37 **Authors' contributions:** DF conceived of the study. DF, JV, and AG initiated the study design  
38 and DF, JV, JW, GMV, ER, PC, CG, MH, AS, UB, FD, YC, AK, and  
39 AG helped with implementation.

40 FD, YC, and AK are grant holders.

41 PJ provided statistical expertise in clinical trial design and in conducting  
42 the primary statistical analysis.

43 All authors contributed to refinement of the study protocol and approved  
44 the final manuscript.

45 **DOI Statement:** None of the authors have any competing/conflicting interests to declare

46 **Authorship Role:** All authors collaborated in the writing/editing of the manuscript

47 **Article Type:** Original article – RCT

48 **Running Head:** Losartan for COVID-19

49

50 **ABSTRACT**

51 *Background*

52 ACEi/ARB medications have been hypothesized to have potential benefit in COVID-19. Despite concern  
53 for increased ACE-2 expression in some animal models, preclinical and observational-retrospective and  
54 uncontrolled trials suggested possible benefit. Two RCTs of the ARB losartan from University of  
55 Minnesota showed no benefit yet safety signals for losartan in outpatient and hospitalized COVID-19  
56 patients. COVID MED, started early in the pandemic, also assessed losartan in a RCT in hospitalized  
57 patients with COVID-19.

58 *Methods*

59 COVID MED was quadruple-blinded, placebo-controlled, multicenter randomized clinical trial (RCT).  
60 Hospitalized COVID-19 patients were randomized to receive standard care and hydroxychloroquine,  
61 lopinavir/ritonavir, losartan, or placebo. Hydroxychloroquine and lopinavir/ritonavir arms were  
62 discontinued after RCTs showed no benefit. We report data from the losartan arm compared to combined  
63 (lopinavir-ritonavir and placebo) and prespecified placebo-only controls. The primary endpoint was the  
64 NCOSS slope of change. Slow enrollment prompted early stopping.

65  
66 *Results*

67 Of 432 screened patients, 14 were enrolled (3.5%), 9 received losartan and 5 combined control  
68 (lopinavir/ritonavir [N=2], placebo [N=3]); 1 hydroxychloroquine arm patient was excluded. Most  
69 baseline parameters were balanced. Treatment with losartan was not associated with a difference in  
70 NCOSS slope of change in comparison with combined control ( $p=0.4$ ) or placebo-only control ( $p=0.05$ )  
71 (trend favoring placebo). 60-day mortality and overall AE and SAE rates were numerically but not  
72 significantly higher with losartan.

73 *Conclusions*

74 In this small blinded RCT in hospitalized COVID-19 patients, losartan did not improve outcome vs.  
75 control comparisons and was associated with adverse safety signals.

76

80 COVID-19, SARS-CoV-2, randomized clinical trial (RCT)

81

## 82 INTRODUCTION

83 Angiotensin converting enzyme inhibitors (ACEi) and angiotensin II receptor blockers (ARB) have been  
84 hypothesized to have benefit in COVID-19 secondary to inhibition of pneumocyte ACE-2 receptors  
85 resulting in decreased SARS-CoV-2 entry, as well as local vasodilation/vasoconstriction alteration and  
86 anti-inflammatory effects. Animal studies suggested potential for benefit. Safety concerns have included  
87 observations of increased ACE-2 receptor expression in some animal models and potential for medication  
88 class adverse events (e.g., acute kidney injury [AKI]). Retrospective and observational continuation-  
89 discontinuation trials [1-10], open-label interventional trials [11-15], and a meta-analysis [16] showed  
90 trends favoring benefit. Two blinded RCTs, however, showed no benefit yet adverse safety signals [17-  
91 18]. We initiated the COVID MED trial at the pandemic onset prior to publication of ACEi/ARB  
92 COVID-19 clinical trials, aiming to assess the ARB losartan (and hydroxychloroquine and  
93 lopinavir/ritonavir) in hospitalized COVID-19 patients.

