Sleep EEG in 22q11.2 deletion syndrome

23 *Abstract*

24 *Background*

25 Young people living with 22q11.2 Deletion Syndrome (22q11.2DS) are at increased risk of
26 schizophrenia, intellectual disability, attention-deficit hyperactivity disorder (ADHD) and autism
27 spectrum disorder (ASD). In common with these conditions, 22q11.2DS is also associated with
28 sleep problems. We investigated whether abnormal sleep or sleep-dependent network activity in
29 22q11.2DS reflects convergent, early signatures of neural circuit disruption also evident in
30 associated neurodevelopmental conditions.

31 *Methods*

32 In a cross-sectional design, we recorded high-density sleep EEG in young people (6-20 years) with
33 22q11.2DS (n=28) and their unaffected siblings (n=17), quantifying associations between sleep
34 architecture, EEG oscillations (spindles and slow waves) and psychiatric symptoms. We also
35 measured performance on a memory task before and after sleep.

36 *Results*

37 22q11.2DS was associated with significant alterations in sleep architecture, including a greater
38 proportion of N3 sleep and lower proportions of N1 and REM sleep than in siblings. During sleep,
39 deletion carriers showed broadband increases in EEG power with increased slow-wave and
40 spindle amplitudes, increased spindle frequency and density, and stronger coupling between
41 spindles and slow-waves. Spindle and slow-wave amplitudes correlated positively with overnight
42 memory in controls, but negatively in 22q11.2DS. Mediation analyses indicated that genotype
43 effects on anxiety, ADHD and ASD were partially mediated by sleep EEG measures.

44 *Conclusions*

45 This study provides a detailed description of sleep neurophysiology in 22q11.2DS, highlighting
46 alterations in EEG signatures of sleep which have been previously linked to neurodevelopment,
47 some of which were associated with psychiatric symptoms. Sleep EEG features may therefore
48 reflect delayed or compromised neurodevelopmental processes in 22q11.2DS, which could inform

Sleep EEG in 22q11.2 deletion syndrome

49 our understanding of the neurobiology of this condition and be biomarkers for neuropsychiatric
50 disorders.

51 *Funding*

52 This research was funded by a Lilly Innovation Fellowship Award (UB), the National Institute of
53 Mental Health (NIMH 5UO1MH101724; MvdB), a Wellcome Trust Institutional Strategic Support
54 Fund (ISSF) award (MvdB), the Waterloo Foundation (918-1234; MvdB), the Baily Thomas
55 Charitable Fund (2315/1; MvdB), MRC grant Intellectual Disability and Mental Health: Assessing
56 Genomic Impact on Neurodevelopment (IMAGINE) (MR/L011166/1; JH, MvdB and MO), MRC
57 grant Intellectual Disability and Mental Health: Assessing Genomic Impact on Neurodevelopment 2
58 (IMAGINE-2) (MR/T033045/1; MvdB, JH and MO); Wellcome Trust Strategic Award 'Defining
59 Endophenotypes From Integrated Neurosciences' Wellcome Trust (100202/Z/12/Z MO, JH).

60 NAD was supported by a National Institute for Health Research Academic Clinical Fellowship in
61 Mental Health and MWJ by a Wellcome Trust Senior Research Fellowship in Basic Biomedical
62 Science (202810/Z/16/Z). CE and HAM were supported by Medical Research Council Doctoral
63 Training Grants (C.B.E. 1644194, H.A.M MR/K501347/1). HMM and UB were employed by Eli Lilly
64 & Co during the study; HMM is currently an employee of Boehringer Ingelheim Pharma GmbH &
65 Co KG.

Sleep EEG in 22q11.2 deletion syndrome

68 Introduction

69 22q11.2 microdeletion syndrome (22q11.2DS) is caused by a deletion spanning a ~2.6 megabase
70 region on the long arm of chromosome 22. It occurs in ~1:3,000-4,000 births and is associated
71 with increased risk of neuropsychiatric conditions including intellectual disability, autism spectrum
72 disorder (ASD), attention-deficit hyperactivity disorder (ADHD), and epileptic seizures.
73 (Cunningham et al., 2018; Eaton et al., 2019; Moulding et al., 2020; Niarchou et al., 2014).
74 22q11.2DS is also considered to be one of the largest biological risk factors for schizophrenia, with
75 up to 41% of adults with 22q11.2DS having psychotic disorders (Karayiorgou et al., 1995; Monks et
76 al., 2014; Schneider et al., 2014). However, the neurobiological mechanisms underlying psychiatric
77 symptoms in 22q11.2DS remain unclear. Deep phenotyping of young people with 22q11.2DS may
78 allow their elucidation and therefore enable early detection and/or intervention.

79 The electroencephalogram (EEG) recorded during non-rapid eye movement (NREM) sleep
80 features spindle and slow-wave (SW) oscillations: highly conserved and non-invasively measurable
81 signatures of neuronal network activity generated by corticothalamic circuits (Adamantidis et al.,
82 2019). The properties and co-ordination of these oscillations are candidate biomarkers of brain
83 dysfunction in neuropsychiatric disorders (Ferrarelli & Tononi, 2017; Gardner et al., 2014; Manoach
84 et al., 2016).

85 Sleep EEG features are altered across many neurodevelopmental disorders, including
86 schizophrenia, including first episode psychosis, as well as first degree relatives (Chouinard et al.,
87 2004; Cohrs, 2008; Ferrarelli et al., 2007, 2010; Göder et al., 2015; Bartsch et al., 2019;
88 Demanuele et al., 2017; Wamsley et al., 2012; Manoach & Stickgold, 2019; Castelnovo et al.,
89 2017; Keshavan et al., 1998); ADHD (Cortese et al., 2009; Gorgoni et al., 2020; Lunsford-Avery et
90 al., 2016), ASD (although findings have been inconsistent (Gorgoni et al., 2020; Lehoux et al.,
91 2019)) and a range of rare genetic conditions, including Down syndrome, Fragile-X syndrome and
92 Angelman syndrome (Angriman et al., 2015).

93 We have recently shown that the majority of young people with 22q11.2DS have sleep problems,
94 particularly insomnia and sleep fragmentation, that associate with psychopathology (Moulding et

Sleep EEG in 22q11.2 deletion syndrome

95 al., 2020). However, this analysis was based on parental report; the neurophysiological properties
96 of sleep in this condition remain unexplored. Furthermore, it has been demonstrated that
97 neuroanatomical features associated with psychopathology in 22q11.2DS significantly converge
98 with those in idiopathic psychiatric disorders (Ching et al., 2020). Therefore studying the sleep
99 EEG in 22q11.2DS may produce insights that can be generalized to broader populations, affording
100 a unique opportunity to clarify the relationship between sleep EEG and psychiatric risk.

101 We hypothesized that 22q11.2DS would be associated with alterations in sleep EEG features
102 relative to controls, including altered spindle and SW events, and aberrant spindle-SW coupling.
103 We investigated these hypotheses in a cross-sectional study of young people with 22q11.2DS and
104 unaffected sibling controls, combining detailed neuropsychiatric assessments with overnight high-
105 density EEG recordings and a sleep-dependent memory task.

Sleep EEG in 22q11.2 deletion syndrome

106 Results

107 *Psychopathology and sleep architecture in 22q11.2 DS*

108 Young people living with 22q11.2DS (n = 28) and healthy control siblings (n = 17) completed semi-
109 structured research diagnostic interviews to quantify Full Spectrum Intelligence Quotient (FSIQ),
110 neuropsychiatric symptoms and self- and carer-reported sleep behavioral problems (**Table 1 and**
111 **Figure 1 – Supplement 1**). Participants with 22q11.2DS had a lower mean FSIQ (reported as
112 Odds Ratio (OR) or group difference (GD) with [95% confidence interval]): FSIQ, GD = -28.70 [-
113 40.48, -16.92], $p < 0.001$), and higher incidence of anxiety (OR = 3.10 [1.93, 4.99], $p < 0.001$),
114 ADHD (OR = 9.46 [5.12 – 17.48], $p < 0.001$) and ASD symptoms (Odds Ratio [OR] = 7.46 [4.76,
115 11.70], $p < 0.001$), but did not show significantly more psychotic experiences than controls (OR =
116 4.05 [0.67, 43.67], $p = 0.096$). Details of the specific psychotic symptoms reported are shown in
117 **Table 2**.

118 Participants with 22q11.2DS also experienced more sleep problems (OR = 6.27 [2.12, 18.56], $p =$
119 0.001); more sleep problems were associated with younger age, 22q11.2DS genotype and anxiety
120 symptoms but not with gender, family income, psychotic experiences, ADHD or ASD symptoms
121 (**Table 3**).

