23 **ABSTRACT**

24 The Cohort Size Shrinkage Index (CSSI) is the most widely used intensity measure in studies of
25 the Chinese famine of 1959-1961. We examined requirements to construct a valid CSSI measure:
26 reliable information on birth cohort size; a stable cohort size trend outside the famine years; and
27 limited migrations. We used census data to examine the cohort size trend and concentrated on the
28 time window of 1950-1970 to exclude events with a large impact on cohort size trends other than
29 the famine. We observed a significant difference in cohort size trends comparing pre-famine and
30 post-famine births. Compared to pre-famine based CSSI (p-CSSI), pre- & post-famine based
31 CSSI (pp-CSSI) tends to overestimate famine intensity at higher mean CSSI levels and
32 underestimate intensity at lower mean levels. In Sichuan province, we demonstrated a less
33 pronounced dose-response relation between famine intensity and tuberculosis outcomes using p-
34 CSSI as compared to pp-CSSI. These observations demonstrates that the CSSI is not a robust
35 measure as had been assumed previously. We recommend the use of p-CSSI and encourage
36 researchers to re-examine their results of Chinese famine studies.

39 Tuberculosis after famine

40 **Introduction**

41 The Great Chinese Famine of 1959-1961 (Chinese famine) originated from a combination of
42 radical agricultural and economic policies and crop failures (Cao 2005; Chang and Wen 1998;
43 Lin and Yang 1998, 2000; Yang 1996). The famine led to over 30 million excess deaths and is
44 the largest famine recorded (Chang and Wen 1997; Garnaut 2014; Peng 1987; Zhao and
45 Reimondos 2012). It had different intensity levels across regions (Ashton et al. 1992; Cao 2005;
46 Chang and Wen 1997; Peng 1987). There has been an extensive literature on the famine's
47 demographic consequences (Aird 1982; Ashton et al. 1992; Banister 1984; Cai and Feng 2005;
48 Coale and Banister 1994), its main causes (Chang and Wen 1998; Kasahara and Li 2020; Kung
49 and Lin 2003; Meng, Qian and Yared 2015), and its potential long-term health and economic
50 impact (Almond et al. 2007; Fan and Qian 2015; Li and Lumey 2017; Xu et al. 2016). Chinese
51 famine studies rely heavily on appropriate indicators of famine intensity as these are being used
52 either as dependent or as independent variables in statistical models to address specific research
53 questions (Li and Lumey 2017; Li et al. 2019).

54
55 It has been a challenge to construct robust indicators of the famine's intensity. First, there is no
56 general agreement on what elements should be used to define and assess a famine's intensity and
57 magnitude (Gráda 2009; Howe and Devereux 2004). An optimal measure will depend on the
58 field of research and specific research questions. Second, there is scant reliable information on
59 food availability and consumption at the time of Chinese famine and mortality data are
60 incomplete (Li and Lumey 2017; Li et al. 2019; Lumey, Stein and Susser 2011). Facing these
61 challenges, scholars have proposed a number of demographic indicators to quantify regional
62 famine intensity in China (Li 2022). These include the excess death rate (EDR) (Chang and Wen

63 1998; Peng 1987; Yang 1996), the cohort size shrinkage index (CSSI) (Huang et al. 2010b; Xu et
64 al. 2016), the abnormal death proportion (Cao 2005; Song, Wang and Hu 2009), and the infant
65 mortality rate (Song et al. 2009). Although none of the indicators are direct measures of famine
66 intensity - as this would require recording individual level calorie intakes, they do reflect
67 demographic changes caused by a famine and capture important aspects of a famine's intensity.

68
69 Among famine intensity measures, the EDR and CSSI have traditionally been the most widely
70 used. In recent years, the CSSI has enjoyed a growing popularity as an alternative to the EDR,
71 especially in economics and the health sciences (**Figure 1**). This is because of concerns about the
72 quality of mortality statistics at the time of the famine and their limited accessibility at the local
73 prefecture and county levels (Huang et al. 2010b; Xu et al. 2016). CSSIs avoid these potential
74 problems as they are derived from population census data that are deemed to be more reliable.
75 CSSIs have therefore been increasingly applied to relate famine intensity to later economic and
76 health outcomes in populations affected by famine (**Table A1 of the online Appendix**).

77
78 The CSSI compares observed cohort sizes of populations born in famine years to expected cohort
79 sizes in the absence of famine and is estimated by averaging cohort sizes of pre- & post-famine
80 births (Huang et al. 2010b; Xu et al. 2016). There has been little consistency, however, in exactly
81 how CSSIs were constructed or applied in different studies. There has been a wide variety in the
82 selection of data sources, estimating methods, geographic regions, and definitions of famine and
83 non-famine years (**Table A1**). Almost all studies combined pre- & post-famine births to estimate
84 an expected cohort size for famine years (**Figure A1**). As we later demonstrate, CSSIs estimated
85 from pre- & post-famine births can introduce unrecognized biases when estimating a potential

86 dose-response relationship between famine intensity and later health outcomes when pre-famine
87 and post-famine cohort trends are different(Li, Zhou and Lumey 2021).

88
89 For CSSI to be a useful measure of famine intensity at the local level, reliable information will
90 be needed on several variables: first on the size of birth cohorts, perhaps from census data at the
91 province or prefecture level; second, to confirm a stable cohort size trend over time in the non-
92 famine period as this will be needed to identify any famine related deviations from existing
93 trends, and third, on migrations between localities if place of birth is not known and populations
94 have to be classified instead by current residence, an imperfect indicator of place of birth (Xu et
95 al. 2016; Xu et al. 2018). To date, no studies have examined the adequacy of the information
96 used to construct CSSIs. Also, it remains unknown how sensitive CSSI measures are to
97 variations in their component parts. These variations include data sources and estimating
98 methods.