94

## 95 MATERIALS AND METHODS

96 COVID MED (NCT04340557) was approved by the Institutional Review Boards of Bassett Medical  
97 Center (Cooperstown, NY [April 3, 2020] [#1581969]), Goshen Health (Goshen, IN) and Reid Health  
98 (Richmond, IN). Initiated at the pandemic onset, we could not project COVID-19 admission numbers,  
99 thus, an arbitrary N of 4,000 hospitalized patients with laboratory-confirmed SARS-CoV-2 (screening  
100 criteria) was selected with prespecification for sample size/power calculations and updating after interim  
101 analysis. Our primary objective was to assess whether treatment with hydroxychloroquine,  
102 lopinavir/ritonavir, or losartan, would result in more rapid improvement in the 7-point NIAID COVID-19  
103 Ordinal Scale Score (NCOSS) in comparison with placebo. NCOSS is as follows: 1) Death; 2)  
104 Hospitalized, on mechanical ventilation or ECMO; 3) Hospitalized, on NIV/high flow oxygen; 4)  
105 Hospitalized, requiring oxygen; 5) Hospitalized, not requiring oxygen; 6) Not hospitalized, with  
106 limitations; 7) Not hospitalized, without limitations. Enrolled patients were followed for up to 60 days.

107 Target recruitment was maximized by daily assessment of positive SARS-CoV-2 swab tests from  
108 Bassett's laboratory in hospitalized patients with review of inclusion/exclusion criteria for all such  
109 patients by the study's enrollment nurse and offering enrollment to all interested in participating after a  
110 comprehensive informed consent process (see Supplementary material for Informed Consent Form  
111 [ICF]). Post-consent, patients were randomly assigned by an unblinded enrollment research nurse in a  
112 2:2:2:1 ratio in blocks to one of four groups using a computer-generated randomization schedule provided  
113 by the study's statistician (without stratification): hydroxychloroquine, lopinavir/ritonavir, losartan, or

114 placebo; this ratio was selected because early in the pandemic patients declined participation in trials with  
115 low likelihood of receiving ‘active’ drug. Allocation concealment was ensured by having only the  
116 enrollment research nurse be unblinded and with maintaining confidentiality of the allocation.

117 All groups received standard care, which transformed over time. Hydroxychloroquine and  
118 lopinavir/ritonavir enrollment were halted after other RCTs showed no benefit [19-20]; a 2:1 ratio  
119 computer-generated randomization schedule for losartan and placebo was used thereafter. Herein, we  
120 focus on the trial design and results for losartan vs. combined control groups (we included 2  
121 lopinavir/ritonavir patients as other RCTs showed no benefit or safety concerns [20]. We also report ITT  
122 data for the comparison of the losartan and placebo-only group, per our prespecified statistical analysis  
123 plan (SAP). Low enrollment led to study termination (July 2021).

124 Inclusion criteria were (1) hospitalized; (2) >18 years-old; (3) laboratory-confirmed SARS-CoV-2  
125 infection; (4) randomization within 72 hours of admission; and (5) able to provide consent. General  
126 exclusion criteria applicable to all groups included (1) ESRD; (2) severe hepatic insufficiency; (3)  
127 nausea/vomiting/aspiration risk precluding oral medications unless can be given by nasogastric tube; (4)  
128 use of another SARS-CoV-2 medication; (5) pregnancy/breast feeding; (6) no contraception; and (7)  
129 inability to obtain consent. Each treatment group had specific exclusions based on the medication’s  
130 safety profile. Specific losartan group exclusion criteria included (1) ARB allergy/intolerance; (2) taking  
131 ACEi/ARB; (3) hypotension; (4) hyperkalemia; (4) severe renal dysfunction; (5) severe volume  
132 depletion/AKI; (6) ascites; (7) aortic/mitral stenosis; (8) renal artery stenosis; and (9) co-administration of  
133 CYP3A interacting drugs. Minor modifications were made during the study. There were no placebo group  
134 specific exclusion criteria. After hydroxychloroquine and lopinavir-ritonavir enrollment was stopped,  
135 inclusion/exclusion criteria were the same for the losartan and placebo groups.