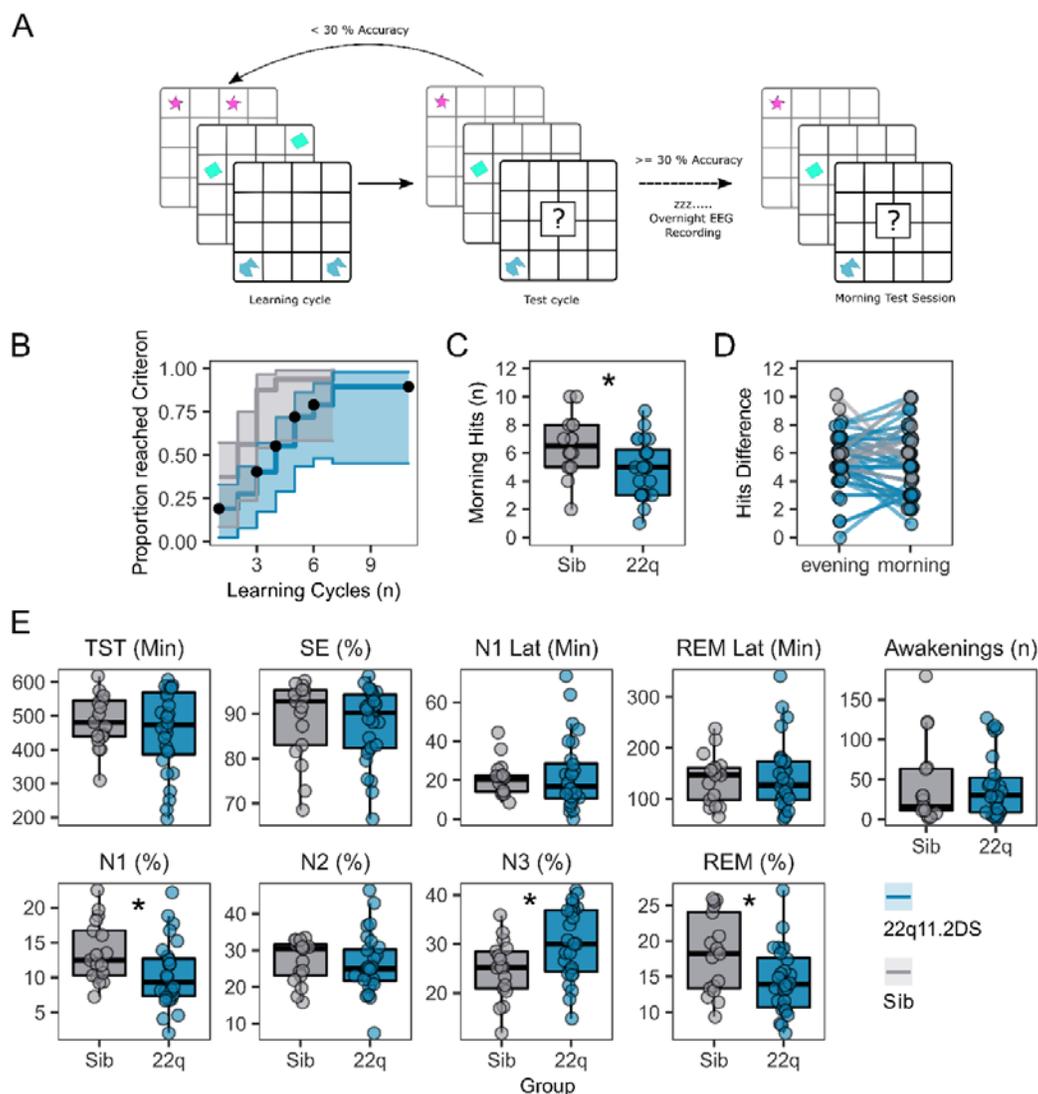

122 Participants were asked to perform a delayed recall 2D object location task (**Figure 1A**) to test
123 sleep-dependent memory consolidation. Of 42 participants who engaged in the task, those with
124 22q11.2DS needed more training cycles to reach a 30% performance criterion (Hazard Ratio
125 [95%CI] = 0.328 [0.151, 0.714], $p = 0.005$, **Figure 1B, Table 4**) and made fewer correct responses
126 in the morning test session (OR = 0.631 [0.45, 0.885], $p = 0.008$, **Figure 1C, Table 4**). However,
127 there was no difference between groups in overnight change in correct responses between the
128 evening learning session and the morning test session (**Figure 1D, Table 4**). Additionally, there
129 was no association between task performance or accuracy in the morning test session and any
130 psychiatric measure, or FSIQ (**Table 4**).

Sleep EEG in 22q11.2 deletion syndrome

131 All participants completed one night of full polysomnography with 64-channel high density EEG
132 recorded at their home. After expert sleep scoring, we compared sleep architecture between
133 22q11.2DS and controls (**Figure 1E** and **Table 1**). There was no difference in gross measures of
134 sleep such as Total Sleep Time and Sleep Efficiency, suggesting that our EEG recordings did not
135 disrupt sleep differently between groups. However, 22q11.2DS was associated with a reduced
136 percentage of N1 (GD = -2.71 [-5.05, -0.36], $p = 0.044$) and REM sleep (GD = -4.20 [-7.10, -1.30],
137 $p = 0.012$) while the percentage of N3 sleep was increased (GD = 5.47 [1.98, 8.96], $p = 0.009$).
138 There were no significant relationships between sleep architecture metrics and psychiatric
139 measures or FSIQ in 22q11.2DS (**Table 5**).

Sleep EEG in 22q11.2 deletion syndrome

140 Figure 1: Memory task performance and sleep architecture features of 22q11.2DS

141

142 **Figure 1 Legend:**

143 *A: Schematic of the 2D object location task. The evening before sleep EEG recordings,*
 144 *participants first were sequentially presented with pairs of images on a 5 x 6 grid. In a subsequent*
 145 *test cycle, they were presented with one image of the pair, and were required to select the grid*
 146 *location of the other half of the pair. If the participant did not achieve > 30% accuracy, they would*
 147 *have another learning cycle. In the morning a single test cycle was undertaken.*

148 *B: Plot of performance in acquiring the 2D object location task, showing the proportion of*
 149 *participants in each group reaching the 30% performance criterion after each learning cycle.*

Sleep EEG in 22q11.2 deletion syndrome

150 *Shaded areas represent the 95% confidence interval. Black dots show when participants were*
151 *right-censored due to stopping the task prior to reaching the 30% criterion.*

152 *C: Box plots of performance in the morning test session, where participants had one cycle of the*
153 *memory task. Number of correct responses is out of a possible 15. Asterix indicate the group*
154 *difference is statistically significant, generalised linear mixed model, $p < 0.05$ (see **Table 2** for full*
155 *statistics).*

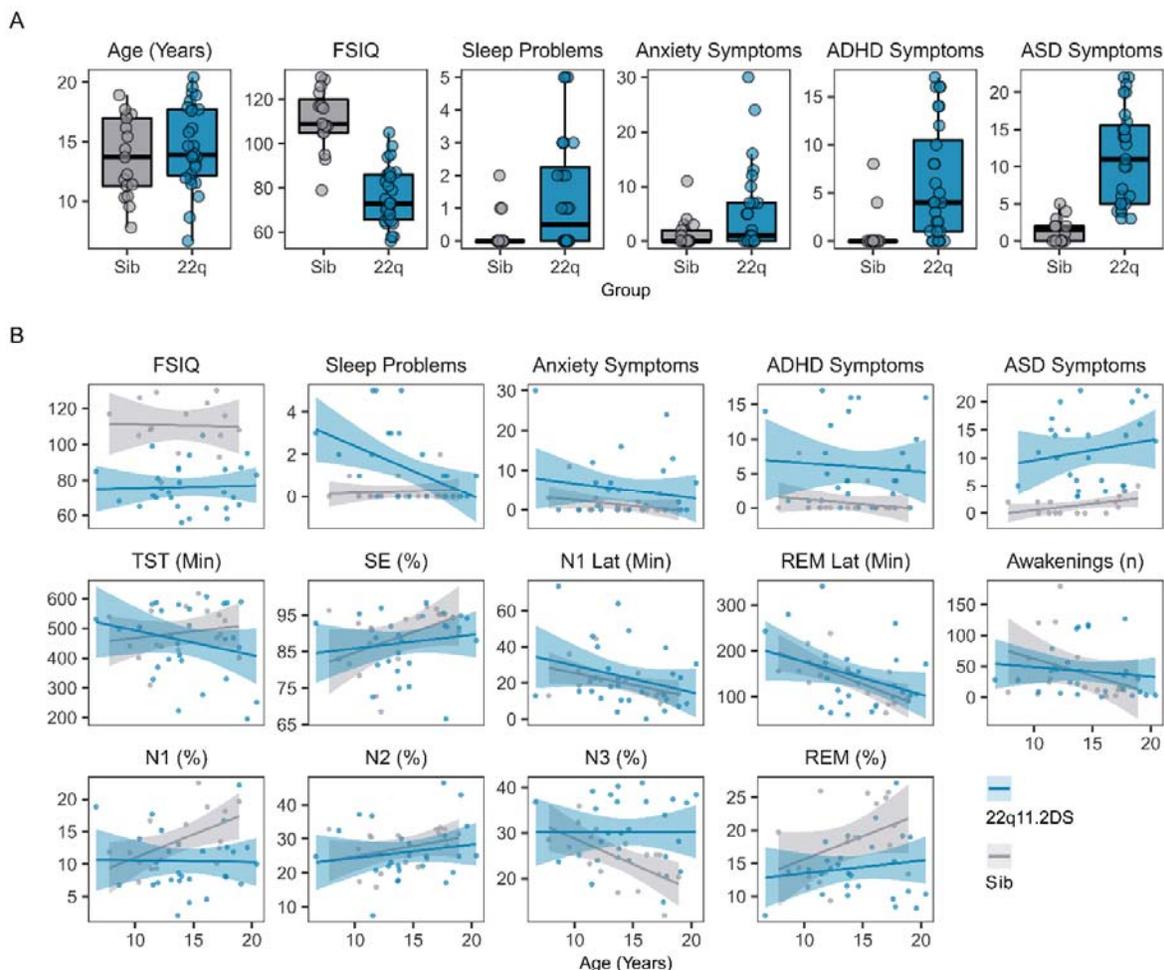

156 *D: Plots of change in performance between the final evening learning session and the morning test*
157 *session. Each participant is represented as a point, with a line connecting their evening and*
158 *morning performance. Points have been slightly jittered to illustrate where multiple participants had*
159 *the same score.*

160 *E: Box and whisker plots showing sleep architecture features: Total sleep time (TST) in minutes,*
161 *Sleep efficiency (SE) as a percentage, Latency to N1 sleep (minutes), Latency to first REM sleep*
162 *(minutes), Number of awakenings after sleep onset (n), Percentage of hypnogram in N1 sleep,*
163 *Percentage of hypnogram in N2 sleep, Percentage of hypnogram in N3 sleep, and Percentage of*
164 *hypnogram in REM sleep. Asterixes indicate the group difference is statistically significant, linear*
165 *mixed model, $p < 0.05$ (see **Table 1** for full statistics). Boxes represent the median and IQR, with*
166 *the whiskers representing 1.5 x the IQR. Individual participant data are shown as individual points.*
167 *Points have been slightly jittered in the x direction only to illustrate where multiple participants had*
168 *similar results.*

231 *22q11.2DS. Regression models were fit with linear mixed models, with family identity as a random*
232 *(varying) intercept. Data presented are regression beta coefficients with 95% confidence intervals.*

233

Sleep EEG in 22q11.2 deletion syndrome

234 *Altered Spectral Properties of the Sleep EEG in 22q11.2DS*

235 Given the above evidence for an altered overall distribution of sleep stages in 22q11.2DS, we next
236 used spectral analyses to quantify sleep EEG oscillations in our sample.

237 Before analyzing all 60 EEG electrodes, we calculated power spectral density (PSD) across
238 frequencies from 0.5 – 20 Hz for controls and in 22q11.2DS for electrode Cz, as both spindle and
239 slow wave oscillations can be reliably detected at this location (**Figure 2A**). We found that power in
240 lower frequencies appeared to be increased in 22q11.2DS across N2 and N3 as well as across a
241 range of frequencies during REM sleep (cluster-corrected $p < 0.05$).

242 To investigate potential changes in specific oscillatory components of the EEG (particularly at the
243 sigma and SO frequency bands), we first z-scored raw EEG recordings in the time domain to
244 eliminate broadband power differences between recordings, and again compared the PSD (**Figure**
245 **2B**). This analysis revealed reduced relative power in the sigma frequency band in 22q11.2DS in
246 N2 and N3 sleep (cluster-corrected $p < 0.05$).

247 Next, we used irregular-resampling auto-spectral analysis (Hahn et al., 2020; Wen & Liu, 2016) to
248 separate the oscillatory and fractal (1/f) components of the EEG. This analysis demonstrated that
249 the power of the fractal component of the PSD was increased in 22q11.2DS across a wide range
250 of frequencies in N2, N3 and REM sleep (**Figure 2C**). However, in the oscillatory component of the
251 EEG we found that power in the sigma band appeared to be reduced in 22q11.2DS (**Figure 2D**)
252 but to have a higher peak frequency. Every participant had a distinct peak in oscillatory activity in
253 the sigma frequency band (**Figure 2 – Supplement 1A**).

