L_g} \sum_{l}^{L_g} \left(G_{l,j}^d - {}^{avg} G_j^d \right)^2}$$

667

where *j* is *x* or *y*, and ${}^{avg}G_j^d$ represent the mean of $G_{l,j}^d$ within each sliding window. Then, $I_{14,x}$ and $I_{14,y}$ were computed by averaging σ_j along each axis, across all video sub-segments.

670

671 4-3. I15: Area of Body Centre Excursion

The area within the outer circumference of the trajectory of the body centre excursion within each video sub-segment was computed by averaging the areas in the sliding temporal windows of length L_g . The stride of the sliding windows was one frame. Then, I_{15} was computed by averaging the area of body excursions across all video sub-segments.
