33 Abstract

34 Monitoring severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) on surfaces is
35 emerging as an important tool for identifying past exposure to individuals shedding viral RNA.
36 Our past work has demonstrated that SARS-CoV-2 reverse transcription-quantitative PCR
37 (RT-qPCR) signals from surfaces can identify when infected individuals have touched surfaces
38 such as Halloween candy, and when they have been present in hospital rooms or schools.
39 However, the sensitivity and specificity of surface sampling as a method for detecting the
40 presence of a SARS-CoV-2 positive individual, as well as guidance about where to sample, has
41 not been established. To address these questions, and to test whether our past observations
42 linking SARS-CoV-2 abundance to *Rothia* spp. in hospitals also hold in a residential setting, we
43 performed detailed spatial sampling of three isolation housing units, assessing each sample for
44 SARS-CoV-2 abundance by RT-qPCR, linking the results to 16S rRNA gene amplicon
45 sequences to assess the bacterial community at each location and to the Cq value of the
46 contemporaneous clinical test. Our results show that the highest SARS-CoV-2 load in this

47 setting is on touched surfaces such as light switches and faucets, but detectable signal is
48 present in many non-touched surfaces that may be more relevant in settings such as schools
49 where mask wearing is enforced. As in past studies, the bacterial community predicts which
50 samples are positive for SARS-CoV-2, with *Rothia* sp. showing a positive association.

51

52 **Importance**

53 Surface sampling for detecting SARS-CoV-2, the virus that causes coronavirus disease 2019
54 (COVID-19), is increasingly being used to locate infected individuals. We tested which indoor
55 surfaces had high versus low viral loads by collecting 381 samples from three residential units
56 where infected individuals resided, and interpreted the results in terms of whether SARS-CoV-2
57 was likely transmitted directly (e.g. touching a light switch) or indirectly (e.g. by droplets or
58 aerosols settling). We found highest loads where the subject touched the surface directly,
59 although enough virus was detected on indirectly contacted surfaces to make such locations
60 useful for sampling (e.g. in schools, where students do not touch the light switches and also
61 wear masks so they have no opportunity to touch their face and then the object). We also
62 documented links between the bacteria present in a sample and the SARS-CoV-2 virus,
63 consistent with earlier studies.

64

65 **Body**

66 Environmental monitoring for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-
67 2) RNA by reverse transcription-quantitative polymerase chain reaction (RT-qPCR) is
68 increasingly gaining acceptance. In the Safer at School Early Alert (SASEA)
69 (<https://saseasystem.org/>) project, daily surface swabbing was employed as part of an effort to
70 detect coronavirus disease 2019 (COVID-19) cases in nine elementary schools. This study
71 identified 89 clinically positive COVID-19 cases, 33% preceded by a room-matched surface
72 positive (1). As pandemic response measures like SASEA become more widely implemented,
73 understanding where SARS-CoV-2 signatures will most likely be found reduces cost and labor
74 of surface swabbing in large facilities. Previous work has focused on sampling arbitrary surfaces
75 in isolation and congregate care facilities, homes, and hospitals, with varying detection
76 performance obscuring which surfaces are best for monitoring COVID-19 spread (2-6).
77 Counterintuitively, high-touch hospital surfaces expected to accumulate viral load, including
78 door handles and patient bed rails, can yield *lower* SARS-CoV-2 detection rates, presumably
79 because they are cleaned more often (7-8).

80

81 Most microbes in the built environment come from human inhabitants (9-11). Oral, gut, and skin
82 microbiomes of COVID-19 patients change during disease (8,12-13); therefore, SARS-CoV-2
83 positive built environmental samples may differ in *bacterial* communities from SARS-CoV-2
84 negative samples. This has been documented in a hospital setting, with associations between
85 SARS-CoV-2 status (Detected/Not Detected) and both overall microbial community and *Rothia*
86 spp. specifically (8).

87

88 To extend these results to a residential setting and understand how SARS-CoV-2 is distributed
89 in the living space of an infected individual, we performed environmental sampling in the
90 apartments of three people who recently tested positive for COVID-19 (Sup. Fig. S1) while

91 quarantined in an isolation facility. On the day of swabbing, each quarantining individual
92 provided an anterior nares swab sample (Average Cq: 29.5, 28.4, 28.6 for Apartments A, B, and
93 C respectively). Although apartments differed in size, floor plan, and features (furniture,
94 appliances, etc.), similar features at similar densities were swabbed across all three
95 (n=140,116,125).

96
97 Each sampled surface was swabbed twice in immediately adjacent locations: first with a swab
98 premoistened and stored in 95% ethanol, then by a second swab premoistened and stored in a
99 0.5% SDS w/v solution (Supplementary Methods). Ethanol samples underwent 16S V4 rRNA
100 gene amplicon (16S) sequencing, and SDS samples underwent RT-qPCR for SARS-CoV-2
101 detection. 16S sequences were demultiplexed, quality filtered, and denoised with Deblur (14) in
102 Qiita (15) using default parameters. Resulting feature tables were processed using QIIME2 (16).