254 We then focused on a set of PSD derived measures from N2 and N3 sleep: power in the slow delta
255 (< 1.25 Hz) and sigma (10 – 16 Hz) bands, and peak sigma frequency. Additionally, we calculated
256 the y-intercept (cons) and the negative exponent (beta) of a 1/f line fit to the fractal component of
257 the signal to allow comparison of non-oscillatory activity between groups, for N2, N3 and REM
258 epochs. We extracted these measures across all 60 EEG electrodes and fitted generalized additive
259 mixed models to the data from all electrodes for each measure. **Table 6** shows all spectral EEG
260 measures calculated. A detailed topographical analysis revealed that 22q11.2DS showed lower
21

Sleep EEG in 22q11.2 deletion syndrome

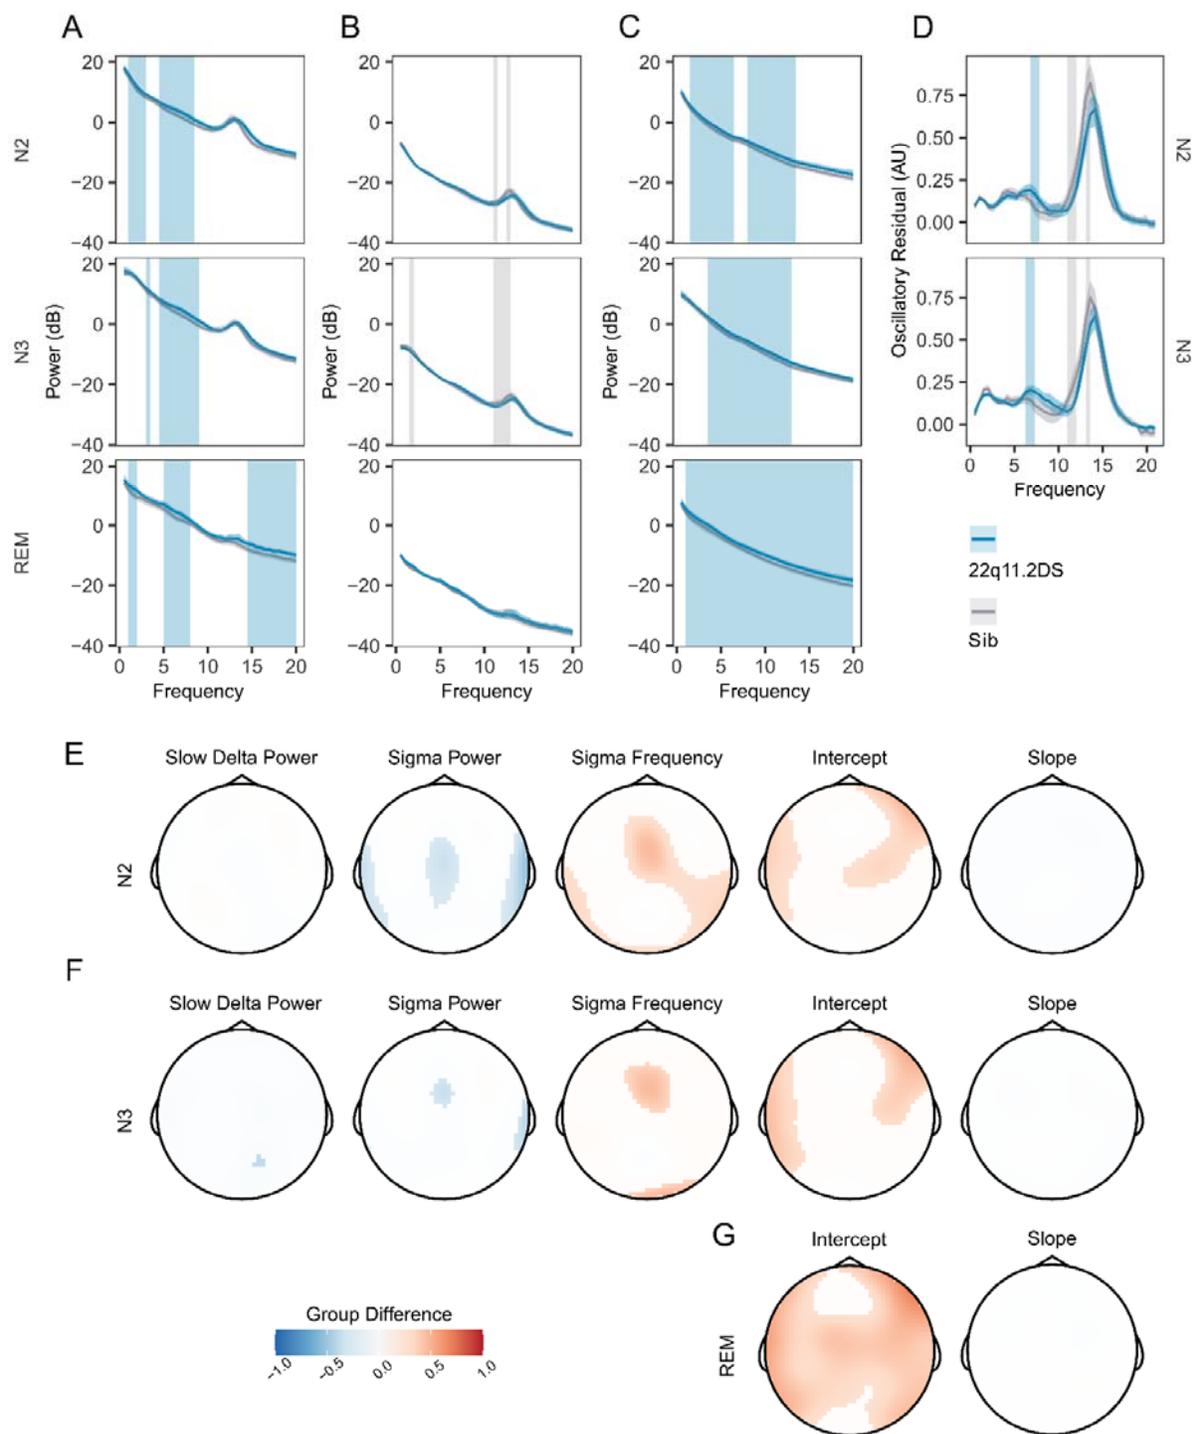

261 sigma power, but higher sigma frequency during N2 and N3 sleep in central regions, and higher
262 total power, as indexed by the 1/f intercept measure across N2, N3 and REM sleep, particularly in
263 fronto-lateral regions (**Figure 2E-G**). In contrast, there were no substantial differences in slow delta
264 power or 1/f slope between groups.

265 Individual data and group boxplots for this set of spectral measures extracted at electrode Cz are
266 shown in **Figure 2 – Supplement 1B**, and plots of spectral measures with age are shown in
267 **Figure 2 – Supplement 1C**, demonstrating clear positive relationships between age and sigma
268 frequency, and negative relationships between age and the overall PSD power (constant) and
269 slope (beta), as previously demonstrated (Hahn et al., 2020).

Sleep EEG in 22q11.2 deletion syndrome

324 *Spindles and Slow Waves in 22q11.2DS*

325 To further interrogate the thalamocortical oscillations underlying genotype-dependent alterations in
326 spectral power and frequency, we quantified individual spindle and slow wave (SW) events using
327 automated detection algorithms. For spindle detection, for each participant and each electrode, we
328 individualized the frequency used for spindle detection, using the peak sigma band frequency from
329 our spectral analysis.

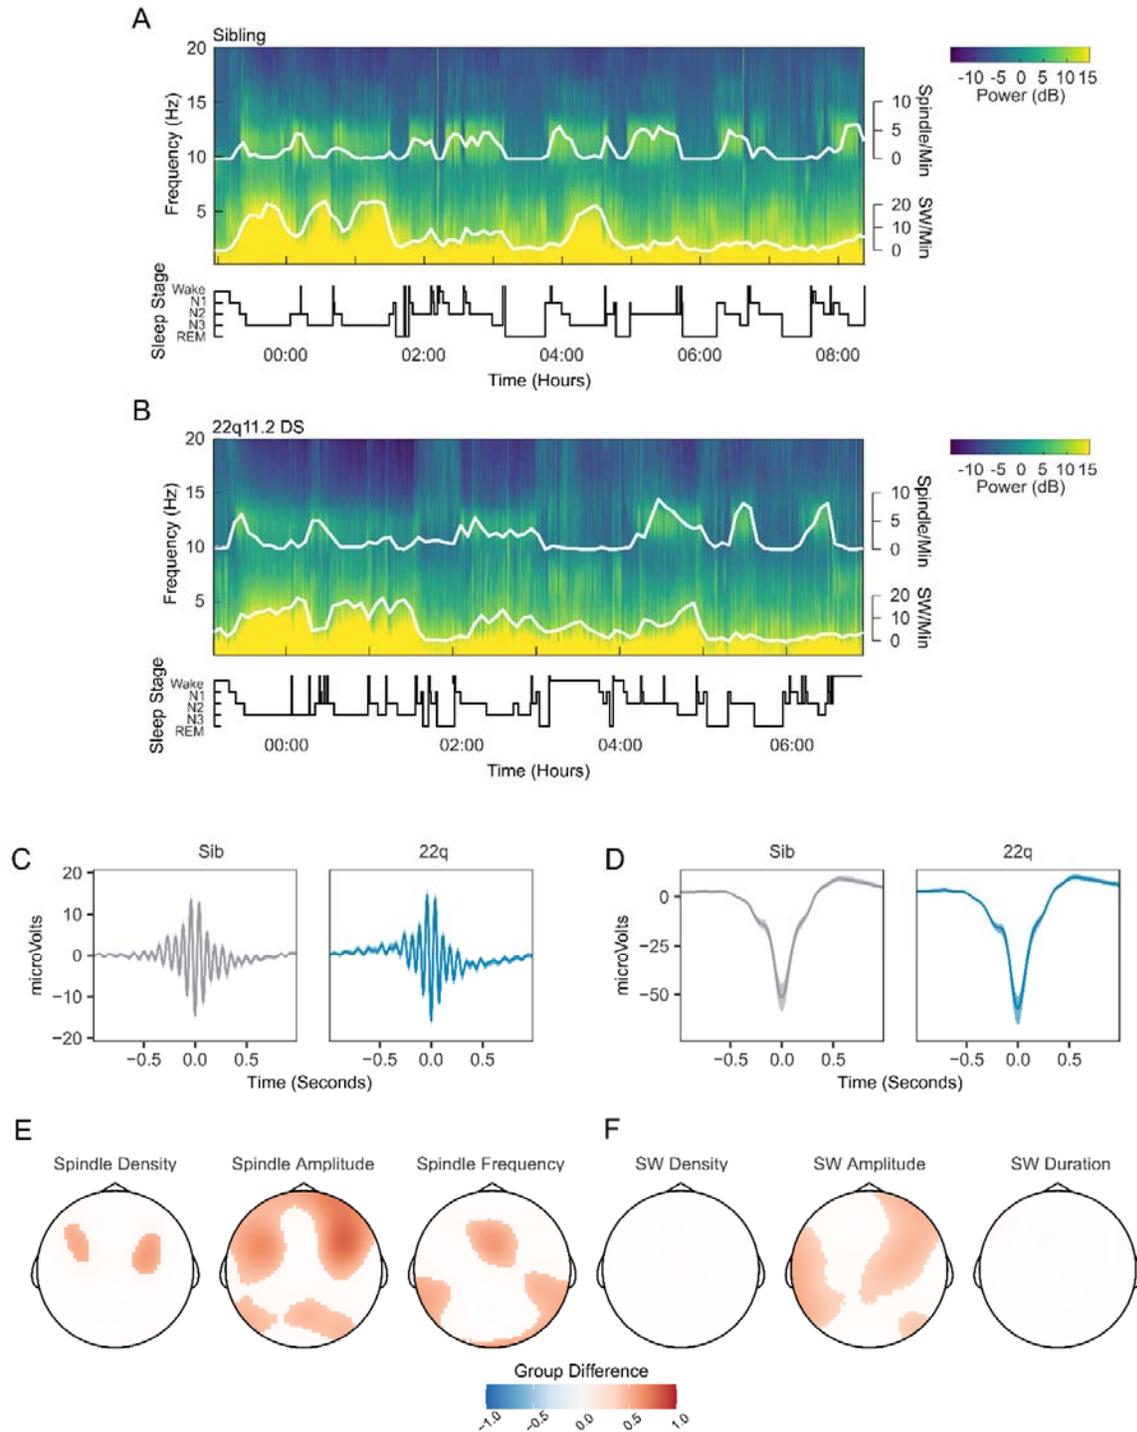

330 **Figure 3A and B** show example spectrograms from electrode Cz for a pair of siblings; one control
331 (**Figure 3A**), one with 22q11.2DS (**Figure 3B**), with detected spindle and SW events overlaid. As
332 expected, these plots clearly indicate the presence of co-occurring spindle and SW events during
333 NREM sleep.

