## 14 Abstract

15 Tumor growth is the result of the interplay of complex biological processes in huge numbers of  
16 individual cells living in changing environments. Effective simple mathematical laws have been  
17 shown to describe tumor growth in vitro, or simple animal models with bounded-growth dynamics  
18 accurately. However, results for the growth of human cancers in patients are scarce. Our study  
19 mined a large dataset of 1133 brain metastases (BMs) with longitudinal imaging follow-up to find  
20 growth laws for untreated BMs and recurrent treated BMs. Untreated BMs showed high growth  
21 exponents, most likely related to the underlying evolutionary dynamics, with experimental tumors  
22 in mice resembling accurately the disease. Recurrent BMs growth exponents were smaller, most  
23 probably due to a reduction in tumor heterogeneity after treatment, which may limit the tumor  
24 evolutionary capabilities. In silico simulations using a stochastic discrete mesoscopic model with  
25 basic evolutionary dynamics led to results in line with the observed data.  
26

## 27 Introduction

28 Macroscopic tumor growth is a complex process resulting from the interplay of different biological  
29 elements at the cellular and subcellular levels. These include the driving molecular alterations and  
30 their associated heterogeneity, angiogenesis, the immune system, the tumor microenvironment,  
31 and surrounding healthy structures, the effect of treatments on the different tumor phenotype-  
32 s/genotypes, etc.

33 Mathematical growth laws have been shown to describe longitudinal tumor growth dynamics  
34 effectively in simple experimental models. [1–5]. A great deal of data is available for those models,  
35 which do not have the biological complexity of human tumors. One would expect that describing  
36 cancer growth mathematically in humans would be far more difficult because of the different  
37 biological mechanisms that drive it over distinct tumor stages.

38 Assessing complex tumor growth dynamics over time, given the large genotypic and phenotypic  
39 variability developed during tumorigenesis, is very difficult with current techniques. Medical images  
40 are performed routinely in most cancer patients and provide rough global macroscopic information -

42 the so-called imaging phenotype- which integrates the several processes occurring at the microscale,  
43 potentially providing information on the underlying tumor biology.

44 Longitudinal datasets for untreated malignant tumors are rare, and of limited quality, since  
45 therapeutic action is typically performed promptly. This is why studies of untreated tumor dynamics  
46 laws in humans have been mostly limited to the use of two time points per patient what allows  
47 only for the identification of average growth rates [6, 7]. Only recently has a study using more  
48 time points shown explosive dynamics, argued to be the result of evolutionary dynamics in human  
49 cancers [8].

50 Our goal in this study combining clinical data and mathematical models, was to provide more  
51 evidences on the macroscopic growth dynamics of both treated and untreated tumors in human  
52 patients. We focused on growth dynamics of brain metastases (BMs) integrating mathematical  
53 and computational models with data analysis methods on a patient database with longitudinal  
54 MR imaging follow-up and more than a thousand lesions. BMs are the most common intracranial  
55 tumor and a major complication of many cancers, with 20%-30% of cancer patients developing  
56 the condition in the course of their disease [9, 10]. Here we focused on two scenarios. The first  
57 one was the growth of untreated BMs. Human beings as well as mice data were studied. The  
58 second scenario considered BMs under different treatment modalities. Therapy options for BMs are  
59 surgery, whole brain radiation therapy (WBRT), gamma knife radiosurgery, stereotactic radiosurgery  
60 (SRS), targeted and systemic therapies.

61 We wanted to investigate whether there was a measurable effect on the growth dynamics of the  
62 expected loss of tumor heterogeneity after treatment. To this end, we performed an analysis of the  
63 growth dynamics of untreated BMs, and BMs treated under different types of therapy, by fitting a  
64 general tumor growth law [11]. The results obtained were endorsed by *in silico* simulations with  
65 a discrete stochastic model of tumor growth, which helped to gain insight into the causes of the  
66 behavior observed in BMs.