136 Study drug (losartan or TicTacs placebo [lopinavir-ritonavir in 2 patients]) was prepared by a pharmacist  
137 who inserted the ‘pills’ into blank capsules – enabling cost-effective quadruple-blinding (patient, clinical  
138 nurse/physician, study nurse, investigators); only the enrollment study nurse was unblinded but he/she  
139 had no other responsibilities after enrollment. Unblinding was not done. If crushed drug or drug in  
140 solution had to be administered (nasogastric/gastric tube), eye shields were used to maintain blinding.  
141 Dosing was initially twice daily in all groups to mask varying regimens (losartan group: losartan and  
142 placebo; placebo group: placebo and placebo; lopinavir/ritonavir group: lopinavir/ritonavir twice daily).  
143 The losartan dose was 25 mg; the lopinavir/ritonavir dose was 400/100 mg. After hydroxychloroquine  
144 and lopinavir/ritonavir groups enrollment ceased, losartan and placebo dosing were daily. Dosing duration  
145 target was 14 days (minimum 5 days) if tolerated (no clinically relevant related AEs/SAEs such as  
146 hypotension, hyperkalemia, or worsening renal function). Adherence to study dosing was monitored and

147 noted by the study's research nurse. Patients discharged early were administered a shorter 5-day course  
148 with a minimum of 1.5 days as an in-patient (3 doses) and 3.5 days as an out-patient (7 doses).

149 With the initial study plan to recruit up to 4,000 subjects, the 2:2:2:1 assignment was predicted to result in  
150 571 subjects in the placebo group and 1,143 subjects in each treatment group. An independent, conflict-  
151 free, and multidisciplinary Data Monitoring Committee (DMC) was convened at the study's outset and  
152 agreed to its processes and goals; unexpected SAE reports were shared with the DMC. Interim analysis  
153 was planned for each treatment group at an information fraction of 0.1, which would occur when a  
154 treatment group had slopes for 114 subjects, and the control group has slopes for 57. After  
155 hydroxychloroquine and lopinavir/ritonavir were dropped, we planned interim analysis and sample size  
156 optimization upon enrollment of 114 losartan and 57 placebo subjects. However, the study was stopped  
157 due to slow enrollment prior to the first planned DMC interim analysis.

158 Protocol CRFs were used to collect standardized efficacy/safety data; telephone follow-up was used as  
159 much as possible after discharge to obtain planned efficacy/safety data but inability to meet participants  
160 due to COVID-19 safety restrictions precluded complete data collection. Additional blood tests for more  
161 extensive safety monitoring were completed for patients who consented. AEs were classified in  
162 accordance with NCICTC for Adverse Events, version 4.0 (standard grading procedures). COVID MED  
163 was carried out in accordance with principles of the Code of Ethics of the World Medical  
164 Association (Declaration of Helsinki) and GCP guidelines of the International Conference on  
165 Harmonization, with general principles of protection of humans participating in research. Data from CRFs  
166 and AE/SAE reports were entered into REDCap using secure login/password entry; data were  
167 deidentified in working documents which were available only to study investigators; all study identifying  
168 data will be destroyed/deleted upon publication to allow wider sharing if requested.

169

### 170 *Statistical Analysis*

171 As per our prespecified SAP, subjects had NCOSS values recorded for up to 11 timepoints (days 0, 1-7,  
172 14, 30, and 60). These 11 X (time) Y (NCOSS) pairs were be used to calculate the slope of the change in  
173 NCOSS values over time for each subject. Only X-Y pairs up to and including the first attainment of  
174 NCOSS level 7 were included. These slopes of the change in NCOSS levels over time served as the  
175 primary endpoint for each subject.

176 The study design was such that it constituted three unique trials, all of which utilized the same control  
177 (placebo) group. Means of the slopes for each of the three different treatments were compared separately  
178 to mean slope in the control group using Student's t-test. We report methods/results for comparison of the

179 losartan vs. placebo-only arms per the prespecified SAP, but also, because of our small N, post-hoc  
180 comparison with combined controls (lopinavir/ritonavir and placebo).

