13 Funding statement: The research was supported by a grant to DNF from the Canadians Institutes
14 for Health Research (2019 COVID-19 rapid researching funding OV4-170360).

15

16 Declaration of competing interests: DNF has served on advisory boards related to influenza and
17 SARS-CoV-2 vaccines for Seqirus, Pfizer, Astrazeneca and Sanofi-Pasteur Vaccines, and has
18 served as a legal expert on issues related to COVID-19 epidemiology for the Elementary
19 Teachers Federation of Ontario and the Registered Nurses Association of Ontario. ART was
20 employed by the Public Health Agency of Canada when the research was conducted. The work
21 does not represent the views of the Public Health Agency of Canada.

22

23 **Abstract**

24

25 **Background:** Provision of safe and effective vaccines has been a remarkable public health
26 achievement during the SARS-CoV-2 pandemic. The effectiveness and durability of protection
27 of the first two doses of SARS-CoV-2 vaccines is an important area for study, as are questions
28 related to optimal dose combinations and dosing intervals.

29 **Methods:** We performed a case-cohort study to generate real-world evidence on efficacy of first
30 and second dose of SARS-CoV-2 vaccines, using a population-based case line list and
31 vaccination database for the province of Ontario, Canada between December 2020 and October
32 2021. Risk of infection after vaccination was evaluated in all laboratory-confirmed vaccinated
33 SARS-CoV-2 cases, and a 2% sample of vaccinated controls, evaluated using survival analytic
34 methods, including construction of Cox proportional hazards models. Vaccination status was
35 treated as a time-varying covariate.

36 **Results:** First and second doses of SARS-CoV-2 vaccine markedly reduced risk of infection
37 (first dose efficacy 68%, 95% CI 67% to 69%; second dose efficacy 88%, 95% CI 87 to 88%).
38 In multivariable models, extended dosing intervals were associated with lowest risk of
39 breakthrough infection (HR for redosing 0.64 (95% CI 0.61 to 0.67) at 6-8 weeks).

40 Heterologous vaccine schedules that mixed viral vector vaccine first doses with mRNA second
41 doses were significantly more effective than mRNA only vaccines. Risk of infection largely
42 vanished during the time period 4-6 months after the second vaccine dose, but rose markedly
43 thereafter.

44 **Interpretation:** A case-cohort design provided an efficient means to identify strong protective
45 effects associated with SARS-CoV-2 vaccination, particularly after the second dose of vaccine.

46 However, this effect appeared to wane once more than 6 months had elapsed since vaccination.

47 Heterologous vaccination and extended dosing intervals improved the durability of immune

48 response.

49

50 **Introduction**

51

52 The rapid introduction of highly effective vaccines against SARS-CoV-2 represents a
53 remarkable scientific achievement amidst the current global pandemic (1). It has been estimated
54 that these vaccines have averted hundreds of thousands of deaths (2, 3). While mRNA vaccines
55 represent the first application of a novel and highly immunogenic vaccine construct, viral vector
56 vaccines have also been extremely effective in preventing severe illness and death (4). The
57 introduction of novel vaccines against a virus that has been recognized for only two years (5),
58 means that there is of necessity a great deal of uncertainty related to their application. The
59 relative protection afforded by vaccines against emerging variants of concern (6), vaccine safety
60 (7, 8), the immunogenicity of mixed vaccine schedules (9), optimal spacing between
61 administration of doses (10), the number of doses required for a full primary series (11), and the
62 necessity of future boosting (12), are all the subject of active study.

63 The Canadian province of Ontario represents a large (population 14.6 million) and
64 diverse jurisdiction, with high levels of 2-dose SARS-CoV-2 vaccine coverage (approximately
65 77% as of December 2021) (13, 14). The province has made use of several different vaccine
66 formulations, predominantly BNT162b2 (BNT/Pfizer, “Cominrtv”), mRNA-1273 (Moderna,
67 “SpikeVax”), and ChAdOX1-S (AstraZeneca, “Covishield”). Ontario’s vaccination program has
68 prioritized risk groups over time. For example, the program initially focussed on vaccinating
69 residents of long-term care facilities and health-care workers (15). Once higher risk groups were
70 vaccinated, eligibility was expanded using a descending age-based approach. The province also
71 consciously chose to offer extended dosing intervals to lower risk populations, due to supply
72 constraints and the potential advantages of rapid, maximal coverage with first doses of vaccine

73 (16). Pediatric vaccination programs for those aged 5 to 11 years were introduced in in late
74 November 2021 (17).

75 Beginning in autumn 2021, third doses have been offered to a growing list of individuals
76 identified as being at elevated risk due to age, medical comorbidity or congregate living
77 residence. Although there was some evidence suggesting that the use of prolonged dosing
78 intervals in the primary series had resulted in durable immunity that made third doses
79 unnecessary (18), the province expanded access to third vaccine to all aged 50 and over
80 December 2021 (19). In late December, the rapid spread of the Omicron variant of concern in the
81 province resulted in an expansion of third dose eligibility to all aged 18 and over who received
82 their second dose at least 3 months previously.