## 67 Results

### 68 Brain metastasis growth is explosive in untreated patients but not in treated ones

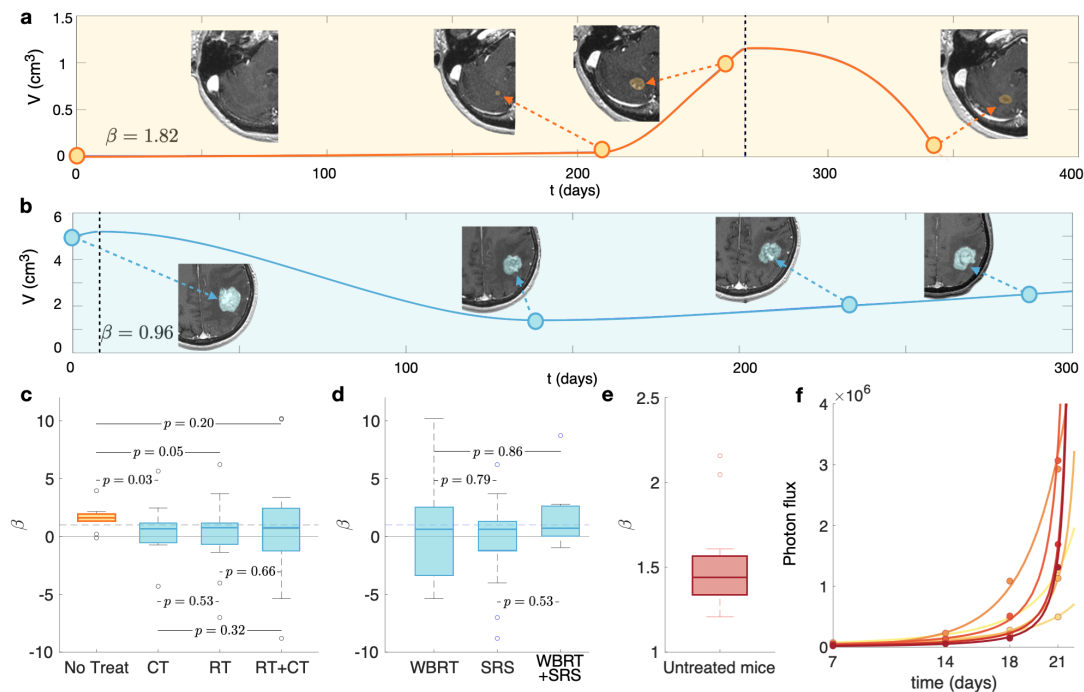

69 The Von-Bertalanffy model [11]

$$\frac{dV}{dt} = \alpha V^\beta - bV, \quad (1)$$

70 has been proven recently to describe the longitudinal dynamics of growing human tumors [8]. It  
71 has been argued, and supported with data from different human cancers, that malignant tumors  
72 with heterogeneous clonal composition have exponents  $\beta > 1$ . The reason is that in heterogeneous  
73 tumors there would be a range of phenotype/genotypes to choose from, leading to selection for  
74 more aggressive phenotypes/genotypes, and an acceleration of the growth rate, which would  
75 manifest in the form of faster-than-exponential explosive unbounded growth. In this paper will  
76 focus on scenarios of growing tumors for which the first term in Eq. (1) dominates over the second.  
77 In this context, it will be assumed that  $b \simeq 0$ , meaning that most of the metabolic requirements are  
78 routed towards biosynthesis rather than basal energy consumption. Moreover, our dataset having  
79 time intervals with three consecutive longitudinal measurements without treatment ( $V_0, V_1, V_2$ ) allows  
80 us to identify at most three parameters for each tumor ( $V_0, \alpha, \beta$ ) but not more. When  $b$  is assumed  
81 to be zero, for a clonally homogeneous tumor with only a fraction of the cells proliferating due  
82 to necrosis, nutrient limitations, etc., exponents  $0 < \beta < 1$ , correspond to growth slower than  
83 exponential, but with volumes still increasing with time.

84 Three patient groups were studied in a first batch of analyses. They included the cases of (i)  
85 growing untreated and (ii) relapsing post-radiotherapy BMs, and also (iii) growing BMs from patients  
86 under chemotherapy (CT) but with no specific treatment for the BMs. Patients in the last group  
87 included only drugs crossing the blood-brain-barrier (BBB) as described in 'Methods'. Figure 1(a,b)  
88 shows examples of BM longitudinal growth dynamics as observed in MRI studies. The growth  
89 exponent  $\beta$  governing the dynamic for each patient was obtained as described in the Methods

90 section. The median value of the fitted individual exponents for untreated BMs ( $N = 10$ ) was  
 91  $\beta = 1.59$ . This suggests substantial growth acceleration with  $\beta \approx 3/2$ . It is interesting to note that  
 92 this number differs from the value  $5/4$  obtained from metabolic scaling data of primary tumors [8].