103

104 Findings

105 We collected 381 matched 16S and SARS-CoV-2 surface samples from the three apartments,
106 of which 178 (47%) were positive for SARS-CoV-2 (Fig 1) (Table 1). Apartments A and C had
107 comparable positivity rates (53% and 61%, respectively), but Apartment B was substantially
108 lower (24%). In all three apartments, the rate of detection was highest in the bedroom (72% on
109 average vs 47% overall). We estimated surface viral load, in viral Genomic Equivalents (GE's),
110 from Cq's using published regression curves (17) and mapped resulting viral loads onto 3D
111 renderings of each apartment. High-touch surfaces, including handles and switches, had
112 highest viral load across all apartments, followed by floor samples and then high-use objects
113 (fridge, sinks, toilets, beds) (Fig. 1). The maps for each apartment were studied to understand
114 patterns of SARS-CoV-2 detection and deposition by room use. In the kitchens, objects with
115 planar faces and handles, such as the refrigerator, cabinets, and drawers, revealed that only the
116 touched handles had detectable RT-qPCR signal (Fig. 1C inset, as an example). We could not
117 detect viral RNA on adjacent planar faces, which were presumably breathed on but not touched.

118

119 For quality control of 16S sequencing from low-biomass samples, we sequenced surface swabs
120 from the apartments together with positive and negative controls using KatharoSeq
121 (Supplementary Methods) (Sup. Fig. S2A) (18). Of 381 samples that underwent 16S
122 sequencing, 121 fell below the KatharoSeq threshold and were excluded (Sup. Fig. 2C).
123 Informed by alpha rarefaction curves (Sup Fig 2B), remaining samples were rarefied to 4000
124 features, removing an additional 36 samples from the analysis. Therefore, 157 samples were
125 excluded from downstream analyses (122 SARS-CoV-2 negative matched swabs, 35 positive)
126 (Sup Fig 2C).

127

128 Bacterial alpha diversity analysis demonstrated that 16S amplicon read count associated with
129 SARS-CoV-2 detection status (Sup. Fig. S3). Forward stepwise redundancy analysis (RDA)
130 using the unweighted UniFrac beta diversity metric identified four non-redundant variables of
131 significant effect size (apartment, surface type, type of room, and SARS-CoV-2 detection status)
132 which accounted for 45.4% of the variation in the data (Sup. Fig. 4B). Analyzed by apartment,
133 only in apartment B did virus detection lack significant effect. When subsetting the entire dataset
134 by room type, detection status had a significant effect on variability across all rooms.

135
136 To test whether the bacterial community predicted SARS-CoV-2 status, we built a random forest
137 classifier using sOTU data. The overall Area Under the Precision-Recall Curve (AUPRC) was
138 0.78, suggesting a statistically significant association, but insufficiently strong to predict SARS-
139 CoV-2 status of a single sample from the bacterial community (Fig. 2A). Cross-application of
140 models trained from one apartment or room type to other apartments or room types generally
141 performed well (AUPRC=0.7-0.96), suggesting generalizable associations (Fig. 2B). We also
142 applied multinomial regression to our dataset to identify differentially abundant microbes
143 between SARS-CoV-2 status groups. The top 32 features identified by the random forest
144 classifier and the ranked log-fold-changes in feature abundance from the multinomial regression
145 are shown in Figure 2C. Agreeing with previously published findings, *Rothia dentocariosa* was
146 one of the top features identified by the classifier and was relatively positively associated with
147 SARS-CoV-2 positive samples in the regression (8,12). Six sOTUS belonging to members of
148 the genus *Corynebacterium* were also highly ranked as predictive for positive samples.

149 150 **Discussion**

151 Our results show that detailed spatial mapping of SARS-CoV-2 RNA abundance and associated
152 bacterial signatures from built environment surfaces provides useful insight into potential
153 sampling locations and associations between the viral and bacterial components of the
154 microbiome. In the residential setting, high-touch surfaces have especially high viral loads,
155 although confirming this with detailed spatial maps in other settings (hospitals, isolation hotels,
156 schools) may be useful for guiding sampling designs. We note that sensitivity of arbitrary single
157 surface sampling to detect presence of even an unmasked SARS-CoV-2 individual is low, so
158 multiple samples or samples from selected surfaces should be collected. These results reinforce
159 the utility of surface sampling as a cost-effective method for locating SARS-CoV-2 signals in the
160 environment.

161
162 Our findings also corroborate SARS-CoV-2 associated changes in the microbiome published
163 previously. *Rothia dentocariosa* specifically has been identified across different sample types in
164 diverse settings, although reasons for these associations remain unclear. We also see multiple
165 sOTUs belonging to the genus *Corynebacterium* predictive of a SARS-CoV-2 detection event, in
166 contrast to the findings of another study that found *Corynebacterium* significantly decreased in
167 the oral microbiome of individuals with COVID-19 (12). We hypothesize that *Corynebacterium*
168 signal in this study might be evidence of human skin contamination of indoor surfaces through
169 contact, leading to SARS-CoV-2 deposition on surfaces. It has been established that the
170 occupants of a room contribute to the environmental microbiota, but our findings are among the
171 first to demonstrate that disease-associated changes in the microbiome are mirrored in the built
172 environment.