334 The average waveforms of spindle and SW events detected on electrode Cz are shown in **Figure**
335 **3C and Figure 3D**, exemplifying group differences in spindle and SW properties: participants with
336 22q11.2DS showed increased spindle amplitude across fronto-lateral regions, with accompanying
337 increases in spindle density and frequency across smaller regions (**Figure 3E**). SW amplitude was
338 also increased in central, frontal and lateral areas, but there were no differences in SW density or
339 duration between groups (**Figure 3F**). Individual data from all participants for the measured spindle
340 and SW properties are presented in **Figure 3 – Supplement 1**, and group topoplots for each
341 property in **Figure 3 – Supplement 2**.

- 384

Sleep EEG in 22q11.2 deletion syndrome

385 *Increased Spindle-SW Coupling in 22q11.2DS*

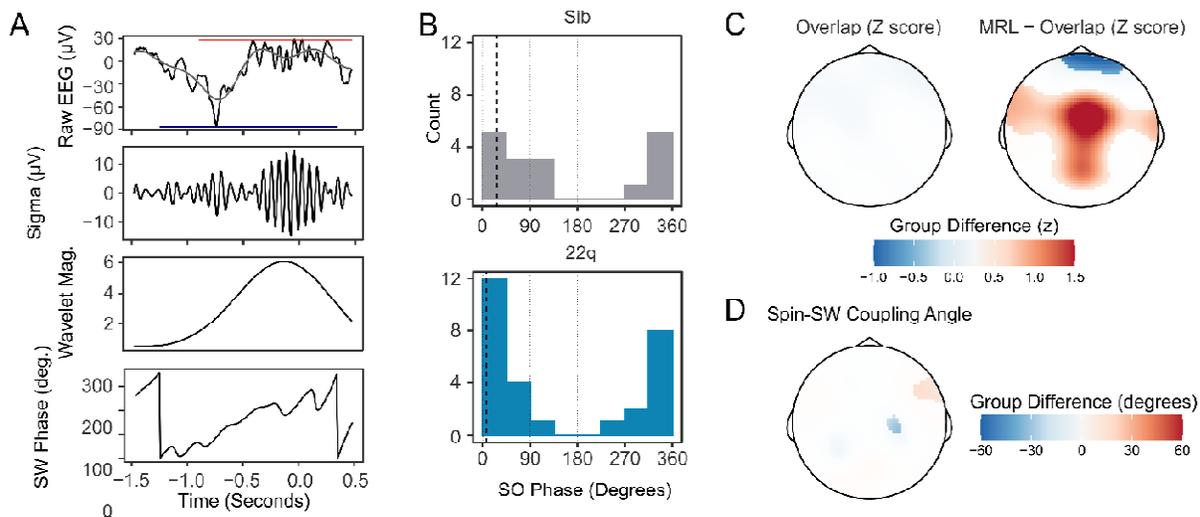

386 The relative timing of spindle and SW events is coupled during NREM sleep, and thought to reflect
387 limbic-thalamic-cortical interactions (Bartsch et al., 2019; Demanuele et al., 2017; Djonlagic et al.,
388 2020; Helfrich et al., 2018; Latchoumane et al., 2017). An illustrative example of an overlapping
389 spindle and SW detection is shown in **Figure 4A**. To investigate whether 22q11.2DS was
390 associated with alterations in spindle-SW coupling, we first calculated the proportion of spindles
391 that overlapped a detected SW (where a spindle peak fell within +/- 1.5 seconds of a detected SW
392 negative peak). We then calculated the SW phase angle at the point of peak amplitude in each
393 spindle, and the mean resultant length (MRL, a measure of the circular concentration of phase
394 angles, with greater values indicating a more consistent spindle-SW phase relationship (Djonlagic
395 et al., 2020)) at the peak of each spindle.

396 The mean angle of spindle-SW coupling showed a non-uniform distribution, confirming that
397 spindles tended to consistently occur at particular SW phases (**Figure 4B** shows coupling angles
398 for spindles detected at electrode Cz); at electrode Cz both control and 22q11.2DS participants
399 had significantly non-uniform distributions of spindle-SW coupling phase angles (siblings: mean
400 angle = 27.6°, SD = 0.959, Rayleigh Test for non—uniformity statistic = 0.632, $p < 0.001$;
401 22q11.2DS: mean angle = 9.51°, SD = 0.769, Rayleigh test statistic 0.744, $p < 0.001$), but no
402 difference in coupling angle was observed between groups: Watson Williams test $F_{1,43} = 1.341$, $p =$
403 0.253.

404 We then compared coupling between groups across all electrodes. Compared to siblings,
405 22q11.2DS was not associated with any change in the proportion of spindles overlapping SW, but
406 was associated with increased MRL across a central region, indicating less variable spindle-SW
407 phase coupling (**Figure 4C**). There were only minor differences in preferred coupling angle in
408 22q11.2DS (**Figure 4D**). Per participant data for the overlap and MRL measures recorded on
409 electrode Cz are presented in **Figure 4 – Supplement 1** and group topoplots in **Figure 4 –**
410 **Supplement 2**.

Sleep EEG in 22q11.2 deletion syndrome

411 **Figure 4: Increased Spindle-SW Coupling in 22q11.2DS**

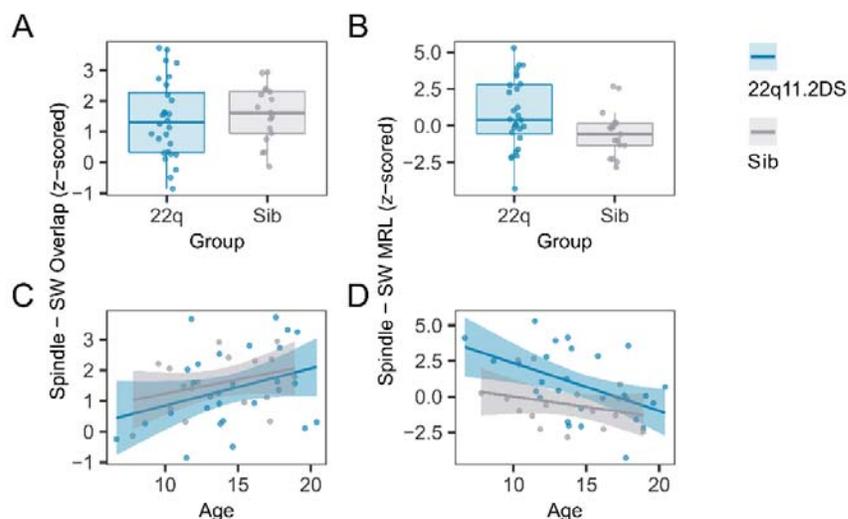

412

413 **Figure 4 Legend:**

449

Sleep EEG in 22q11.2 deletion syndrome

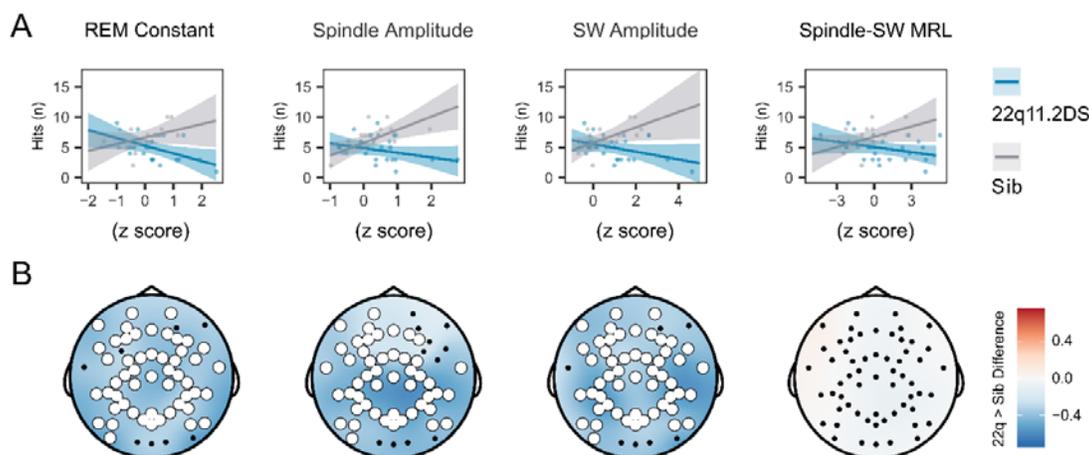

450 *Sleep Feature Associations with Memory Recall*

451 Next, we tested whether features of the sleep EEG which demonstrated significant group
452 differences (REM 1/f intercept, spindle amplitude, SW amplitude and spindle-SW MRL), interacted
453 with group effects on accuracy in the morning test session. As there were no group differences in
454 change in task performance overnight, but groups differed in morning test performance, we
455 focused on number of correct responses in the morning memory test session. For features
456 extracted at electrode Cz (**Figure 5A**), significant features x genotype interactions were observed
457 (all $p < 0.05$). Applying the same analysis across all recording electrodes (**Figure 5B**), we found
458 significant clusters of negative interactions between group and REM intercept, spindle and SW
459 amplitude across multiple central and posterior electrodes: higher spindle and SW amplitudes were
460 associated with higher accuracy in controls; in 22q11.2DS, higher amplitudes were associated with
461 lower accuracy. We did not observe any interaction between spindle-SW MRL and task
462 performance.

463

465

466 **Figure 5 Legend:**

467 A. Scatter plot of the relationship between EEG measures (recorded on electrode Cz) and hits
468 in the memory task test session, by group. Lines represent predicted mean values, with
469 95% confidence interval, from linear mixed model).

470 B. Topoplots of the value of the group*EEG feature interaction term, for models fit to hits in the
471 morning test session. Electrodes highlighted in white indicate a significant interaction for an
472 EEG measure detected on that channel, after correction for multiple comparisons. Note all
473 topoplots are on the same color scale.