99
100 In this study, we use the 1% China 2000 Census as the main data source to examine cohort sizes
101 by year of birth. We construct CSSIs using varying combinations of non-famine years (pre-
102 famine years vs pre- & post-famine years) and then compare CSSI distributions at the province
103 and prefecture levels. We examine the impact of migrations on CSSI by comparing place of birth
104 and residence from census information. We use the tuberculosis surveillance study in Sichuan
105 province as a case-study to examine how empirical results may change with the application of
106 CSSIs using non-famine years as reference (Cheng et al. 2021; Cheng et al. 2020; Li et al. 2021).
107 Our findings demonstrate that the choice of non-famine years is by far the most important
108 determinant of CSSI, shaping both its distribution and the results of empirical studies.

109

110 **Data and Methods**

111 **Main Data and Variables**

112 To date, cohort size shrinkage indexes (CSSIs) at different regional levels have been used by
113 over 30 Chinese famine studies, using different national census waves collected between 1982-
114 2000. (**Table A1**). This study is mainly based on the 1% China 2000 Census
115 (<https://international.ipums.org/international/>) (Minnesota Population Center 2020), because it
116 provides the most extensive demographic information, including birth year, place of birth at the
117 province level, and place of residence both at the prefecture and province levels (Lavelly 2001).
118 This enables comparison of place of birth and place of residence to examine inter-province
119 migrations. The 1% China 1982 and 1990 census do not provide information on place of birth
120 but will be important for sensitivity analysis as described later.

121

122 Our study includes 29 province level regions and 340 prefectures. The province level regions
123 are: Sichuan (SC), Anhui (AH), Guizhou (GZ), Hunan (HuN), Henan (HeN), Qinghai (QH),
124 Jiangsu (JS), Ningxia (NX), Guangxi (GX), Gansu (GS), Shandong (SD), Yunan (YN), Hubei
125 (HuB), Fujian (FJ), Hebei (HeB), Zhejiang (ZJ), Jiangxi (JX), Guangdong (GD), Liaoning (LN),
126 Shanxi (SX), Shaanxi (SaX), Jilin (JL), Inner Mongolia (IM), and Heilongjiang (HLJ). Before
127 the 1980s, Hainan was part of Guangdong province, and Chongqing (CQ) was part of Sichuan
128 province. Separately grouped are the province level regions formed by the cities of Beijing (BJ),
129 Tianjin (TJ) and Shanghai (SH) where population policies were different than in other regions
130 and early family planning policies were introduced in the 1960s (Yang 2004). Also grouped
131 apart are the two provinces Xinjiang (XJ) and Tibet (TB) to which government population

132 policies encouraged active immigration (Sabit and Mamat 2008). We arranged the above listing
133 of the 24 regular provinces by CSSI rank from the highest to the lowest and separately show the
134 three city provinces and the two active immigration provinces (see also **Table A3**).

135

136 **Cohort Size Projection and CSSI Construction**

137 The 2000 census includes births between 1900 and 2000. For optimal CSSI estimates, a
138 relatively stable period for births will be required to use as a reference period against which to
139 identify deviations caused by the famine. We selected the period 1950-1970 as the most suited
140 for this purpose because its start marks the establishment of the People's Republic of China in
141 1949 after chaotic periods of the Second Sino-Japanese War and the Chinese Civil War (Coale
142 and Chen 1987; Xizhe 1989). And its end marks the introduction of family planning policies
143 across China in the 1970s (Poston 1992). This window also includes the famine and non-famine
144 years selected by previous Chinese famine studies that used CSSIs (**Figure A1**).

145

146 These famine studies calculated CSSI as $\frac{N_{\text{non-famine}} - N_{\text{famine}}}{N_{\text{non-famine}}}$ at different regional levels, where

147 N_{famine} is the observed average cohort size of famine births and $N_{\text{non-famine}}$ is the average
148 cohort size of the combined pre- & post-famine births. The $N_{\text{non-famine}}$ is assumed to reflect the
149 expected cohort size in the absence of famine. However, the potential impact of different trends
150 of pre-famine and post-famine births on CSSI has not been systematically examined before.

151 Trends could be different because post-famine births in China show a rebound after the famine
152 and this rebound could be related to the severity of the decline (Li et al. 2021). Therefore, CSSIs
153 may also be sensitive to the choice of non-famine years (pre-famine years vs. pre- & post-famine
154 years combined).

155
156 To examine these questions, we divided the period of 1950-1970 into three periods and defined
157 1950-1957 as pre-famine years, 1959-1961 as famine years, and 1963-1970 as post-famine years.
158 We excluded births in 1958 or 1962 from analysis because births in these years could be
159 misclassified on famine exposure status comparing different provinces with different famine start
160 and end years. We examined birth trends based on pre-famine births and post-famine births alone
161 and compared trends at the regional level.