83 A large, highly-vaccinated population like Ontario's, which has received a several
84 different vaccination regimens, with variable dosing intervals, provides an opportunity to
85 generate real-world evidence on efficacy of vaccination against breakthrough infections. The
86 province's vaccination database and COVID-19 case line provide detailed information on
87 vaccine administration as well as individual-level covariates that can be used to adjust for
88 confounding by factors associated with both infection risk and vaccination priority. Our
89 objective was to use these data to generate estimates of 1- and 2-dose vaccination protection over
90 time, against breakthrough SARS-CoV-2 infection; we also performed exploratory analyses to
91 generate hypotheses related to optimal dosing intervals and the relative efficacy of different
92 vaccine combinations.

93

94

95 **Methods**

96

97 *Data Sources*

98 We created a cohort of individuals who received vaccination against SARS-CoV-2 in
99 Ontario, without record of infection prior to the date of receipt of first vaccine dose. We
100 included all reported cases of infection meeting these criteria, as well as a 2% random sample of
101 vaccinated individuals with no record of infection. Cases were identified in the Province’s Case
102 and Contact Management (CCM) database as described elsewhere (20, 21); we included only
103 cases with a unique “pseudo-health card number”, which permitted linkage with the provincial
104 vaccination database. Vaccination information on cases and controls was extracted from the
105 Province’s COVaxON dataset (21), which includes dosage dates, vaccines used, basic
106 demographic information, and fields on indication for vaccination, including residence in a
107 congregate setting (including residence in a nursing home, retirement community, or other
108 congregate setting), priority health condition, and healthcare worker status. As with cases, the
109 pool of potential controls was limited to individuals with a pseudo-health card number. A flow
110 diagram outlining creation of the cohort is presented in **Figure 1**.

111 We considered individuals to have been vaccinated with a first dose of vaccine during
112 time at risk 14 or more days after the date of the first vaccine dose; individuals were considered
113 vaccinated with two doses of vaccine during time at risk 14 or more days after second vaccine
114 dose. While some researchers, including ourselves (21-23), have previously defined two dose-
115 vaccinated time as commencing 7 or more days after second dose, we use the longer window for
116 consistency with Canadian public health authorities (24).

117 *Analysis*

118 We performed a case-cohort analysis using survival analytic methods. As person time data were
119 available, we were able to estimate hazard ratios directly using Cox proportional hazards models,
120 rather than approximate such ratios via risk set sampling. Controls were reweighted by a factor
121 of 50 to account for 2% selection probability. We stratified within-person time at risk according
122 to an individual's vaccination status, which was treated as a time-varying covariate.

123 We created Cox proportional hazards models including only vaccination as an exposure
124 (unvaccinated, single-dose vaccinated, or fully vaccinated), as well as adjusted models that
125 adjusted for variables that we expected to confound observed vaccine effect. We evaluated the
126 proportional hazards assumption both graphically using log-log plots, and statistically based on
127 Schoenfeld residuals (25). As we found hazards of infection following vaccination to be non-
128 proportional through inspection of log-log plots and testing of Schoenberg residuals
129 (**Supplementary Figure**), we re-ran our Cox proportional hazards models with time at risk
130 further stratified by 2-month blocks, within a given vaccination status.

131 Lastly, we performed restriction analyses in which we restricted cases individuals with
132 infection due to a non-variant of concern viral strain, to infection with N501Y+ variants of
133 concern (alpha, beta and gamma variants), and to infection with likely delta infection.
134 Classification of likely variant status of the infecting strain was as described previously (21). We
135 conducted all analyses in Stata version 15.1 using sts, stox and related commands. The study was
136 conducted in accordance with the STROBE guidelines for observational research (26), and
137 received ethics approval from the Research Ethics Board at the University of Toronto.

138

139

140

141 **Results**

142 Our final cohort consisted of 52,948 cases and 211,373 controls. Cases and controls
143 differed significantly according to age distribution, sex, vaccine combination received,
144 documented priority health condition, residence in a congregate setting, and healthcare worker
145 status, as well as interval between first and second doses (**Table 1**). Crude time to breakthrough
146 infection by vaccination status is presented as a Kaplan-Meier curve (**Figure 2**); vaccination was
147 associated with significant reduction in infection risk, with 2-dose vaccination reducing risk
148 relative to single dose vaccination ($P < 0.001$ by log-rank test for all comparisons).