**Figure 1. Growth dynamics of untreated and post-treatment relapsing BMs.** Longitudinal dynamics observed in **a.** an untreated breast cancer BM and **b.** a relapsing post-SRS lung cancer BM. SRS treatment times are marked with a vertical dashed blue line. Yellow dots are the measured volumes and the solid blue lines are the result of interpolating longitudinal volumetric data with chirped cubic splines (shown only to guide the eye). Axial slices of the contrast-enhanced T1-weighted MRI sequences are displayed. **c.** Box plots comparing the growth exponents  $\beta$  of the different groups: untreated ( $N = 10$ ), growing during chemotherapy treatment (CT,  $N = 16$ ), recurrent BMs receiving only radiation therapy (RT,  $N = 23$ ), or both (RT+CT,  $N = 33$ ). Growth exponents were obtained for each BM using Eqs. 3. **d.** Box plots of the growth exponent  $\beta$  for BMs after RT: WBRT ( $N = 16$ ), SRS ( $N = 31$ ) and both ( $N = 9$ ). The Kruskal-Wallis test gives non-significant  $p$ -values, showing no differences between growth exponents  $\beta$  in these groups. **e.** Box plot of the growth exponents  $\beta$  in mice ( $N = 20$ ) injected with an human lung adenocarcinoma brain tropic model (H2030-BrM). **f.** Total tumor mass growth curves for some of the studied mice where dots correspond to the measured values.

93 Median growth exponent for BMs growing under CT was  $\beta = 0.64$  ( $N = 16$ ). For BMs growing after  
 94 completing radiation therapy (RT) we obtained  $\beta = 0.72$  ( $N = 23$ ). Finally, for those having received RT  
 95 and under CT we got  $\beta = 0.68$  ( $N = 33$ ), where RT can stand for WBRT, SRS or a combination of both.  
 96 Box plots are shown in Fig. 1(c). Similar growth exponents were obtained after receiving different  
 97 RT modalities (see Fig. 1 (d)). Thus, volumetric growth of treated BMs had lower  $\beta$  exponents on  
 98 average than those obtained for untreated BMs.

### 99 Animal models recapitulating BM's natural history display superexponential dy- 100 namics

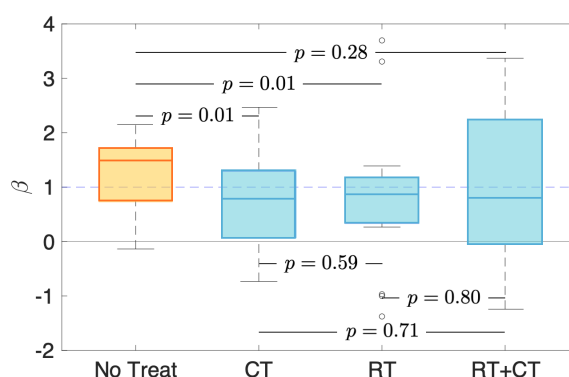

101 To investigate the growth patterns of untreated BMs in faithful animal models, experiments in  
 102 mouse models were performed as described in Methods. For the experiments, the human lung  
 103 adenocarcinoma brain tropic model H2030-BrM3 was used since it is injected into the hearts of  
 104 nude mice and leads to the formation of brain metastases from systemically disseminated cancer  
 105 cells. Thus, the cell line used recapitulates at least in part the complex sequences of transformations  
 106 required for cells to metastasize.

107 Since more than three points were available in the mice dataset, the growth exponents were  
108 computed using a different fitting technique as described in 'Methods'. The median value of the  
109 individual exponents  $\beta$  was 1.44 ( $N = 20$ ) (Fig. 1 (e,f)).

### 110 Sensitivity analysis of the exponents calculation

111 Since three points per patient were available to obtain three parameters, the fitting could be very  
112 sensitive to small variations in the data. Those variations in volumetric data could be given either  
113 by the time between MRIs or by image segmentation, regardless of being performed by the same  
114 image expert, and revised by another expert and a radiologist. In order to assess the effect of small  
115 changes in measured volumes on the results, an analysis of sensitivity was performed as explained  
116 in 'Methods'.