181 Continuous and categorical secondary endpoints were compared using Student's t-test and Fisher's exact  
182 test, respectively. Secondary analyses included but were not limited to hospital LOS, mechanical  
183 ventilation duration, and 60-day mortality. Time to resolution of nasopharyngeal viral shedding (PCR)  
184 was compared. For safety, the primary outcome was the intention-to-treat (ITT) 60-day overall SAE rate;  
185 secondary measurements included overall AE rates, and AKI, hypotension, and hyperkalemia AE/SAE  
186 rates. Adjusted and subgroups analyses were not done due to small sample size. For the primary outcome,  
187 missing values were addressed with conventional last-observation-carried-forward (LOCF).

188

## 189 **RESULTS**

### 190 *Screening/enrollment*

191 Of 432 screened patients, 14 were enrolled (3.5%), 9 receiving losartan and 5 receiving control  
192 (placebo=3, lopinavir/ritonavir=2); 1 hydroxychloroquine arm patient was not included herein. Reasons  
193 for non-inclusion at Bassett: patient declined (12.0%), taking ACEi/ARB (26.9%), outside enrollment  
194 window (20.1%), hypotension (1.6%), hyperkalemia (2.1%), renal disease (4.2%), altered mental status  
195 precluding consent (11.6%), hospitalized for non-COVID-19 reasons (asymptomatic) (10.4%), and other  
196 (11.1%).

197

### 198 *Baseline parameters/demographics*

199 Comparisons of losartan and combined control baseline data revealed balanced parameters other than  
200 comorbidities. Specifically, mean age was 63.7 vs. 61.8 years, and males accounted for 66.7% vs. 60%,  
201 respectively. 100% were Caucasian and 100% were ward patients in both groups. Mean NCOSS was 3.6  
202 vs. 4.0, (p=0.5), qSOFA 0.33 and 0.6 (p=0.4), and creatinine 0.7 vs. 0.9 (p=0.4), respectively. Chest x-ray  
203 opacities consistent with pneumonia were seen in 88.9 vs. 100% (p=0.9). PSI scores were similar – 54.9  
204 and 59.3 (p=0.5). Mean BMI was 31.0 and 31.8 (p=0.4). The mean targeted comorbidities rate (per  
205 subject) was lower with losartan than combined control (1 vs. 2.6, p=0.02); a similar trend was seen for  
206 the Charlson Score (2.5 vs. 4.5, p=0.08). Treatment occurred at a median of 9.3 vs. 7.4 days after  
207 symptoms onset (p=0.3). Treatment duration mean was 9.6 vs. 13.3 days, respectively (p=0.3). 88.9 vs.  
208 50% of patients received corticosteroids (p=0.5). Most patients were enrolled between the spring of 2020  
209 and the winter of 2021 (88.9 vs. 80%). Baseline comparisons for losartan vs. placebo-only control were  
210 similar (see Table 1).

211

212 *Efficacy*

213 NCOSS data were recorded for 97% of losartan group timepoints (3% missingness), 94.5% of combined  
214 control (lopinavir/ritonavir and placebo) group timepoints, and 100% of placebo-only control group  
215 timepoints. The slopes of the change for NCOSS were 0.00365 for losartan ( $p=0.5$ ), 0.02091 for  
216 combined control ( $p=0.07$ ), and 0.05268 for placebo-only control ( $p=0.002$ ). Comparisons of the slopes  
217 of the change for NCOSS, our primary outcome measurement, revealed: losartan vs. combined control  
218 ( $p=0.4$ ), losartan vs. placebo-only control ( $p=0.05$ ) (trend favoring placebo), combined control vs.  
219 placebo-only control ( $p=0.267$ ) (see Figure 1).

220

221 Mean NCOSS change at 60 days was numerically but not significantly lower with losartan (0.7) than  
222 combined control (1.8) ( $p=0.6$ ). Mortality at 60 days (44.4 vs. 20%,  $p=0.9$ ), mean LOS (16.4 vs. 7.0 days,  
223  $p=0.2$ ), and mean mechanical ventilation duration (8.5 vs. 0 days) were worse with losartan but also not  
224 significantly (see Table 2).