162
163 We compared two approaches to estimating birth deficits during the famine period. The first
164 examines deviations from expectations based on a linear extrapolation of pre-famine births
165 (1950-1957) and the second examines deviations from the commonly used linear interpolation of
166 combined pre- & post-famine births (1950-1957 & 1963-1970). This corresponds to calculating
167 CSSIs from either pre-famine birth cohorts alone (p-CSSI) or combining pre- & post-famine
168 birth cohorts together (pp-CSSI). Both p-CSSI and pp-CSSI were mapped at the province and
169 prefecture levels. In sensitivity analyses, we compared findings based on the 1% China 1990
170 population census and examined the robustness of CSSI measures to variations in the exact years
171 defined as non-famine years.

172 173 **Applying CSSIs to Tuberculosis Surveillance Study in the Sichuan Province**

174 We applied the p-CSSI and pp-CSSI approaches to the empirical study in the Sichuan province
175 of tuberculosis cases diagnosed between 2005 and 2018 (Cheng et al. 2020). The study data were
176 publicly available at the Github repository https://github.com/qu-cheng/TB_famine. In line with
177 previous approaches, we evaluated associations between famine intensity and tuberculosis risk

178 by mixed-effects meta-regressions. (Cheng et al. 2021; Cheng et al. 2020; Li et al. 2021). For
179 famine births, we fit linear models to examine the relation between famine intensity as
180 represented by CSSI on the log of the ratio of the observed vs expected non-famine incidence
181 rates. We modeled multiple sets of CSSI using either varying combinations of non-famine years
182 (pre-famine years vs pre- & post-famine years) at the prefecture level in Sichuan province or the
183 full Sichuan 2000 Census or the 1% China 2000 Census for Sichuan province.

184

185 **Results**

186 **Cohort Size Trends Differ When Selecting Either Pre-Famine or Post-Famine Births as the** 187 **Non-Famine Population**

188 Panel a of **Figure 2** shows the observed cohort sizes by birth year between 1900 and 2000 at the
189 national level as documented by the 1% China 2000 Census. For individuals born until the late
190 1950s, a monotone relation is seen between higher mortality and advancing age, demonstrating
191 the smallest number of survivors among the oldest individuals. The trend is interrupted in three
192 periods that show a marked decline in cohort size: for individuals born between 1958-1962,
193 1971-1980, and after 1990. A similar pattern is seen at the province level (**Figure A2**).

194

195 Panel b of **Figure 2** shows the cohort size pattern between 1950 and 1970 and compares the
196 national cohort size trend among pre-famine births (1950-1957) (Red hatched line) to post-
197 famine births (1963-1970) (Blue hatched line). The first trend increases by birth year while the
198 second is flat. At the province level, the pre-famine based cohort size trends are also different
199 from the post-famine based trends (**Figure A3**). These differences remain after excluding the
200 birth peak in 1963 immediately after the famine ended.

201
202 **CSSI Estimates Also Critically Depend on the Choice of Non-Famine Years**
203 Because cohort size trends differ for pre-famine births and post-famine births, estimated CSSIs
204 will likely vary depending on the choice of non-famine births. We compared the observed cohort
205 sizes of famine births in 1959-1961 with the projected populations in these years estimated from
206 linear regressions at the province level using either the pre-famine births (1950-1957) alone or
207 the pre- & post-famine births (1950-1957 & 1963-1970) combined (**Table A2**). The projected
208 populations are larger than the observed populations in all provinces. The estimated birth deficits
209 also vary with the choice of non-famine years: estimated CSSIs based on pre-famine births as
210 non-famine years (p-CSSI) differ from CSSIs based on pre- & post-famine births as non-famine
211 years (pp-CSSI). **Table A3** shows the CSSI values and rankings for all provinces. The difference
212 between p-CSSI and pp-CSSI ranges from -16.2% in Qinghai province (35.4% vs 51.6%) to
213 +14.1% in Liaoning province (38.0% vs 23.9%). It is more extreme for the five regions grouped
214 separately, ranging from -60.6% in Xinjiang (-38.8% vs 21.8%) to +39.3% in Shanghai (38.5%
215 vs -0.8%) (**Table A4**).

216
217 The geographical distribution of CSSIs is shown in **Figure 3**, with p-CSSI in Panel a and pp-
218 CSSI in Panel b. The Sichuan, Anhui, Guizhou and Hunan provinces show the largest estimated
219 shrinkage regardless of estimation method. pp-CSSIs tend to be higher than p-CSSIs in the
220 Midwest of China however and lower in the Northeast and Southeast of China (Panel c).
221 Compared to p-CSSIs, pp-CSSIs tend to be systematically larger at higher CSSI values and
222 smaller at lower values with a crossover at the mean (Panel d). Although p-CSSI and pp-CSSI

223 have similar mean values (37.4% vs 37.7%), their distributions differ, the former values being
224 spread more narrowly around the mean (SD 9.8) than the latter (SD 14.5) (Appendix **Figure A4**).

225

226 **Other Factors Besides the Choice of Non-Famine Years Have Little Effect on CSSI**

227 First, our findings do not depend on the choice of census waves. The 1% China 1990 Census has
228 been the most widely used data source for previous studies although place of birth was not
229 available (**Table A1**). CSSIs as estimated from the 1% 1990 census show the same cross-over
230 pattern (**Figure A5**) as the 1% 2000 census. Second, we compared p-CSSI using place of
231 residence from the 1990 or the 2000 census and place of birth from the 2000 census. The
232 findings are highly consistent with inter-correlations exceeding 0.95 (**Table A5**). Third, p-CSSI
233 estimates are robust to adding a quadratic term to linear regression trend extrapolations; fourth,
234 to changing pre-famine years from 1950-1957 to 1940-1957; and fifth, to limiting analysis to the
235 rural population instead of the entire population, with inter-correlations ranging from 0.95 to
236 0.99 for all comparisons.