474

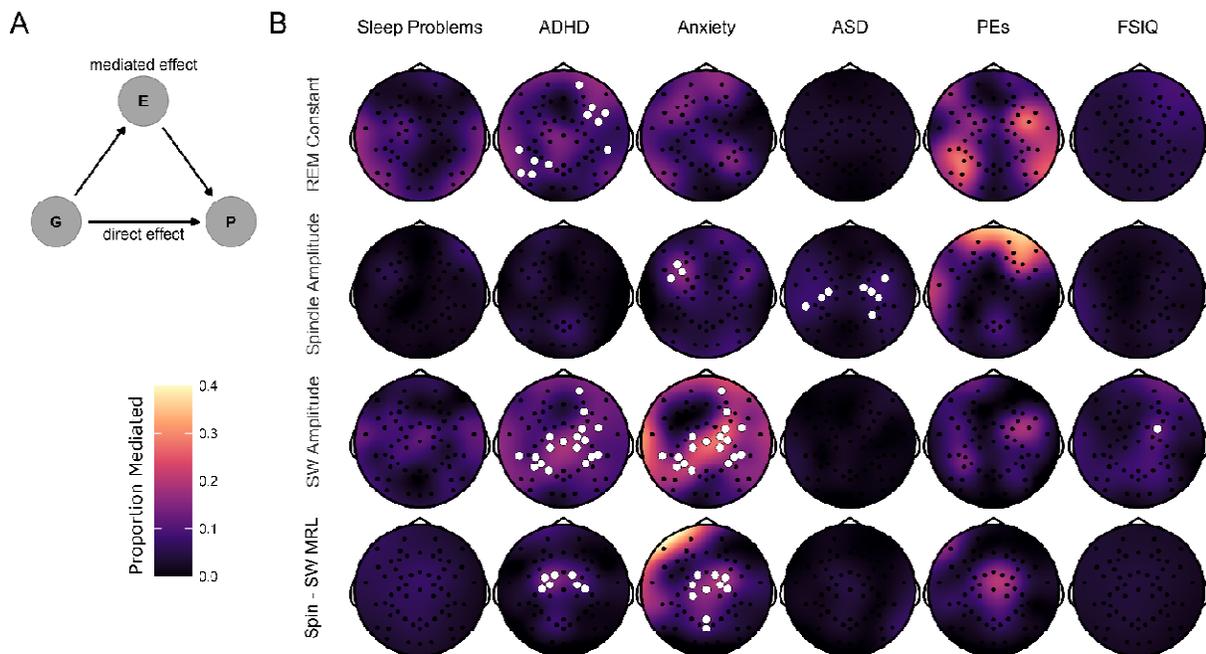

Sleep EEG in 22q11.2 deletion syndrome

475 *Mediation of Genotype Effects on Psychiatric Symptoms by EEG Features*

476 Finally, we used mediation models to investigate whether the effects of 22q11.2DS genotype on
477 psychiatric symptoms and FSIQ were potentially mediated via sleep EEG measures (**Figure 6A**);
478 such mediation would support the potential role for quantitative sleep EEG measures serving as
479 biomarkers for psychiatric disorders e.g. (Manoach & Stickgold, 2019). We calculated the total
480 effect of genotype on psychiatric measures and IQ, the indirect (mediated) effect of EEG
481 measures, and the proportion of the total effect that may be mediated by EEG measures,
482 correcting for multiple comparisons using cluster-based permutation testing. The largest effects
483 were of mediation of genotype effects on anxiety and ADHD symptoms by SW amplitude and
484 spindle – SW coupling, with mediation of genotype effects on ADHD symptoms by REM constant,
485 and genotype effect on ASD symptoms by spindle amplitude (**Figure 6B and Table 7**). There was
486 little evidence for consistent mediation of genotype effects on sleep problems, psychotic
487 experiences or FSIQ.

Sleep EEG in 22q11.2 deletion syndrome

488 Figure 6: Mediation of Psychiatric Symptoms and FSIQ by Sleep EEG Features

489

490 **Figure 6 Legend:**

491 A. Directed acyclic graph describing the mediation model fit to EEG data. The effect of Group
492 (G) on psychiatric measures and FSIQ (P) was hypothesized to be mediated by (E) – sleep
493 EEG features.

494 B. Topoplots of the proportion of the effect of genotype on psychiatric measures and FSIQ
495 mediated by one of four NREM sleep EEG features (REM constant spindle amplitude, SW
496 amplitude and spindle-SW MRL). Fill color represents the Proportion Mediated. Electrodes
497 are highlighted in white where a mediation model fit on data from that electrode had a
498 significant mediated effect and a significant total effect, corrected for multiple comparisons
499 by the cluster method.

500

Sleep EEG in 22q11.2 deletion syndrome

501 Table 7: Average proportions of genotype effects on psychiatric measures and IQ mediated by
502 sleep EEG measures
503

Measure	Mediator	Proportion Mediated
ADHD Symptoms	REM Constant	0.11 (0.02)
ADHD Symptoms	SW Amplitude	0.14 (0.03)
ADHD Symptoms	Spin - SW MRL	0.16 (0.03)
Anxiety Symptoms	Spindle Amplitude	0.17 (0)
Anxiety Symptoms	SW Amplitude	0.21 (0.05)
Anxiety Symptoms	Spin - SW MRL	0.19 (0.07)
ASD Symptoms	Spindle Amplitude	0.08 (0.02)
FSIQ	SW Amplitude	0.18

504

505 **Table 7 Legend:** Proportions of genotype effect on psychiatric measures and FSIQ mediated
506 (Measure) by select sleep EEG features (Mediator) of for all electrodes in significant clusters. Data
507 shown are mean (SD). Note FSIQ does not have an SD as there was only one electrode in a
508 significant cluster.

Sleep EEG in 22q11.2 deletion syndrome

509 Discussion

510 *Summary of Findings*

511 We performed an analysis of sleep EEG characteristics in 22q11.2DS, correlating these with
512 psychiatric symptoms, sleep architecture and performance in a memory task.

513 Our previous results, based on primary carer reports, discovered sleep disruption, particularly
514 insomnia and restless sleep in 22q11.2DS (Moulding et al., 2020), which was associated with
515 psychopathology. We extend these findings to show that, compared to unaffected control siblings,
516 22q11.2DS is associated with decreased N1 and REM sleep, increased N3 sleep, increased
517 overall EEG power and altered power and frequency in the sigma band during NREM sleep.

518 These finding were accompanied by changes in NREM sleep-related events: increased spindle
519 amplitude, density, and frequency; increased SW amplitude; and increased spindle-SW phase
520 coupling. The relationship between spindle and SW features and performance of a spatial memory
521 task differed by group, with a positive correlation between spindle and SW amplitude and
522 performance in controls, but a negative relationship in 22q11.2DS. Finally, group differences in
523 anxiety, ADHD and ASD symptoms were mediated by several EEG measures, particularly SW
524 amplitude and spindle – SW coupling, across multiple electrodes.

525 *Relationship to previous findings – Spindles and Spindle Slow Wave-coupling*

526 We observed increased spindle amplitude, frequency, and density in 22q11.2DS, accompanied by
527 increased spindle-SW coupling, and evidence that spindle amplitude and spindle - SW coupling
528 mediated genotype effects on anxiety, ADHD and ASD symptoms.

529 The clinical presentation of 22q11.2DS is heterogenous (Cunningham et al., 2018), including
530 anxiety, ADHD and ASD symptoms, reduced IQ and increased risk of psychotic disorders
531 (Schneider et al., 2014). Adult schizophrenia is consistently associated with reduced spindle
532 activity (Ferrarelli et al., 2007, 2010; Lai et al., 2022), a finding replicated in a study of early onset
533 schizophrenia (Gerstenberg et al., 2020), and meta-analytic evidence suggests spindle deficits
534 increase with higher symptom burden and longer illness duration (Lai et al., 2022). However,

Sleep EEG in 22q11.2 deletion syndrome

535 increased spindle amplitudes and densities have been observed in healthy adolescents with raised
536 polygenic risk scores for schizophrenia (Merikanto et al., 2019). In contrast, no clear differences in
537 spindle properties have been found in other 22q11.2DS-associated neurodevelopmental disorders
538 such as ADHD (Prehn-Kristensen et al., 2011) and ASD (Maski et al., 2015).

539 Spindle properties and spindle – SW relationships change across the lifespan (Djonlagic et al.,
540 2020; Hahn et al., 2020, 2022; Purcell et al., 2017; Zhang et al., 2021): spindle density, power and
541 frequency increases from childhood to adolescence alongside spindle-SW coupling, while power in
542 lower frequency declines (Hahn et al., 2020; Jenni & Carskadon, 2004; Tarokh & Carskadon,
543 2010). Our findings could therefore be interpreted in the context of alterations in developmental
544 processes in 22q11.2DS: higher spindle amplitude, density and frequency in young, at-risk
545 populations for psychosis could mark an aberrant maturational state, which leads to reduced
546 spindle activity in adulthood for individuals who go on to develop psychotic disorders, with higher
547 symptom burden and illness duration linked to greater reductions in spindle activity.

548 *Relationship to previous findings – Slow Waves*

549 We observed increased SW amplitude in 22q11.2DS and mediation of genotype differences in
550 anxiety and ADHD symptoms by SW amplitude (and spindle-SW coupling). A previous study found
551 delta frequency (<4 Hz) EEG activity to be reduced in ADHD patients not using psychostimulant
552 medication (Furrer et al., 2019); the authors related their finding to reduced cortical grey matter,
553 and delays in its maturation in ADHD (Nakao et al., 2011; Shaw et al., 2006, 2010). In contrast,
554 imaging studies have suggested increased cortical grey matter thickness in 22q11.2DS, alongside
555 changes in corticothalamic networks (Lin et al., 2017; Sønderby et al., 2021; Sun et al., 2020),
556 which may reduce across adolescence (Schaer et al., 2009). This could therefore explain our
557 finding of increased SW amplitude in 22q11.2DS, and its relationship with ADHD symptoms, as it
558 has been previously demonstrated (in adults) that greater SW amplitude is associated with greater
559 cortical thickness (Dubé et al., 2015).

560 Anxiety and ADHD symptoms in late childhood (~ age 10) are associated with subsequent
561 psychotic symptoms in 22q11.2DS (Chawner et al., 2019; Niarchou et al., 2019), although ASD

Sleep EEG in 22q11.2 deletion syndrome

562 symptoms are not. Brain imaging studies have demonstrated that individuals with 22q11.2DS who
563 developed psychotic symptoms had a trajectory of thicker frontal cortex in childhood and early
564 adolescence, which then more rapidly thinned during adolescence, than individuals with
565 22q11.2DS who did not develop psychotic symptoms (Bagautdinova et al., 2021; Ramanathan et
566 al., 2017). Therefore, increased spindle and SW amplitude in 22q11.2DS in childhood/adolescence
567 could reflect aberrant cortical development processes which clinically associate with ADHD and/or
568 anxiety symptoms in this age group, but then progress to thinner frontal cortex, increased risk of
569 psychotic disorders and potentially decreased spindle/SW density in adulthood.

570 *Relationship to previous findings – Aperiodic Signal Component*

571 We discovered increased broadband EEG power in 22q11.2DS during sleep, particularly in REM.
572 Furthermore, the intercept of the aperiodic signal component in REM was observed to be a
573 mediator of genotype effects on ADHD symptoms. One possibility is that the increased power is
574 related to the increased cortical grey matter thickness observed in 22q11.2DS, as has been
575 observed in brain imaging studies (Lin et al., 2017; Sønderby et al., 2021; Sun et al., 2020).