225

226 *Safety*

227 The primary safety outcome measurement, the overall SAE rate (per subject), was numerically higher  
228 with losartan vs. combined control (2.0 vs. 0.6%) and vs. the placebo-only control (2.0 vs. 0%). The  
229 overall AE rate (per subject) trend was similar, being higher with losartan than combined control (3.9 vs.  
230 1.0%) and vs. placebo-only control (3.9 vs. 0%). AKI AE and SAE rates were similar, but hypotension  
231 and hyperkalemia, as well as respiratory failure AE and SAE rates, were numerically higher with losartan  
232 than combined control and placebo-only control. No safety comparison was statistically significantly  
233 different (see Table 3).

234

235 Planned subgroups analysis and adjustment for baseline parameters was not done due to the small N of  
236 the enrolled population.

237

238 **DISCUSSION**

239 COVID MED, to our knowledge, the third blinded, placebo-controlled RCT assessing an ARB in  
240 COVID-19, did not find significant group differences in the NCOSS score for hospitalized patients  
241 treated with losartan vs. control. A statistically insignificant trend favoring control was found for our  
242 prespecified primary efficacy outcome measurement, the ITT comparison of the NCOSS slope of the  
243 change vs. placebo-only control ( $p=0.05$ ). Our primary safety outcome measurement, overall SAE rate,  
244 was numerically but not statistically significantly higher with losartan. Secondary outcomes also

245 numerically favored placebo but no group comparisons were statistically significantly different –  
246 including mortality.

247 Although COVID MED was small and pilot-like in scope, its results are value-added in that they add  
248 randomized, blinded, and placebo-controlled data to the limited ACEi/ARB literature in COVID-19. Our  
249 results are similar to those found in two larger blinded RCTs [17-18]; these three RCTs do not support  
250 empiric starting of ACEi/ARB, at least ARB, in COVID-19 outside of RCTs. Given the negative results  
251 of these blinded studies, it is worth reviewing the evidence for ACEi/ARB in COVID-19.

#### 252 *Preclinical data*

253 SARS-CoV and SARS-CoV-2 viruses enter cells by binding to cellular ACE2 receptors which are  
254 expressed on lung type II pneumocytes, enterocytes, kidney, and vascular cells [21-26]. Animal viral  
255 pneumonia models provided indirect support showing improved outcome with losartan, including  
256 amelioration of lung injury, edema, and lung failure in a SARS-CoV infection model [26], and of lung  
257 injury, edema, and leukocyte infiltration in an influenza A H5N1 mouse model [27].

258 Some researchers raised concern early in the pandemic that ACEi/ARB might worsen COVID-19  
259 outcome [28-29] because in some (not all) animal models, ACE2 expression may be upregulated by these  
260 drugs potentially increasing virus cell injury [30-37]. Human studies do not show increased plasma ACE2  
261 levels with ACEi/ARB [38-40]. ARB have been hypothesized to stabilize with the AT<sub>1</sub>-ACE2  
262 complex causing AT<sub>1</sub>7 generation leading to vasodilation and diminished inflammation [41]. These  
263 effects may be more important than ACE-2 inhibition/viral entry inhibition.

264 In sum, animal studies have shown potential for benefit with ACEi/ARB in viral pneumonias and  
265 inconsistent data suggesting potentially adverse increased ACE-2 expression.

#### 266 *Retrospective/observational clinical trials*

267 A Chinese retrospective study compared mortality in hypertensive hospitalized COVID-19 patients who  
268 were taking ACEi/ARB or were not [1]. Unadjusted and adjusted mortality was lower with ACEi/ARB.  
269 In another Chinese retrospective study in hypertensive hospitalized COVID-19 patients, progression to  
270 severe disease/mortality was similar in those taking vs. not taking ACEi/ARB [2]. An observational  
271 database of international hospitalized COVID-19 patients showed similar in-hospital mortality for  
272 ACEi/ARB use [3]. A NYU database review found no association for ACEi/ARB use and COVID-19 or  
273 severe COVID-19 [4]. An Italian case-control study found no association for ACEi/ARB use and  
274 COVID-19 [5].