117 The growth exponent values were consistent in 74% of the BMs used in the study when a  
118 random error was added. Once sensitive cases were excluded, the results were in line with those of  
119 the entire cohort of BMs (Fig 2), ensuring the strength of the study.

**Figure 2. Growth dynamics of untreated and post-treatment relapsing BMs for the group with the most stable values of the growth exponent.** Box plots comparing the growth exponents  $\beta$  of the different groups after a sensitivity analysis: untreated ( $N = 8$ ), growing during chemotherapy treatment (CT,  $N = 14$ ), recurrent BMs receiving only radiation therapy (RT,  $N = 18$ ), or both (RT+CT,  $N = 21$ ).

### 120 Growth exponents best fitting the dynamics display super-exponential growth for 121 untreated patients and subexponential growth for treated ones

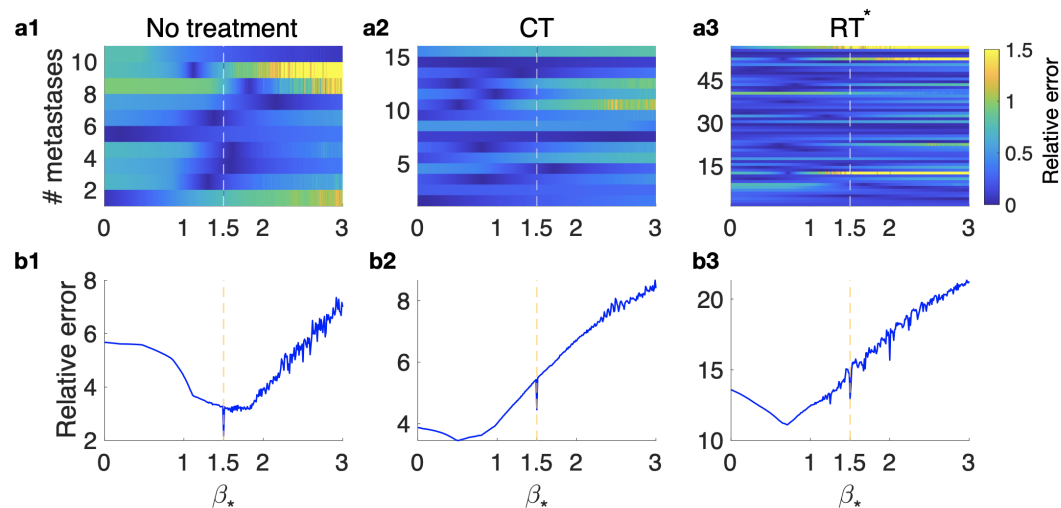

122 An alternative approach to obtaining  $\beta$  was designed by looking for the value  $\beta_*$  that provided the  
123 best fit for all patients in each subgroup (untreated, growing while in CT treatment, and relapsing  
124 post-RT -with or without CT-RT\*). The absolute errors weighted by volume, relative errors, were  
125 computed for each  $\beta_*$  value and each group of patients.

126 The exponent best fitting the whole dataset of untreated BMs was  $\beta_* = 1.5$  ( $n = 10$ ). For treated  
127 relapsing tumors, the best fit was obtained with  $\beta_* = 0.51$  (CT,  $n = 16$ ) and  $\beta_* = 0.71$  (RT\*,  $n = 56$ ),  
128 showing again a slowing down of the post-treatment growth dynamics (Fig. 3.b).

129 It's interesting to note that at  $\beta_* = 1.5$ , a minimum (absolute or relative) appears in each dataset.  
130 Such minima are absolute for untreated lesions and relative in the case of treated ones, which  
131 indicates that after treatment, when the best growth exponent defining the group is lower than  
132 one, there is still a relevant tumoral component in some cases.

### 133 Evolutionary dynamics of tumor complexity

134 It is known that cancer treatments lead to a reduction of the clonal complexity at the point of  
135 maximal response, due to the selective pressures exerted by the therapies [12-15]. Competition  
136 between clonal populations with different traits is a key ingredient leading to the increase of the

**Figure 3. Growth exponent best fitting the dynamics for the dataset of untreated, CT and RT groups.** Relative errors obtained when the  $\beta$  growth exponent is fixed. **a.** Errors computed for each metastasis in the different groups: untreated (**a1**), CT (**a2**), RT\* (**a3**). **b.** Cumulative errors for each subgroup of BMs as a function of  $\beta_*$  for each of the different groups: untreated (**b1**), CT (**b2**), RT\* (**b3**).