237

238 **P-CSSI And Pp-CSSI are not Only Different at the Provincial but Also at the Prefecture** 239 **Level**

240 Because information on place of birth at the prefecture level was not available in any of the
241 census waves, CSSI at this level was constructed instead using place of residence. **Figure 4**
242 shows spatial variations of residence based CSSIs at both the province and prefecture levels.
243 Panels a to c of **Figure 4** are comparable to those of **Figure 3**, showing findings at the province
244 level using either information on place of birth or place of residence. Panels d and e of **Figure 4**
245 show substantial variations at the prefecture level within most provinces. This is illustrated

246 numerically by the wide range of p-CSSI at the prefecture level (**Table A6**). Panel f of **Figure 4**
247 shows that the differences between p-CSSI and pp-CSSI at the province level also hold at the
248 prefecture level. In the online Appendix, **Table A7** presents p-CSSIs and pp-CSSIs at the
249 prefecture level for use in future comparative studies.

250

251 **Differences in P-CSSI and Pp-CSSI Characteristics Generate a Different Dose-Response** 252 **Pattern Comparing Famine Intensity to Adult Health**

253 A recent study in Sichuan province used the pp-CSSI to report a dose-response relationship
254 between famine intensity and adulthood tuberculosis at the prefecture level (Cheng et al. 2020).
255 We compared p-CSSI and pp-CSSI in this study. p-CSSI had a smaller mean and wider range
256 compared to pp-CSSI (**Table A8**). Using the reported full 2000 Sichuan Census (Cheng et al.
257 2021), the dose-response estimate for (log) tuberculosis IRR in relation to a CSSI unit increase
258 was less than half for p-CSSI compared to pp-CSSI (IRR 0.38; 95% CI: -0.12, 0.88 vs IRR 0.91;
259 95% CI: 0.19, 1.62) (**Figure 5 and Table A9**). By bootstrapping, we estimated a significant IRR
260 difference between the two estimates (0.55; 95% CI: 0.06, 10.4). This demonstrates how
261 sensitive CSSIs can be to the choice of non-famine years and their effect on estimated relations
262 between famine intensity and later health outcomes.

263

264 The p-CSSI based IRR is not sensitive to changes in the time window used to define pre-famine
265 years, with an IRR of 0.37 (95% CI: -0.12, 0.86) using 1949-57 as pre-famine years and 0.40
266 (95% CI: -0.02, 0.82) using 1945-57 as pre-famine years compared to 0.38 (as in the above) for
267 years 1950-1957. Findings using the 1% China 2000 Census data for Sichuan agree with these
268 results from the full Sichuan 2000 Census.

269

270 **Discussion**

271 In this study, we examined alternative approaches to construct CSSIs in Chinese famine studies
272 and reviewed study findings based on this measure. We established that CSSI distributions can
273 be highly sensitive to the choice of non-famine years (pre-famine years vs. pre- & post-famine
274 years combined). This demonstrates that CSSI is not a robust estimator of famine intensity. By
275 contrast, the choice of census waves, the use of province of residence vs province of birth, the
276 exact timing of pre-famine years, and the form of statistical extrapolation models had little
277 impact on CSSI. Perhaps of greater importance, we demonstrated that different CSSIs (p-CSSI
278 vs. pp-CSSI) will generate a different understanding of the relation between famine intensity and
279 later life health outcomes.

280

281 For Chinese famine studies, it is critically important to select time windows that are as free as
282 possible from extraneous events (Garnaut 2014; Peng 1987; Zhao and Reimondos 2012). As an
283 example of later post-famine events, family planning pilot programs introduced in some regions
284 from the 1960s and nationwide in the 1970s most likely contributed to the cohort size trend
285 irregularities observed by others for individuals (Aird 1982; Attane 2002; Poston Jr and Gu
286 1987). We took these circumstances into account by examining large cities in separate strata and
287 limiting our post-famine observations to births 1963-1970.

288

289 Chinese famine studies to date have also failed to recognize that the cohort size trends among
290 pre-famine births and post-famine births differ too much for pp-CSSI to be representative of a
291 general trend. That this leads to biases can be seen from the comparison of pp-CSSI with p-CSSI

292 measures that show systematic differences over the CSSI range: pp-CSSI tends to be
293 systematically larger than p-CSSI at higher means of CSSI and lower at lower means of CSSI. A
294 high correlation between declines in famine births and post-famine rebounds was already
295 reported before (Huang et al. 2014; Huang et al. 2010a; Huang et al. 2010b; Huang et al. 2013).
296 Our study confirms these observations based on a correlation of -0.36 and this finding was one of
297 our motivations to recommend against the use of pp-CSSI. Other famine studies that also
298 avoided pp-CSSI include the examination of excess deaths in China (Peng 1987) and in Ukraine
299 for the 1932-1933 famine (Rudnytskyi et al. 2015).