275 In another hospitalized COVID-19 patient cohort, adjusted death/ICU transfer occurred less frequently  
276 with ACEi vs. non-ACEi use [6]. Danish national registry retrospective cohort and case-control studies  
277 found no significant associations for mortality and composite mortality/severe COVID-19 in patients  
278 taking vs. not taking ACEi/ARB [7]. An observational trial evaluating hydroxychloroquine/chloroquine  
279 found baseline ACEi (but not ARB) use to be associated with decreased mortality [3]. A Cleveland Clinic  
280 Health System retrospective cohort study reported no association for ACEi/ARB use and COVID-19 [8].  
281 In a retrospective Stanford study of COVID-19 inpatients/outpatients, ACEi/ARB use was not associated  
282 with higher hospitalization, ICU risk, or death; hospitalization was lower [9].

283 In sum, these retrospective studies showed no safety signals for ACEi or ARB in COVID-19 [10] and  
284 possible benefit in some, supporting RCTs.

#### 285 *Retrospective/observational clinical trials in influenza*

286 A query of UK's Clinical Practice Research Datalink showed lower influenza rates with ACEi/ARB use  
287 vs. non-use [42]. Influenza A relies on the ACE2 receptor for lung entry, like SARS-CoV-2.

#### 288 *Prospective clinical trials*

289 The BRACE CORONA trial compared discontinuation vs. continuation of ACEi/ARB already taken by  
290 659 mild-moderate hospitalized COVID-19 patients in Brazil [11]. Median time from symptoms onset  
291 was 6 days. The trial found no differences in the primary outcome of days alive outside the hospital at day  
292 30 (mean, 21.9 vs. 22.9 days). No significant differences in mortality and AEs were seen.

293 A second similar discontinuation vs. continuation trial of ARB already taken by 152 hospitalized COVID-  
294 19 patients was also published (REPLACE COVID) [12]. Median time from symptoms onset was 6.5-6.8  
295 days. There was no difference in the study's primary outcome, a global rank score including time-to-  
296 death, mechanical ventilation time, renal replacement, vasopressor time, and MOF. Mortality (13 vs.  
297 15%), ICU admission/mechanical ventilation (18 vs. 21%), and AEs (36 vs. 39%) did not differ.

298 We are aware of five published ACEi/ACE in COVID-19 intervention trials (four inpatient, one  
299 outpatient).

300 The first, from University of Kansas, was a single-arm open-label trial assessing the ARB losartan in  
301 hospitalized COVID-19 patients requiring oxygen [13]. Thirty active treatment patients vs. 30 post-hoc  
302 external controls using propensity scores were compared, with the primary outcome being AE incidence.  
303 AE incidence (80 vs. 97%) and AE rates were lower with losartan (2.2 vs. 3.3); Poisson regression  
304 adjusted AE incidence ratio remained lower with losartan (0.69; 95% CI: 0.49-0.97); elevated creatinine  
305 AEs occurred in 30 vs. 23%, and elevated AST in 33 vs. 63%. No significant differences were found for

306 death (1/30 vs. 3/30) or mechanical ventilation (2/17 vs. 5/17) (trends favored losartan); hospital and ICU  
307 LOS and days requiring oxygen or mechanical ventilation were similar. Study limitations included single-  
308 arm, nonrandomized, open-label design with external historical controls, and between-group imbalance.  
309 34 of 347 screened patients were enrolled (10%).

310 The second, an open-label RCT compared the ARB telmisartan and SOC vs. SOC alone in two  
311 hospitalized COVID-19 patients in Argentina up to 4 days post symptoms onset (earlier than our trial)  
312 [14]. The primary outcome was CRP at days 5 and 8. In an interim analysis, 40 telmisartan/SOC vs. 38  
313 SOC were compared. Mean CRP was significantly lower in telmisartan/SOC vs. SOC groups at days 5  
314 (24.2 vs. 51.1 mg/L [ $p<0.05$ ]) and 8 (9.0 vs. 41.6 mg/L [ $p<0.05$ ]). Median time to discharge was shorter  
315 with telmisartan, 9 vs. 15 days ( $p=0.01$ ) and 30-day mortality trend favored telmisartan (5.26 vs. 11.76%,  
316  $p=0.41$ ); there were no differences for ICU admission, mechanical ventilation, and a composite of ICU  
317 admission, mechanical ventilation, and death; fewer patients receiving telmisartan needed oxygen at day  
318 15 (2/4 vs. 13/14,  $p<0.05$ ). No telmisartan related AEs occurred and BP was similar. 82 of 185 screened  
319 patients were enrolled (56% [higher than our trial]).