576 We also observed that the slope and intercept of the aperiodic part of the signal reduced with age,
577 similar to previously reported findings in awake resting state EEG in children and adolescents (Hill
578 et al., 2022), and aging adults (Voytek et al., 2015). The slope of the 1/f component of the EEG has
579 also been associated with changes in level of arousal across different sleep stages, with REM
580 being associated with the steepest slopes (Kozhemiako et al., 2021; Lendner et al., 2020).
581 However, we did not observe any differences between groups in 1/f slope.

582 *Mechanisms of sleep EEG changes in 22q11.2DS*

583 Our EEG findings together suggest a complex picture of sleep neurophysiology in 22q11.2DS. On
584 the one hand, increased intercept of the aperiodic component of the signal and increased SW
585 amplitude is associated with a younger developmental age in controls; on the other hand, higher
586 spindle frequency and higher spindle-SW coupling is associated with an older developmental age.
587 Furthermore, we found partial mediation of genotype effects on anxiety, ADHD and ASD symptoms
588 by several EEG measures, in addition to opposing relationships between EEG measures and

Sleep EEG in 22q11.2 deletion syndrome

589 memory task performance in 22q11.2DS, again suggesting a complex relationship between sleep
590 physiology and cognition in carriers of this genotype.

591 Although the physiological bases of 22q11.2DS-associated changes in sleep architecture are
592 unknown, genes in the deleted region of chromosome 22 have been implicated in sleep regulation,
593 potentially via a role in sleep promoting GABA-ergic signaling (Maurer et al., 2020). GABA
594 signaling is also integral to the mechanisms of spindle and slow wave oscillations (Feld et al.,
595 2013; Feld & Born, 2020; Ulrich et al., 2018). Although a study using magnetic resonance
596 spectroscopy did not demonstrate gross changes in GABA levels in the anterior cingulate cortex in
597 22q11.2DS (Vingerhoets et al., 2020), a mouse model of 22q11.2DS does harbor a reduction in
598 GABA-ergic parvalbumin containing cortical interneurons in 22q11.2DS (Al-Absi et al., 2020).
599 Therefore, a potential mechanism of altered sleep and sleep-associated EEG oscillations may
600 involve neurodevelopmental changes to cortical structure and GABAergic signaling in cortical
601 inhibitory networks in 22q11.2DS.

602 *Limitations and Future Directions*

603 In this study we made a single overnight EEG recording. Although there were no differences
604 between groups in terms of total sleep time, or awakenings overnight – indicating minimal
605 disruption by the EEG recording setup – it is possible that the recording protocol caused
606 undetected effects that differed between groups, contributing to our EEG findings. A future study
607 which included a baseline night where participants become familiar with the recording equipment
608 would help to address this possibility.

609 We used mediation analyses to infer associations between genotype, psychiatric measures or
610 FSIQ, and a wide range of sleep EEG measures. Although we corrected for multiple comparisons,
611 these initial findings should be replicated and used for generating hypotheses for future studies.
612 Sleep architecture is heterogenous in young people with ADHD and ASD, as it is in adult
613 schizophrenia patients (Chouinard et al., 2004; Cohrs, 2008); it therefore may be unlikely that
614 sleep macrostructure alone (i.e. percentages of different sleep stages, sleep efficiency etc.) will
615 prove a useful biomarker or prognostic indicator of later neurodevelopmental diagnoses in

Sleep EEG in 22q11.2 deletion syndrome

616 22q11.2DS. However, our results suggest that the use of quantitative measurements of sleep
617 microstructure, such as of spindles, SWs and their coupling could be mediators of genotype effects
618 on psychiatric symptoms and therefore be useful as biomarkers of neurodevelopmental disorders
619 in future studies (Manoach & Stickgold, 2019).

620 As expected, age had a large influence on EEG properties in our between-subject, cross-sectional
621 study (Hahn et al., 2020; Markovic et al., 2020; Purcell et al., 2017). It has previously been
622 demonstrated that psychopathology changes with age in 22q11.2DS, including that ADHD
623 symptoms decline with age (Chawner et al., 2019). Therefore, a longitudinal cohort study of sleep
624 EEG biomarkers in 22q11.2DS from childhood and adolescence into adulthood is an important
625 extension of the present study, to elucidate developmental trajectories, as has been achieved with
626 brain imaging (Bagautdinova et al., 2021; Ramanathan et al., 2017). Further, a retrospective cohort
627 study of EEGs for those with 22q11.2DS who go on to develop schizophrenia-spectrum disorders
628 could dissociate which EEG features relate to the development of psychosis.

629 *Conclusion*

630 In conclusion, in this study quantifying sleep neurophysiology in 22q11.2DS, we highlight
631 differences that could serve as potential biomarkers for 22q11.2DS-associated
632 neurodevelopmental syndromes. Future longitudinal studies should clarify the relationship between
633 psychiatric symptoms, sleep EEG measures, and development in 22q11.2DS, with a view to
634 establishing mechanistic biomarkers of circuit dysfunction that may inform patient stratification and
635 treatment.

Sleep EEG in 22q11.2 deletion syndrome

636 **Methods and Materials**

637 *Participants and study recruitment*

638 Participants were recruited as part of the previously described, ongoing Experiences of Children
639 with cOpy number variants (ECHO) study (Moulding et al., 2020). Where available, a sibling (n =
640 17) without the deletion closest in age to the participant with 22q11.2DS (n = 28) was invited to
641 participate as a control. As this study was an exploratory cross-sectional study of a rare
642 neurodevelopmental copy number variant, our sample size was taken as the maximum number of
643 participants who agreed to have an EEG recording.

644 The presence or absence of the deletion was confirmed by a Medical Genetics laboratory and/or
645 microarray analysis in the MRC Centre for Neuropsychiatric Genetics and Genomics laboratory at
646 Cardiff University.

647 Prior to recruitment, primary carers consented for all participants and additional consent was
648 obtained from participants aged ≥16 years with capacity. The protocols used in this study were
649 approved by the NHS Southeast Wales Research Ethics Committee.

650 Age and sex characteristics of the study sample are shown in **Table 1**. Of participants with
651 22q.11.2DS, four were prescribed melatonin, one was prescribed methylphenidate (Medikinet) for
652 ADHD and one was prescribed sertraline for “mood”. No controls were prescribed psychiatric
653 medication. No study participant reported a diagnosis of epilepsy or seizure disorder.

654 All data were collected during study team visits to participants’ family home. Data collection,
655 including EEG recordings from sets of siblings were carried out on the same visit, which were
656 typically on weekends or school holidays.

657 *Psychiatric characteristics and IQ*

658 Psychopathology and subjective sleep quality was measured by the research diagnostic Child and
659 Adolescent Psychiatric Assessment (CAPA) interview (Angold et al., 1995) with either the
660 participant or primary carer. Interviews were carried out during the same visit as EEG recordings.

Sleep EEG in 22q11.2 deletion syndrome

661 Participants were also screened for Autism-Spectrum Disorder (ASD) symptoms using the Social
662 Communication Questionnaire (SCQ, (Rutter et al., 2003)), completed by the primary carer. Full-
663 Scale IQ (FSIQ) was measured using the Wechsler Abbreviated Scale of Intelligence (Wechsler,
664 1999), as the combination of all subscores.

665 *Sleep-dependent memory consolidation task*

666 The effect of sleep on participants' memory performance was evaluated using a 2D object location
667 task (Wilhelm et al., 2008) implemented in *E-Prime*. Participants completed a learning and test
668 session the evening before the EEG recording, and a recall session the next morning. In the task,
669 a 5 x 6 grid of covered square "cards" was presented on a laptop screen. During learning,
670 successive pairs (n = 15) of cards were revealed for 3 seconds, showing matching images of
671 everyday objects and animals. During recall, one of each pair was uncovered, and subjects were
672 required to select the covered location of the matching pair.

673 In the evening, learning and recall sessions alternated until participants reached a performance
674 criterion of 30% accuracy. The next morning a test session was carried out with a single recall
675 session.

676 *Polysomnography data acquisition*

677 High-density EEG and video recordings were acquired with a 60 channel Geodesic Net (Electrical
678 Geodesics, Inc. Eugene, Oregon, USA) and a BE Plus LTM amplifier running the Galileo
679 acquisition software suite (EBNeuro S.p.A, Florence, Italy). Additional polysomnography channels
680 including EOG, EMG, ECG, respiratory inductance plethysmography, pulse oximetry and nasal
681 airflow were recorded with an Embla Titanium ambulatory amplifier. PSG signals were acquired at
682 512 Hz sampling rate with a 0.1 Hz high pass filter. The online references was electrode Cz.

683 On recording visits, a member of the study team came to the participant's home, set up the EEG
684 and PSG recording systems and left; participants went to be at their normal bedtime, slept in their
685 own beds, and as the system was ambulatory, were able to move freely during recordings e.g. to

Sleep EEG in 22q11.2 deletion syndrome

686 use the bathroom overnight. The experimenter returned the following morning to end the
687 recordings, collect equipment and carry out the morning memory task test session.

688 *Sleep scoring*

689 Sleep scoring was performed by an experienced scorer on a standard PSG montage (6 EEG + all
690 PSG channels) according to Academy of American Sleep Medicine criteria. Artefact and Wake
691 epochs of EEG were discarded from further analysis. Sleep architecture was quantified using
692 standard derived variables: total sleep time, sleep efficiency, latencies to N1 and REM sleep and
693 proportion of time spent in N1, N2, N3 and REM sleep.

694 *EEG data analysis*

695 All pre-processing, spectral analysis and event detection algorithms employ methods validated in
696 previously published sleep EEG studies, using the same MATLAB code where available.

697 *Pre-processing*

698 Following acquisition and prior to analysis, EEG data was pre-processed using the following steps:
699 EEG .edf files were imported into MATLAB (Mathworks, Nantick, MA, USA) using the *EEGLAB*
700 toolbox (Delorme & Makeig, 2004). Next, signals were downsampled to 128 Hz and processed:
701 detrended with a high pass filter (cut off 0.25 Hz), 50 Hz line noise removed using the *EEGLAB*
702 *PREP* plugin (Bigdely-Shamlo et al., 2015), artefacts were removed with the Artifact Subspace
703 Reconstruction method (Mullen et al., 2015) implemented in the clean_rawdata *EEGLAB* plugin
704 and re-referenced to a common average. Two additional automated artefact removal steps were
705 then applied. Firstly, full 60 channel recordings were decomposed with independent components
706 analysis (ICA) using the AMICA *EEGLAB* plugin (Delorme et al., 2012) and non-brain components
707 were removed using the ICLabel plugin, including ECG, EMG and EOG artifacts (Pion-Tonachini et
708 al., 2019).