300
301 Other factors besides including post-famine births had a limited impact on CSSI estimates. First,
302 on the use of the 1% China 2000 Census as our main data source, we note that our study findings
303 are highly consistent across census waves (**Table A5**). In different census waves, we found the
304 similar systematic differences between p-CSSI and pp-CSSI. Second, migration could be an
305 important factor influencing famine intensity measures, including CSSI. Using the 1% China
306 2000 Census however we found that place of birth was highly comparable to place of residence
307 for estimating CSSI at the province level (**Figure A6**). This is consistent with our finding that
308 inter-province migration among births 1950-1970 was as low as 6%. A recent study also showed
309 that migration within provinces is not associated with famine intensity (Kasahara and Li 2020).
310 Third, despite the substantial rural-urban difference in famine intensity because government
311 policies prioritized food security in urban areas (Garnaut 2014; Peng 1987; Zhao and Reimondos
312 2012), our CSSI findings are not affected by ignoring urban populations. This can be explained
313 by the fact that over 80 percent of Chinese population at the time lived in rural areas (Gørgens,

314 Meng and Vaithianathan 2012; Peng 1987). Forth, linear and higher order statistical models and
315 varying pre-famine years to project trends over time give the same results.

316
317 As a consequence, including post-famine births to estimating CSSIs has important consequences
318 for understanding the relation between famine intensity experienced at the time of birth and
319 health and economic outcomes in later life. In many current Chinese famine studies (**Table A1**),
320 CSSI has been incorporated in regression models as a continuous measure of famine intensity.
321 Changing cohort size trends of pre-famine births and post-famine births may not only affect
322 CSSI estimates but also their distributions and the interpretation of study findings. We
323 demonstrated that at the province level, pp-CSSI spreads more widely around the mean than p-
324 CSSI. Using data from the tuberculosis surveillance study in Sichuan Province (Cheng et al.
325 2020), we demonstrated that the dose-response relation between famine intensity and
326 tuberculosis appears to be much weaker using p-CSSI than using pp-CSSI, irrespective of the
327 type of census data used. Our findings demonstrate in many ways how the choice of non-famine
328 years determines the nature of observed dose-response relationships between famine intensity at
329 the time of birth and adult health and their interpretation.

330

331 **Strengths and Limitations**

332 Our study has many strengths. We use census data to construct robust measures of famine
333 intensity and demonstrate that combining pre- & post-famine births can lead to unrecognized
334 bias in estimating famine intensity using CSSI. In a study of later life health in Sichuan province,
335 we show that combining pre- & post-famine births can amplify potential dose-response relations

336 between famine exposure level and tuberculosis health outcomes. These strengths provide the
337 basis for our recommendations for the future analysis of famine studies in China.

338

339 There are also some limitations. There is no gold standard for famine intensity. CSSI is a good
340 indicator however of famine related fertility changes and excess deaths; Census data could be
341 biased by selective survival after famine exposure in early life. But in the one study we know on
342 the question (Song, 2009) this does not seem to be the case and our findings based on census
343 waves ten years apart are highly consistent; Migrations can potentially lead to biases but had
344 little impact at the province level. Further studies will be needed on migration at the prefecture
345 level; Potential misclassifications of place of birth could arise if pregnant women migrated
346 during the famine and gave birth in another provinces. A child's place of birth was registered by
347 mother's Hukou status however which neutralizes this concern (Zhu 2010).

348

349 **Suggestions for Future Studies**

350 We advocate the use of p-CSSI in Chinese famine studies to avoid biases related to different pre-
351 famine and post-famine cohort size trends. Current studies (Cheng et al., 2020; Huang et al.,
352 2014; Cheng Huang et al., 2010; Meng et al., 2015; Xu et al., 2016; Xu et al., 2018) should be re-
353 analyzed with this concern in mind and divergent findings compared and discussed. For future
354 studies, we provide data of p-CSSI and pp-CSSI at both the province and prefecture level in
355 supplementary materials (**Table A7 of the online Appendix**). This information will be helpful in
356 identifying provinces and prefectures across China where famine intensity was highest as these
357 will be the most suitable locations for future famine studies. We first suggest studies in one or
358 two of the most famine-severe provinces, including Sichuan and Anhui provinces (**Figure 4 &**

359 **Table A7 of the online Appendix**). Prefecture level studies could be attempted later, guided by
360 substantial variations in famine intensity within province. These studies will generate improved
361 estimates of famine intensity at the local level as improve estimates of the nature of dose-
362 response relationships between famine exposure and its long-term impact.

363

364 **Conclusions**

365 Chinese famine studies to date have failed to recognize that cohort size trends among pre-famine
366 births and post-famine births can differ substantially. This may be problematic as valid CSSI
367 measures assume stable cohort size trends. We demonstrate for China that pre- & post-famine
368 based CSSI is not a robust estimator of famine intensity as had been assumed previously. It will
369 overestimate famine intensity at higher exposure levels and underestimate intensity at lower
370 levels. As an alternative for Chinese famine studies, we therefore recommend CSSI based on
371 pre-famine births alone.

372

373 **Data Availability**

374 All data and code necessary to reproduce the main findings of this study are available at the
375 Github repository: https://github.com/chunyu-yes/CSSI_famine_severity.

376

377 **Acknowledgements**

378 The authors are particularly grateful to the Minnesota Population Center for providing the data of
379 the 1% China 1990 and 2000 Census, the National Bureau of Statistics in China for originally
380 producing the census data, and the research team at Berkely University for making the data of
381 tuberculosis surveillance study in the Sichuan province publicly available.

382

383 **Author contributions**

384 C.L., C.L., and L.H.L designed research; C.L., C.L., H.X., Z.Z. and L.H.L performed research;

385 C.L., C.L., H.X., Z.Z. and L.H.L analyzed data; C.L., C.L., and L.H.L drafted the paper; H.X.

386 and Z.Z. provided technical support; and C.L., C.L., H.X., Z.Z. and L.H.L revised the paper.