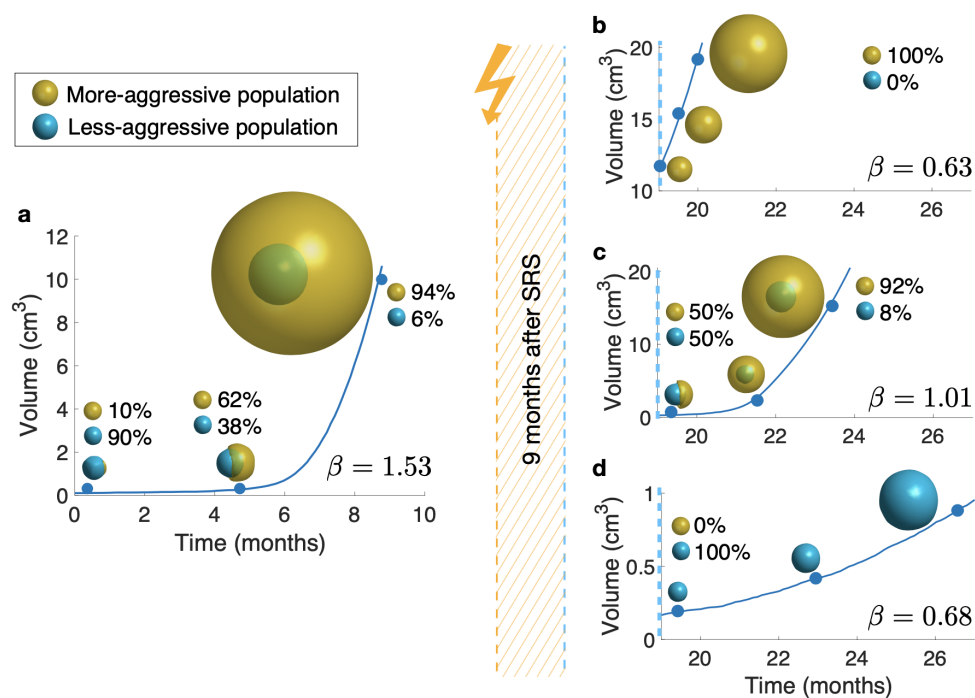

137 growth exponent  $\beta$  [8]. Hence, one would expect this reduction in heterogeneity to be reflected in  
 138 the growth exponents of BMs as observed in our previous analysis.

139 The influence of different clonal compositions on the growth exponent of BMs was assessed  
 140 *in silico* using an adapted version of the mesoscopic model developed in Ref. [16] (as described  
 141 in Methods). We explored computationally a simplified scenario where BMs were made of two  
 142 predominant clonal populations, one being more aggressive than the other. The initially most  
 143 abundant population proliferated and migrated at fixed rates, while the least abundant population  
 144 had an advantage in both processes, and hence was assumed to be more aggressive, due to either  
 145 mutational changes or irreversible phenotype changes, providing evolutionary benefits. In that way  
 146 we accounted for an initial tumor heterogeneity, and competition between the two populations  
 147 was sustained during the early follow-up, several months post SRS.

148 First, the growth exponent  $\beta$  of an untreated virtual BM was evaluated. To do so, we simulated  
 149 starting with a small fraction (10%) of an aggressive population coexisting with a larger population  
 150 of less aggressive cells. After a few months, the tumor was substantially enriched *in silico* in the  
 151 most aggressive population (94% versus 6%) and the growth exponent  $\beta$  was found to be  $\beta = 1.53$   
 152 Fig. 4(a).

153 In a second set of computational experiments, initially growing tumors were treated *in silico* with  
 154 SRS with a differential effect on the two subpopulations. First, one or other of the subpopulations  
 155 was assumed to be very sensitive to SRS, so that one of the populations was completely depleted.  
 156 In both scenarios, depicted in Fig. 4(b,d) growth exponents were respectively  $\beta = 0.63$  and  $\beta = 0.68$ ,  
 157 thus far from even exponential growth. A third, and more realistic, scenario assumed the most  
 158 aggressive population to be more sensitive to treatment, thus restoring equilibrium between the  
 159 two subpopulations. In this scenario, the growth exponent found was  $\beta = 1.01$ , still far from  
 160 super-exponential, Fig. 4(c).