709 Second, we applied an automated iterative epoch-level artefact removal process to N2 and N3
710 epochs (pooled together) using two sets of criteria, similar to that described by (Purcell et al.,
711 2017): firstly, we applied the method described by (Buckelmüller et al., 2006), removing epochs

Sleep EEG in 22q11.2 deletion syndrome

712 where the beta (16 – 25 Hz, 2 SD) or delta (1 – 4 Hz, 2.5 SD) power exceeded a threshold of 2 or
713 2.5 SD relative to the flanking 14 epochs (7 before and 7 after). The resulting set of epochs were
714 then further filtered based on whether an epoch had > 5% clipped signals (e.g., >5% of values in
715 the epoch equal to the minimum or maximum possible value) and then a three-cycle iterative
716 process of removing epochs based on their having a signal RMS or score on the first 3 Hjorth
717 parameters (Hjorth, 1970) that exceeded 2 SD of the whole-signal SD. These processes appeared
718 to remove epochs randomly across the night, although may have removed N3 epochs more than
719 N2. There were no group differences in the proportion of N2 or N3 sleep removed from each
720 recording (mixed models fit to proportion of epochs in N2 and N3 separately, with group as
721 independent variable and gender and age as covariates, both $p > 0.05$). This process was applied
722 to each channel independently as this study did not investigate any cross-channel EEG measures.
723 Sleep montages were then prepared for sleep scoring, and thirty second epochs containing
724 artefacts were flagged for removal after manual review.

725 Time-frequency Analysis

726 We calculated whole-night spectrograms using the multitaper method (Bokil et al., 2010) with a 30
727 second window advanced in steps of 10 seconds and a bandwidth of 1 Hz. The EEG power
728 spectral density (PSD) was calculated for frequencies between 0.25 and 20 Hz using Welch's
729 periodogram (MATLAB function *pwelch* with a 4 second Hanning window advanced in 2 second
730 steps, then averaged over time to give one value per frequency per epoch) and converted to
731 decibels ($10 \cdot \log_{10}(\text{microvolts}^2)$). We then repeated this analysis with EEG signals after z-scoring in
732 signals in the time domain (subtracting the overall signal mean and dividing by the signal standard
733 deviation).

734 Next we used the Irregular Resampling Auto-Spectral Analysis (IRASA) method (Wen & Liu, 2016)
735 to decompose EEG signals into oscillatory and aperiodic (also known as 1/f or fractal) components,
736 using the MATLAB code published by the method's authors. In brief, this method consists of
737 sequentially resampling time domain signals to odd numbered sampling rates and calculating the
738 PSD for this set of stretched or compressed data. The sum of these resampled datasets cancels

Sleep EEG in 22q11.2 deletion syndrome

739 out oscillatory activity, but the aperiodic component is retained. The oscillatory component of the
740 signal can then be recovered by subtracting the aperiodic component from the full PSD in the
741 frequency domain. We calculated differences in PSD between groups through linear mixed models
742 fit at each frequency, and corrected p-values for multiple comparisons using cluster-based
743 correction (where adjacent frequencies were considered to be neighbors (Maris & Oostenveld,
744 2007), with 500 permutation iterations) .

745 From the oscillatory component of the signal, we calculated average power in slow delta (< 1.5 Hz)
746 and sigma bands (10 – 16 Hz), and the sigma-band frequency with maximum power, averaging
747 over all epochs in N2 and N3 sleep separately for each subject. From the aperiodic component of
748 the signal we calculated two measures – a slope and an intercept measure, from fitting an
749 exponential of $y = e^{-\text{slope}} + \text{intercept}$ to the aperiodic data in the frequency domain. We calculated
750 these measures from all N2, N3 and REM epochs separately for all individuals. This gave a total of
751 12 spectral measures per electrode per subject (**Table 7**).

752

Sleep EEG in 22q11.2 deletion syndrome

753 Spindle Detection

754 Sleep spindles were automatically detected from artefact-free epochs of N2 and N3 sleep EEG
755 data using a relative-threshold detector based on previously reported methods using the
756 continuous wavelet transform (Djonlagic et al., 2020; Purcell et al., 2017). To enhance spindle
757 detection signal-noise ratio a Complex-Frequency B-Spline wavelet was used in the place of the
758 more typical Complex Morlet wavelet (Bandarabadi et al., 2020).

759 We determined the wavelet frequency to use for spindle detection from the peak sigma frequency
760 calculated using the IRASA method, for each individual. As we observed almost all participants to
761 have unimodal distributions of sigma power (**Figure 1 - Supplement 1**), and as has been
762 previously suggested in a study of similarly aged participants (Hahn et al., 2020), we did not
763 differentiate between “fast” and “slow” spindles. Therefore, for spindle detection, we used a single
764 wavelet with an individualized centre frequency, a bandwidth parameter of 2, and an order
765 parameter of 2.

766 Putative spindle cores were identified from the magnitude of the continuous wavelet transform of
767 the EEG signal (smoothed with a 0.1 second moving average), with a main threshold of 3 x the
768 median (calculated over the whole signal) and a secondary threshold of 1.5 x the median. We took
769 putative spindles to be crossings of the main threshold flanked with secondary threshold crossings
770 with a minimum event duration of 0.5 seconds and a maximum duration of 3 seconds. Further,
771 putative spindles had to be separated by at least 0.5 seconds; events closer than this were merged
772 unless their combined duration exceeded 3 seconds.

773 Putative spindles were further selected based on a quality metric where the power increase in the
774 sigma band (10-16 Hz) during the putative spindle event (calculated as the FFT of the signal,
775 relative to the whole-night baseline PSD) had to exceed the average increase in the delta, theta
776 and beta bands during the same period, relative to their whole-night baselines.

777 From each putative spindle we extracted the amplitude (maximum peak-to-trough voltage
778 difference in the sigma filtered-EEG, filtered using a least-squares linear-phase FIR filter using
779 MATLAB's *firls* command with 10 – 16 Hz passband filter, an order of 960, and transition frequency

Sleep EEG in 22q11.2 deletion syndrome

780 width of 0.5 Hz) and frequency (reciprocal of the mean time difference between positive voltage
781 peaks within the spindle). We also calculated the average density of spindles over the whole
782 duration of all epochs investigated in each participant, in events per minute, giving a total of 3
783 spindle-related measures per electrode per subject (**Table 7**).

784 Slow-Wave Detection

785 Slow waves were detected from epochs of N2 and N3 sleep using a previously validated method
786 (Djonlagic et al., 2020) as follows: first the EEG signal was band-pass filtered between 0.25 and 4
787 Hz using a Hamming windowed sinc FIR filter (*pop_eegfiltnew* from the EEGLAB toolbox), Next,
788 negative half-waves were detected from positive-to-negative zero crossings and selected as
789 putative SWs if: the putative SW had an amplitude greater 2 x the signal median for all negative
790 half-waves, a minimum length of 0.5 seconds and a maximum length of 2 seconds. These were
791 liberal criteria which detected large numbers of negative half waves; this approach was chosen as
792 we wished to investigate SW-spindle interactions, and therefore wished to maximise our sample of
793 putative SWs. Furthermore, as it has been observed that the overall power of the EEG signal
794 decreases from childhood to adolescence (Hahn et al., 2020), the use of an absolute threshold for
795 SW detection could introduce bias in detections based on participant age. We therefore considered
796 a relative threshold most appropriate for our dataset.

797 From each SW we extracted the amplitude (as the peak negative deflection), the duration (the time
798 between the initial positive-to-negative zero crossing to the negative-to-positive zero crossing), and
799 from the total set of SWs calculated the average SW density in events per minute, giving a total of
800 3 SW-related measures per electrode per subject (**Table 7**).

801 Spindle–SW Coupling

802 Spindle - SW coupling was measured using three metrics. First, we calculated the simple
803 proportion of detected spindles whose peaks overlapped with any detected SWs, where overlap
804 was defined as spindles whose peak sample fell within a window of +/- 1.5 seconds of the negative
805 peak of a detected SW. Second, we calculated the mean resultant length (MRL) vector of the
806 phase of the slow oscillation at the time of peak spindle amplitude, for spindles which overlapped

Sleep EEG in 22q11.2 deletion syndrome

807 an SW. The MRL metric was calculated as follows: the phase angle of the filtered slow oscillation
808 signal was calculated using the Hilbert transform (where 0 degrees was the first positive-to-
809 negative crossing of the SW). The phase value at the index of each spindle peak was taken, and
810 the overall MRL for that signal was calculated as $mrl = abs(mean(exp(1i*phase)))$, where phase is
811 a vector of all spindle peak phase values in a recording. Third, we took the mean angle of the SW
812 phase at the peak of all SW-overlapping spindles where $angle = angle(mean(exp(1i*phase)))$. For
813 the overlap and MRL measures, we converted the raw measure to a z-score relative to a
814 resampling distribution calculated by randomly shuffling each spindle peak either within its local 30
815 second epoch (overlap measure) or shuffling only within the overlapping detected SW (MRL
816 measure). This resampling procedure was repeated 1,000 times to create a null distribution from
817 which the mean and standard deviation was calculated for deriving the z-score for each signal. We
818 then calculated these three measures for each electrode, for each subject (**Supplementary Table**
819 **4**).

820 *Statistical analysis*

821 Following acquisition, preprocessing and feature identification and extraction, summary data were
822 exported into R 4.1.0 (R Development Core Team, 2017) for statistical analysis.

823 *Psychiatric, Sleep Architecture and Memory Data*

824 Psychiatric and sleep architecture data were analyzed using a mixed model approach, with subject
825 family entered into models as a random (varying) intercept, to account for the shared genetic and
826 environmental influences within sibling pairs. Mixed models are also robust to missing data.

827 For memory task data, the number of learning cycles to reach the 30% performance criterion were
828 modeled using mixed effects Cox Proportional Hazard Regression (*coxme* in the *coxme* package),
829 with right censoring as some participants (22q11.2DS n = 6, siblings n = 0) completed numerous
830 training cycles but never reached criterion before stopping the task.

831 Accuracy in the morning memory test was measured using a binomial model (*glmer* with *family =*
832 *binomial(link = "logit")* in the *lme4* package (Bates, 2010)) with the number of hits from the 15 trials

Sleep EEG in 22q11.2 deletion syndrome

833 as the dependent variable. In both models, genotype was the independent variable and age and
834 sex were included as covariates, with family as a random intercept.

835 High-Density Sleep EEG Data

836 Our EEG dataset consisted of 21 EEG measures across 60 channels recorded in 45 participants
837 (**Table 7**). As we used a high-density electrode array, we used multilevel generalized additive
838 models (GAMM) applied to EEG data from all 60 electrodes in one model. The generalized additive
839 model can model non-linear relationships, including spatial relationships, between variables using
840 splines or other smoothers (Wood, 2004, 2017) and can, for example, be used to model complex
841 or spatial relationships in models that also include covariates and random effects structures
842 (Pedersen et al., 2019). In the case of EEG data, this allowed the estimation of a model that
843 included the value of an EEG measure of interest (e.g., spindle density) at all 60 electrodes, with
844 genotype, gender and age as a covariates and participant identity nested in their family identity as
845 a random intercept, giving overall statistics for group differences.

846 This approach represents an extension of traditional EEG topographical plots, which present a
847 smoothed interpolation of an EEG measure onto a 2D grid representing the head, by allowing the
848 modelling of the relationship between multiple independent variables (and random effects) across
849 the 2D representation of the head.