Fig. 1 Chinese famine studies using cohort size shrinkage index (CSSI). Detailed information of listed studies is available in Table A1.

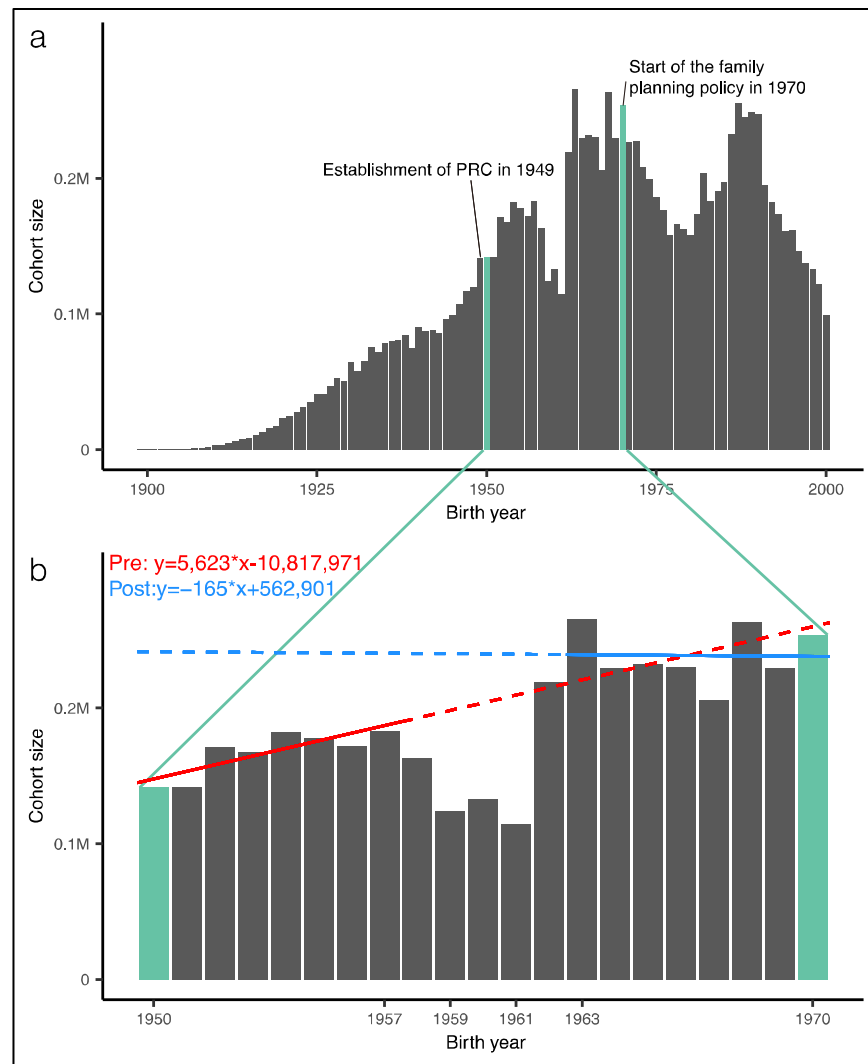

Fig. 2 Cohort size by birth year in China.

Notes: a. Cohort size by birth year, 1990-2000. b. Cohort size trend from linear regression either based on either pre-famine births (1950-1957) or post-famine births (1963-1970).

Source: 1% China 2000 Census, place of birth.