161 To study the influence of different advantages in proliferation and migration of the most  
 162 aggressive population on the growth exponent  $\beta$ , simulations were performed varying the value  
 163 of the advantage coefficients  $v_{div}$  and  $v_{mig}$  (see 'Methods'), and keeping the initial proportion of  
 164 aggressive cells equal to 10%. We observed that the largest growth exponents  $\beta$  were obtained for  
 165 combinations of slight advantages in both processes ( $\beta = 1.758$  for  $v_{div} = 0.8$ ,  $v_{mig} = 0.95$ ; Fig. 5(b))  
 166 and that, for most combinations of coefficients  $v_{div}$  and  $v_{mig}$ , the resulting exponent  $\beta$  is lower than

**Figure 4. Simulations of longitudinal growth of heterogeneous BMs with two initial populations** (turquoise: less aggressive, and ocher: more aggressive). **a.** pre-treatment and **b,c,d** post-treatment cases. The more aggressive population carries an advantage of 80% in proliferation speed and 92.5% in migration speed, compared to the less aggressive population. In **a** the BM is composed of 10% of more aggressive cells, and 90% of less aggressive cells. After eight months, the more aggressive population has overcome its counterpart, becoming dominant. Then, three different situations that can happen after treatment are illustrated: **b.** the less aggressive population is completely removed from the tumor; **c.** both populations remain in a balanced state, and **d.** the more aggressive population is completely removed from the tumor. The betas were computed by choosing a random time point from each third of the total simulated time and are shown on each subplot.

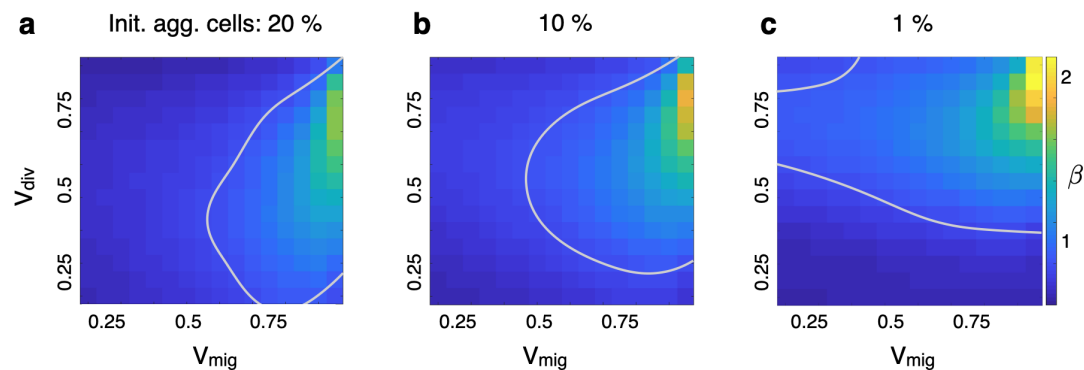

167 1.

168 Therapy is most harmful to the most proliferative cells [17, 18]. Hence, it is to be expected that  
 169 the relative abundance of aggressive cells will decrease after treatment. To explore the influence  
 170 of treatment on the growth exponent  $\beta$ , we repeated the previous analysis but this time the initial  
 171 proportion of aggressive cells was modified to represent scenarios where the treatment was either  
 172 very effective (initial proportion of aggressive cells is 1%, Fig. 5(c)) or not very effective (initial  
 173 proportion of aggressive cells is 20%, Fig. 5(a)). The resulting  $\beta$  maps (each spot corresponds to a  
 174 simulation performed with a fixed pair of coefficients  $v_{div}$  and  $v_{mig}$ ) are qualitatively similar, although  
 175 it can be observed that the maximum exponent  $\beta$  achieved decreases as the initial proportion of  
 176 aggressive cells increases. Again, we observed that most combinations of advantage coefficients  
 177 yield a  $\beta$  lower than 1. This result suggests that, regardless of the resulting proportion of aggressive  
 178 cells after treatment, it is rare to observe a growth exponent  $\beta$  larger than 1 in treated BMs.

## 179 Discussion

180 Evolution is one of the main driving forces of life on Earth and is behind the observed diversity at  
 181 every level of biological organization. Evolutionary processes are used by cancers to survive within  
 182 their hosts and escape from the pressures exerted by treatments. It is a remarkable fact that the  
 183 growth laws of untreated human malignant cancers and their animal model counterparts display a  
 184 signature of the evolutionary processes taking place behind the scenes, in the form of an exponent  
 185  $\beta > 1$  in (1).