850 In order to fit these computationally intensive models consistently, we adopted a Bayesian
851 approach, fitting the models using Hamiltonian Monte Carlo using the R *BRMS* package and Stan
852 (Bürkner, 2017; Carpenter et al., 2017), with 4000 iterations (1000 warm up) on 4 chains, and
853 regularizing priors (in keeping with (McElreath, 2018)). All model posterior information was
854 inspected manually, and all Gelman-Rubin statistics (measures of model convergence) were close
855 to 1.00, which is considered the optimal value. The formula used for all models (except for angular
856 data) was $value \sim s(x, y, by = group, bs = "tp", k = 20, m = 2) + gender + age_eeg + group +$
857 $(1|family) + (1|family:subject)$, where *value* was a placeholder for each EEG feature of interest, and
858 *x* and *y* represented the 2D-projected *x* and *y* co-ordinate for each EEG electrode. This model fits
859 an isotropic smooth with thin plate regression splines to the EEG measure across electrodes, with

Sleep EEG in 22q11.2 deletion syndrome

860 a separate smooth being estimated for 22q11.2DS and sibling controls. The model was fit was a
861 normal distribution and an identity link function.

862 This approach allowed us to generate topographic plots of group differences by taking draws from
863 the posterior fitted values of each model across a grid of spatial locations, for both 22q11.2DS and
864 Siblings. From these posterior samples, we then calculated the genotype difference distribution,
865 and from this, calculated the probability of direction statistic (Makowski et al., 2019), selecting
866 spatial locations where the value of the statistic was less than 0.05 for further plotting.

867 Spindle-SW Coupling Angle Model

868 We modelled Spindle-SW Coupling angle (in radians) with a GAMM with a von Mises distribution
869 (equivalent to a normal distribution on the circle) and a half tan link function. We modelled both the
870 mean angle and kappa (the circular concentration parameter) to improve model fitting. The formula
871 used for the angle model was: $overlap_angle \sim 0 + group + gender + age_eeg + s(x,y,by = group,$
872 $bs = "tp", k = 20, m = 2) + (1|family) + (1|family:subject), kappa \sim 0 + group + gender + age_eeg +$
873 $s(x,y,by = group, bs = "tp", k = 20, m = 2) + (1|family) + (1|family:subject)$. We plot both the mean
874 angle for coupling across the scalp, and model estimated angle differences between groups on
875 topoplots with a circular color scale.

876 Memory Task – EEG Correlation Models

877 We analyzed the correlation between Sleep EEG measures and performance in the test session of
878 our behavioral task the next morning. For each EEG measure and EEG electrode, we fit a
879 generalized linear mixed model, with number of hits in the morning session as dependent variable,
880 the interaction between an EEG measure and genotype as independent variable, and gender and
881 age as covariates, with family identity as a random intercept, and a binomial distribution with logit
882 link function. We then took p-values for the interaction term, corrected using a cluster-correction
883 permutation testing approach with 500 permutations (Maris & Oostenveld, 2007), and plotted those
884 electrodes where the EEG measure * genotype interaction was significant (cluster-corrected p <
885 0.05).

Sleep EEG in 22q11.2 deletion syndrome

886 EEG Mediation Models

887 We analyzed whether genotype effects on psychiatric symptoms or FSIQ were mediated by EEG
888 measures using mediation models (Imai et al., 2010). Mediation analysis is a statistical technique
889 which allows the estimation of whether the effect of one exposure (genotype) on an outcome (here
890 a psychiatric measure or FSIQ) occurs via an effect of the exposure on a third variable (known as
891 the mediator, here an EEG measure) or via a direct effect on the exposure. These models can be
892 estimated by the combination of two statistical models predicting (1) the outcome from the
893 exposure, mediator, and other covariates (including random effects) and (2) the mediator from the
894 exposure, other covariates and random effects.

895 In our mediation analysis, we fit models for each pair of a psychiatric measure or IQ (ADHD,
896 anxiety, ASD symptoms, psychotic experiences, CAPA sleep problems or FSIQ) and an EEG
897 measure (focusing on the 4 measures where we observed raw group differences: REM constant,
898 spindle amplitude, SW amplitude and spindle-SW MRL): one linear mixed model predicting the
899 EEG measure from genotype, age and gender as covariates, and family as a random intercept;
900 and one model predicting the psychiatric measure/IQ from genotype, EEG measure, age and
901 gender, and family as a random intercept. The link function of the second model depended on the
902 measure; poisson count models were used for symptom count data (ADHD, anxiety and ASD), a
903 binomial model for psychotic experiences, or a linear model for FSIQ. These models were fit using
904 the *lme4* package as above, then combined in a mediation analysis using the *mediate* function in
905 the *R mediation* package (Imai et al., 2010). From each model we extracted the estimated direct
906 and mediated effects, and the proportion mediated (the proportion of the total effect of genotype on
907 the psychiatric measure/FSIQ mediated via the EEG measure) and constructed topographic plots
908 of the proportion mediated. We derived p-values from mediation models using the cluster
909 correction method by generating 500 shuffled datasets at each electrode, where group identity was
910 permuted, and refit the models to each. We then plotted those electrodes where there was a
911 cluster-corrected significant mediated effect by the given measure *and* a significant total effect on
912 the same electrode.

913 Source Data and Source Code File Legends

914 This manuscript contains the following source data and source code files:

- 915 • eLife Submission Data.zip
- 916 • eLife Submission Scripts.zip

917 These zip files contain data and R scripts which will reproduce the analysis and figures presented in the
918 manuscript. Note that data files are in the .rds file format, which can be opened using the free open source
919 R statistic programming language.

920 *eLife Submission Data*

921 The .zip file “eLife Submission Data.zip” contains data files which produce the analyses contains the
922 following files:

- 923 • **sleep_study_beh_psych_demographic_data.rds**: Contains data for participant performance on the
924 memory task, psychiatric and cognitive assessments and demographic data
- 925 • **sleep_study_eeg_coupling_example.rds**: Contains EEG data of an example spindle-SW interaction
926 event, used to construct **Figure 4A**
- 927 • **sleep_study_eeg_locations.rds**: Contains the standardized locations of the EEG electrodes used
928 throughout the study
- 929 • **sleep_study_eeg_neighbours.rds**: Contains the neighboring electrode for all 60 electrodes in the
930 recording system used in our study, used in the cluster correction statistics utilized in **Figure 5B** and
931 **Figure 6B**
- 932 • **sleep_study_eeg_spectrogram_example.rds**: Contains example whole night spectrograms for a
933 sibling pair, with hypnogram and spindle and SW detection counts over the night, used in **Figure**
934 **3A-B**
- 935 • **sleep_study_eeg_summary_data.rds**: Contains summary EEG measures (one value per measure
936 per electrode per participant) for the measures in **Table 7**. Data are in their own standard units.

Sleep EEG in 22q11.2 deletion syndrome

- 937 • **sleep_study_eeg_summary_data_z.rds**: Contains summary EEG measures (one value per measure
938 per electrode per participant) for the measures in **Table 7**. Data are z scored.
- 939 • **sleep_study_epoch_removal.rds**: Contains data on the number of epochs removed by our artefact
940 removal process (See **Methods and Materials/EEG data analysis/Pre-processing**)
- 941 • **sleep_study_example_so_waveforms_bootci.rds**: Contains example slow wave waveforms and
942 bootstrapped 95% confidence intervals, used in **Figure 3D**
- 943 • **sleep_study_example_spindle_waveforms_bootci.rds**: Contains example spindle waveforms and
944 bootstrapped 95% confidence intervals, used in **Figure 3C**
- 945 • **sleep_study_interaction_clusters.rds**: Contains the electrode locations and statistics for clusters of
946 significant group*EEG measure interactions, used in **Figure 5B**
- 947 • **sleep_study_interaction_models.rds**: Contains fitted mixed models for group*EEG measure
948 interactions, used in **Figure 5B**
- 949 • **sleep_study_mediation_plot.rds**: Contains cluster-corrected mediation models, used in **Figure 6B**
- 950 • **sleep_study_psd_bootci.rds**: Contains power spectral density plot data, with bootstrapped 95%
951 confidence intervals, used in **Figure 2A-D**
- 952 • **sleep_study_psd_clusters.rds**: Contains the location of clusters of frequencies with significant
953 group differences, used in **Figure 2A-D**
- 954 • **sleep_study_psd_data.rds**: Contains PSD data used to calculate group differences and for cluster
955 correction, to derive the data in **sleep_study_psd_bootci.rds** and **sleep_study_psd_clusters.rds**
- 956 • **sleep_study_topoplot_angle_data.rds**: Contains posterior samples from the GAMM model fit to
957 the coupling angle data. Used to construct the topoplot found in **Figure 4D**
- 958 • **sleep_study_topoplot_posterior_data.rds**: Contains posterior samples from the GAMM models
959 used to construct group difference topoplots for the EEG measures in **Table 7** (except angular data,
960 which is found in **sleep_study_topoplot_angle_data.rds**. Used to construct the topoplots found in
961 **Figure 2E-G, Figure 3E-F and Figure 4C**

962 *eLife Submission Scripts*

963 The .zip file “eLife Submission Data.zip” contains R scripts to reproduce the main figures and analysis.

964 Scripts beginning with the prefix “Analysis” run computations which produce data used in tables and figures

965 (and may run slowly); scripts beginning with the prefix “Figure” produce the figures themselves

966 The following files are included:

- 967 • **Analysis-Artefact-Removal.R**: Code to analyze the effect of artefact removal (See **Methods and**
- 968 **Materials/EEG data analysis/Pre-processing**)
- 969 • **Analysis-Common-Utilities.R**: Code that contains common variables and functions used in the
- 970 paper
- 971 • **Analysis-fitGAMMs.R**: Code that fits the Bayesian GAMMs and extracts posterior samples which
- 972 produce the topoplots of group differences in **Figure 2E-G, Figure 3E-F and Figure 4C**
- 973 • **Analysis-fitMediationModels.R**: Code that fits the mediation models and performs cluster-based
- 974 correction for multiple comparisons, producing data used to plot **Figure 6B**
- 975 • **Analysis-Interaction-Clusters.R**: Code that fits the EEG*genotype interaction models and performs
- 976 cluster-based correction for multiple comparisons, producing data used to plot **Figure 5B**
- 977 • **Analysis-PSD-Clusters.R**: Code that fits models to the PSD data across multiple frequencies, and
- 978 performs cluster-based correction for multiple comparisons, producing the data used to plot **Figure**
- 979 **2A-D**
- 980 • **Analysis-Tables-1-5.R**: Code that produces **Tables 1-5**, including the statistical tests presented in
- 981 those tables
- 982 • **Figure-1-Revised.R**: Code to produce the elements of **Figure 1** and associated figure supplements
- 983 • **Figure-2-Revised.R**: Code to produce the elements of **Figure 2** and associated figure supplements
- 984 • **Figure-3-Revised.R**: Code to produce the elements of **Figure 3** and associated figure supplements
- 985 • **Figure-4-Revised.R**: Code to produce the elements of **Figure 4** and associated figure supplements
- 986 • **Figure-5-Revised.R R**: Code to produce the elements of **Figure 5**

Sleep EEG in 22q11.2 deletion syndrome

- 987 • **Figure-6-Revised.R R:** Code to produce the elements of **Figure 6** and **Table 7**

988 **Acknowledgements**

989 We are extremely grateful to all the families that participated in this study as well as to support
990 charities Max Appeal, The 22Crew and Unique for their help and support. We thank the core
991 laboratory team of the Division of Psychological Medicine and Clinical Neurosciences laboratory at
992 Cardiff University for DNA sample management and genotyping, and the National Centre for
993 Mental Health, a collaboration between Cardiff, Swansea and Bangor Universities, for their
994 support. The authors would also like to thank Dr Ines Wilhelm for kindly donating the 2D object
995 location task implementation.