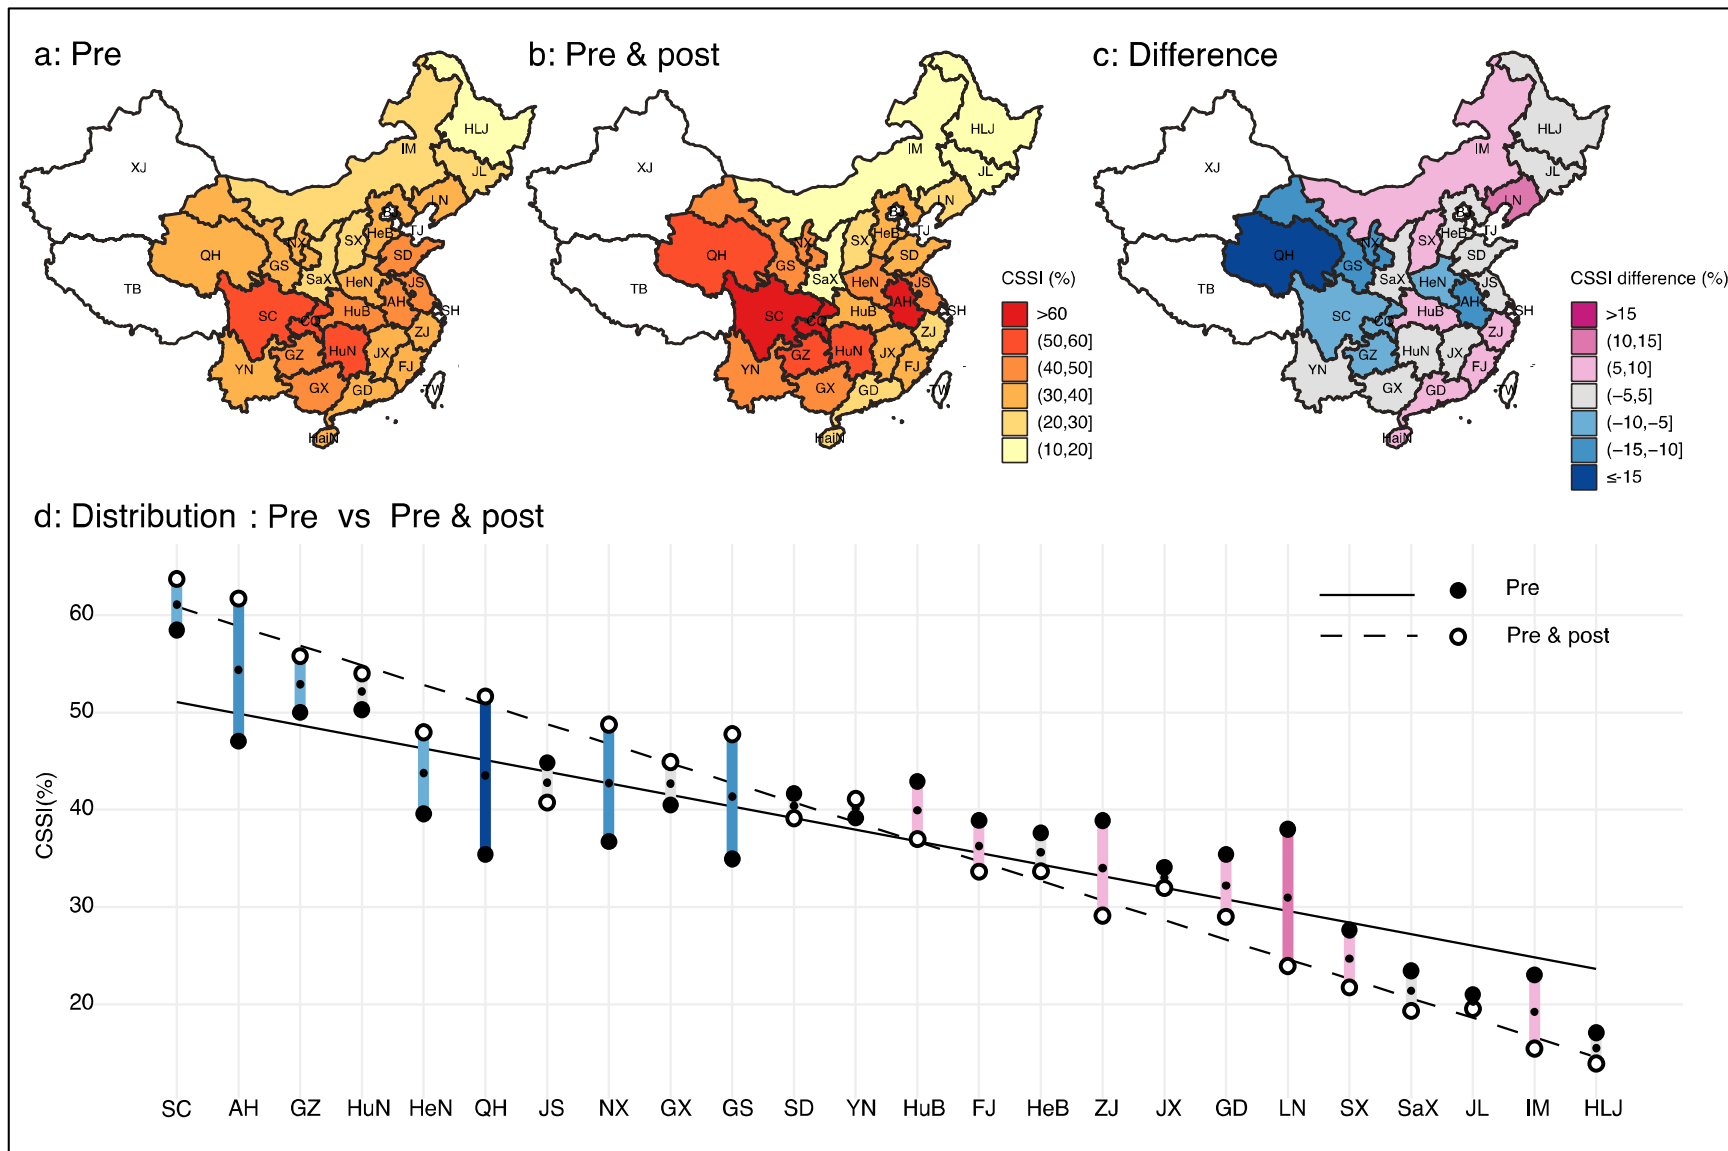

Fig. 3 P-CSSI, pp-CSSI, and their difference at the province level.

Notes: a. Provincial p-CSSI (%) based on births in 1950-57. b. Provincial pp-CSSI (%) based on births in 1950-57 & 1963-70. c. Difference of provincial CSSI (%) between panel a and panel b. d. Provinces are ordered by the average of p-CSSIs and pp-CSSIs. The solid line represents the linear regression of p-CSSI (filled circles) over the average of the two CSSIs. The dash line represents the linear regression of pp-CSSI (unfilled circles) over the average of two CSSIs. Each bar represents the difference of p-CSSIs and pp-CSSIs for each province, and its color coding follows the panel c. Full names corresponding to province abbreviations can be found in ‘Data and Methods’ section.

Source: 1% China 2000 Census, place of birth.