149 We constructed a Cox proportional hazards model that included only vaccination status;
150 the hazard ratio for breakthrough infection after a single dose of vaccine was 0.32 (95% CI 0.31
151 to 0.33); after a second dose of vaccine the hazard ratio declined to 0.12 (95% CI 0.12 to 0.13),
152 corresponding to effectiveness of 68% and 88% against infection. We found little change in
153 these after adjusting for potential confounders in multivariable models (**Table 2**). In
154 multivariable analyses we identified a strong U-shaped relationship between dosing interval and
155 risk of breakthrough infection, with risk lowest when vaccine doses were administered 6-8 weeks
156 apart. Among individuals who received two doses of vaccine, increased risk of breakthrough
157 infection was seen in those who received two doses of ChAdOx1-S, relative to two doses of
158 mRNA vaccine. However, for individuals who received an initial dose of ChAdOx1-S, there
159 was a significant reduction in breakthrough risk following a second dose of mRNA vaccine, in
160 contrast to receipt of two doses of mRNA vaccine. Risk of breakthrough was highest in younger
161 adults (aged 20-49), and was elevated in healthcare workers, those residing in congregate living
162 settings, and in those identified as having priority medical conditions.

163 Models that stratified time at risk both by vaccination status and 60-day time blocks since
164 vaccination generated similar results to initial multivariable models, demonstrating high efficacy
165 of first and second vaccine doses (**Supplementary Table**). The lowest hazard ratio for
166 breakthrough infection was seen between four and 6 months after second vaccine dose but
167 increased after 6 months of observation (**Figure 3**). In exploratory restriction analyses in which
168 we included only cases with non-variant of concern infection, cases with N501Y+ infection
169 (alpha, beta or gamma variants), or cases with delta variant infection, we found significant
170 protection against breakthrough infection with both 1 and 2 doses of vaccine, against all variants.
171 However, there was significant heterogeneity across variants (P for heterogeneity < 0.001 for
172 both 1 and 2 doses), with highest efficacy after two doses seen against N501Y+ infection
173 (96.9%, 95% CI 96.7% to 97.1%), and lower efficacy seen against delta variant (66.1%, 95% CI
174 62.5% to 69.4%) (**Table 3**).
175

176 **Discussion**

177 We find that in a large cohort of vaccinated individuals in Ontario, Canada vaccination
178 provided remarkable protection against breakthrough infection, with increased protection
179 afforded by a second vaccine dose relative to a single dose. We also find that maximal
180 protection against infection is provided 4-6 months after the second dose of vaccine, at which
181 time protection against infection was nearly complete. However, we found that infection risk
182 increased again after 6 months, suggesting the need for third vaccine doses at this interval (11).
183 Consistent with effects demonstrated using viral neutralization assays (10), we find that the
184 extended interval between first and second vaccine doses has resulted in enhanced immune
185 protection, with a relative reduction in risk of approximately 40% when second vaccine doses
186 were provided 6-8 weeks after first doses. We also identified significant protection against
187 infection associated with heterologous vaccine schedules, in particular the use of initial dose
188 ChAdOx1-S, followed by a second dose of mRNA vaccine, though viral vector vaccines are no
189 longer in wide use in Canada due to concerns about risk of vaccine induced thrombotic
190 thrombocytopenia (VITT)(7). However, the observed effects have substantial face validity and
191 are consistent with the previously described immune enhancement seen with heterologous
192 vaccination schedules as well as the high efficacy of mRNA booster vaccination following non-
193 mRNA SARS-CoV-2 vaccination (27-31).

194 Our findings on vaccine efficacy are consistent with those reported by others using more
195 typical cohort designs for study of vaccine efficacy. Our application of a case-cohort design,
196 with both cases and controls contributing person-time to unvaccinated, and single- and double-
197 dose vaccinated exposures, allowed us to generate these estimates without access to an

198 unvaccinated control group. The fact that all individuals in our study chose to be vaccinated
199 potentially eliminates confounding by factors associated with vaccination choices.

200 Like any observational study, ours is potentially subject to confounding by measured and
201 unmeasured factors, though inclusion of available covariates in multivariable models did not
202 significantly change our estimates of vaccine effectiveness. We were also surprised at the sparse
203 nature of data on healthcare worker status, congregate living status and priority health conditions
204 in the CoVaxON dataset. The small number of individuals with these classifications suggests
205 that the dataset is insensitive for these elements. However, inasmuch as CoVaxON data would
206 have been recorded without knowledge of a case's subsequent infection status these missing data
207 should not result in bias.

208 In summary, we use a case-cohort study with stratified person-time analysis of
209 vaccination status to demonstrate the strong protection afforded by SARS-CoV-2 vaccines in
210 Ontario, Canada. Despite this strong protection, we do find that an increase in hazard greater
211 than 6 months after second dose of vaccine; our analysis also suggests that increased intervals
212 between vaccine doses, as widely implemented in Canada, provides more durable protection
213 against infection than shorter dosing intervals.

214

215 **Acknowledgements**

216 The authors wish to thank the staff at Public Health Ontario and Ontario's public health units for
217 collecting, sequencing, analyzing, and providing access to the data used for this analysis.