320 The third, an open-label RCT compared the ARB losartan and SOC vs. SOC alone in 31 SHARP (San  
321 Diego) hospitalized patients with COVID-19 with mild hypoxia (requiring  $\leq 3$  L oxygen) [15]. The  
322 primary measurement was a composite of mechanical ventilation/death. No significant primary or  
323 secondary differences were found: the composite endpoint occurred in 1/16 vs. 1/15 losartan/SOC vs.  
324 SOC patients; mortality occurred in 1/16 vs. 1/15 patients; mean LOS was 9 vs. 10 days; hypotension  
325 occurred in 3/16 vs. 4/15. O<sub>2</sub> requirements were similar.

326 The fourth, the first blinded placebo-controlled RCT, compared losartan to placebo in outpatients with  
327 mild COVID-19 conducted by University of Minnesota [17]. Of 117 enrolled patients, hospitalization  
328 (primary outcome) occurred in 3/58 (5.2%) vs. 1/59 (1.7%) of losartan vs. placebo patients – an  
329 insignificant absolute difference of -3.5% favoring placebo (95% CI -13.2, 4.8%;  $p=0.320$ ). ICU  
330 admissions and viral loads were similar; there were no deaths. The rate of NCOSS  $<5$  at day 15 was 7/55  
331 (12.7%) with losartan and 2/54 (3.6%) with placebo, with an adjusted OR (age and gender) of -1.4 (95%  
332 CI -3.4, 0.2;  $p = 0.096$ ), favoring placebo. AE rates were similar, 0.33 vs. 0.37, respectively; SAE rates  
333 were similar. No significant AKI, hypotension, or hyperkalemia occurred. This RCT was terminated early  
334 due to futility due low rates of events. 117 of 14,371 screened patients were enrolled (0.81%); 89.8% did  
335 not meet inclusion/exclusion criteria.

336 The fifth, also by University of Minnesota, was the second randomized placebo-controlled RCT,  
337 comparing losartan (N=101) and placebo (N=104) in hospitalized COVID-19 patients [18]. Losartan

338 dosing was 50 mg twice daily for 10 days (higher than in our study). The primary outcome, the  
339 PaO<sub>2</sub>/FiO<sub>2</sub> ratio at 7 days was similar [difference -24.8 (95% CI, -55.6 to 6.1; p=0.12)]. There were no  
340 differences in secondary outcomes including 90-day mortality (10.9 vs. 10.6%, respectively), LOS,  
341 oxygen and mechanical ventilation requirement at 10 days, or NCOSS. More losartan vs. placebo patients  
342 needed vasopressors (20 vs. 11%, p=0.08) and vasopressor-free days were lower with losartan (8.7 vs.  
343 9.4, p=0.04); our study found numerically higher hypotension AE/SAE rates analogously. Overall AE and  
344 SAE rates were numerically higher with losartan (not significant); AKIs were more common with losartan  
345 (19.4 vs. 8.8%, p=0.04). This trial's design and applicability was most like ours, including low  
346 enrollment:screening (5%). Notable differences include larger N, higher dosing, and lower mortality;  
347 similarities include lack of efficacy findings accompanied by numerically higher safety signals with  
348 losartan.

349 In sum, the ACEi/ARB continuation:discontinuation trials and small unblinded treatment trials in  
350 hospitalized COVID-19 patients showed equivalent or improved outcome. In contrast, both blinded RCTs  
351 showed lack of efficacy and adverse safety signals [17-18].