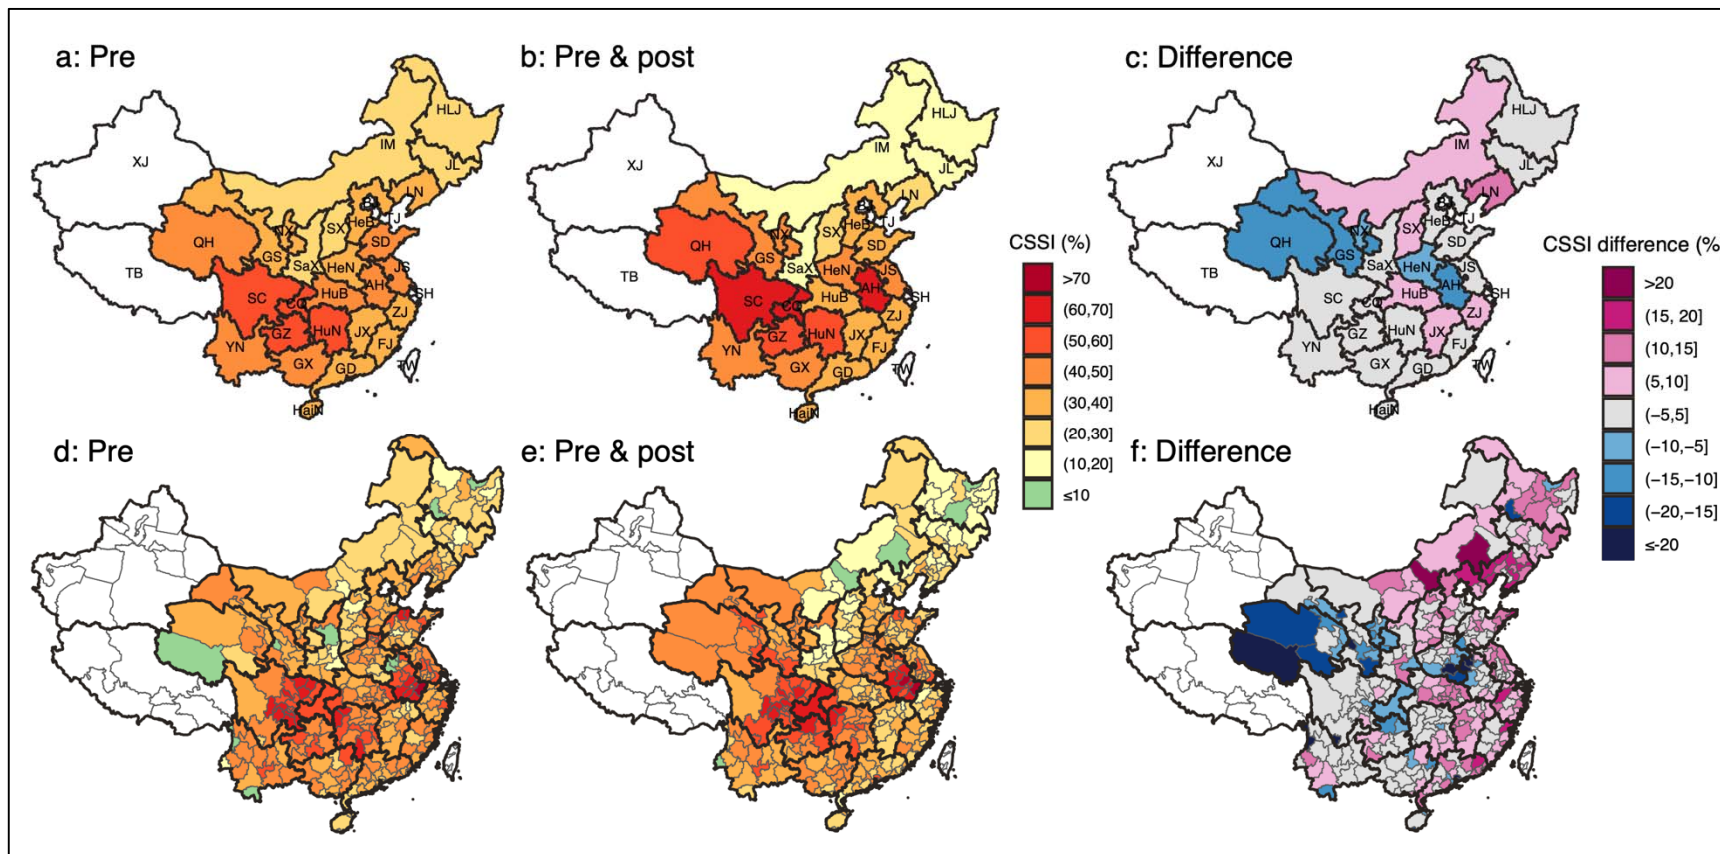

Fig. 4 P-CSSI, pp-CSSI, and their difference at the province level (a-c) and prefecture level (d-f).

Notes: a and d: Provincial and prefecture p-CSSI (%) based on births in 1950-57. b and e: Provincial and prefecture pp-CSSI (%) based on births in 1950-57 & 1963-70. c: Difference of provincial CSSI (%) between a and b. f: Difference of prefecture CSSI (%) between d and e.

Source: 1% China 2000 Census, place of residence.

Fig. 5 Scatterplot of CSSI and incidence rate ratio (IRR) of tuberculosis among F1 across prefectures in Sichuan province
Notes: Each prefecture is represented by a dot. The size of the dot is proportional to the inverse variance of the estimated IRR of each prefecture. The lines represent the meta-regression fits, and the shaded areas represent the 95% CIs.