#### 352 *Meta-analyses*

353 A recent ACEi/ARB COVID-19 continuation:discontinuation meta-analysis (52 studies – 101,949  
354 patients, 26,545 ACEi/ARB) found lower adjusted mortality and SAE rates with ACEi/ARB use [16].

355 Two pooled analyses of ACEi/ARB in COVID-19 are currently being completed and results should be  
356 forthcoming: (1) an IPD-based analysis of North American trials in hospitalized COVID-19 patients; (2) a  
357 larger aggregate data-based international meta-analysis by the International Society of Hypertension of  
358 outpatient and hospitalized COVID-19 patients [43]. COVID MED data are included in both.

#### 359 *Guidelines, professional societies, and reviews*

360 NIH guidelines, professional societies, and reviews recommend that ACEi/ARB, if already taken, should  
361 be continued but not started anew outside RCTs [10, 29-30, 44-49].

#### 362 *Study strengths and limitations*

363 The strengths of our study include its design (randomized, controlled, blinded), minimal primary outcome  
364 measurements missingness, and baseline balance. Limitations include small N, early termination,  
365 inclusion of lopinavir/ritonavir in post-hoc combined control comparisons, and low enrollment rate  
366 making conclusions relevant to a small proportion of hospitalized COVID-19 patients.

#### 367 *Conclusions*

368 Our blinded and controlled RCT comparing losartan and control in hospitalized COVID-19 patients found  
369 no significant efficacy effect (NCOSS or mortality) which is not surprising given its small size, yet it  
370 found potential safety signals. We speculate that class adverse effects of ACEi/ARB may overcome  
371 theorized SARS-CoV-2-ACE-2 binding inhibition and other potential benefits making the overall benefit  
372 to risk ratio for these medications in COVID-19 null or negative. Given that results from our blinded RCT  
373 simulate those of the other two larger blinded RCTs to date, in effect a small third ‘negative’ RCT, unless  
374 forthcoming pooled analyses find conflicting results, ARBs should not be started *de novo* to treat  
375 COVID-19 outside of clinical trials.

376

### 377 *Acknowledgements*

378 We thank our study patients for participating in this RCT during the difficult times of the COVID-19  
379 pandemic. We thank Jessica Kumar, MD, and Elizabeth Dufort, MD, and colleagues at New York State  
380 Department of Health, Albany, NY, for assistance with nasopharyngeal PCR processing and study drug  
381 supply.

### 382 *Funding*

383 This work was supported by a Bassett Research Institute ED Thomas Grant and salary support from the  
384 Bassett Research Institute and Bassett Medical Center’s Department of Internal Medicine.

526 **Figure legends**

527 **Figure 1.** NCOSS over time +/- SEM. Figure on left compares losartan and combined control  
528 (lopinavir/ritonavir and placebo). Figure on right compares losartan and placebo only control.  
529 Comparisons of the slopes of the change for NCOSS, our primary outcome, revealed: losartan vs.  
530 combined control (p=0.4), losartan vs. placebo only control (p=0.05) (trend favoring placebo), combined  
531 control vs. placebo only control (p=0.267).

532

533 **Table legends**

534 **Table 1.** Baseline parameters/demographics. Losartan is compared with combined control  
535 (lopinavir/ritonavir and placebo) and placebo only control. Statistically significant and ‘trend’  
536 comparisons are in bold.

537 **Table 2.** Efficacy. Losartan is compared with combined control (lopinavir/ritonavir and placebo) and  
538 placebo only control. Statistically significant and ‘trend’ comparisons are in bold. Comparison of NCOSS  
539 slope of the change was the study’s primary efficacy outcome measurement.

540 **Table 3.** Safety. AE and SAE rates including relatedness. Losartan is compared with combined control  
541 (lopinavir/ritonavir and placebo) and placebo only control. Statistically significant and ‘trend’  
542 comparisons are in bold. Comparison of SAE rate was the study’s primary safety outcome measurement.

543

	Treatment	Combined control	p	95% CI	Placebo only control	p	95% CI
	Losartan	Lopinavir/ritonavir and placebo			Placebo