186 This study mined a dataset including more than a thousand BMs to test such a surprising result

**Figure 5. Growth exponents  $\beta$  obtained from a parameter sweep varying the advantages in migration and proliferation** Simulations were carried out for different combinations of coefficients  $v_{div}$  (advantage in proliferation; values explored range from 0.2 to 0.9) and  $v_{mig}$  (advantage in migration; values explored range from 0.2 to 0.95). **a** Poor-effectiveness treatment case (proportion of aggressive cells after treatment is 20%). The largest exponent  $\beta$  obtained is equal to 1.615, for a  $v_{div} = 0.75$  and a  $v_{mig} = 0.95$ . **b** Medium-effectiveness treatment case (proportion of aggressive cells after treatment is 10%). The largest exponent  $\beta$  achieved was 1.758, for a  $v_{div} = 0.8$  and a  $v_{mig} = 0.95$ . **c** High-effectiveness treatment case (proportion of aggressive cells after treatment is 1%). The largest exponent  $\beta$  achieved was equal to 1.99, for a  $v_{div} = 0.85$  and a  $v_{mig} = 0.95$ . Gray lines correspond to  $\beta = 1$ .

187 over a time scale of months, i.e. the time interval spanning three MRI studies (6-9 months). BMs  
 188 have a background of heterogeneity that could provide the necessary substrate for evolutionary  
 189 competitive dynamics to happen, leading to super-exponential growth of the tumor mass. Phylo-  
 190 genetic analyses have revealed that BM-competent clones genetically diverge from their primary  
 191 tumors at a relatively early stage in lung adenocarcinoma patients [19]. Genomic analyses of solid  
 192 tumors and matched BMs revealed significant genetic heterogeneity between primary lesions and  
 193 BMs [20], and the degree of genetic heterogeneity of BMs varied significantly among individuals  
 194 with NSCLC, breast, and colorectal cancer [21–23]. In addition to the genetic heterogeneity, BMs  
 195 have significant epigenetic variability [24, 25] and there can be other phenotype-based mechanisms  
 196 playing a role [26].

197 Our results manifested both a macroscopic reflection of the evolutionary dynamics in the form  
 198 of a  $\beta > 1$  exponent for pre-treatment longitudinal dynamics, and also the loss of biological richness  
 199 experienced by BMs after therapy, which lead to substantially reduced exponents  $\beta_* = 0.71$  post-  
 200 SRS. It has been hypothesized, using mathematical models, that treatment strategies in which an  
 201 oncological “first strike” reduces the size and heterogeneity of the population, then followed by  
 202 “second strikes” could lead to cancer extinction in metastatic disease [27, 28]. Our results show  
 203 the effectiveness of the first-line SRS approach in providing an ecoevolutionary first-strike strategy  
 204 for BMs. Independently of the volumetric reduction observed, which ends up being marginally  
 205 irrelevant if the tumor recurs, the substantial reduction of the growth exponent implies a direct  
 206 effect on the tumor ecological complexity. In the case of BMs, “second-strike” strategies could be  
 207 provided by targeted therapies with better penetration than classical drugs across the blood-brain  
 208 barrier, many of which are under investigation [29, 30]. It is also very interesting that information  
 209 obtained from global macroscopic images could provide information on the underlying biological  
 210 richness of these metastatic lesions. Thus  $\beta$  could be understood as an evolutionary exponent  
 211 providing some information on the tumor heterogeneity.

212 It may seem naively counterintuitive that BMs subject to different treatment modalities (SRS,  
 213 WBRT, CT) led to similar growth exponents  $\beta$ , since SRS is known to be substantially more effective  
 214 than WBRT or CT. Our retrospective study focused only on BMs growing after (RT) or under (CT)  
 215 treatment, but of course there would be many BMs with complete response, e.g. to SRS, that were  
 216 not included here. It is also relevant to emphasize that the growth exponent cannot be directly

217 interpreted as a growth rate, e.g. the speed of volumetric growth, but as a measure of the shape of  
218 the tumor growth curve.

219 An intriguing result of our study was the fact that the growth exponent for untreated BMs when  
220 fitted together was close to  $3/2$ . It has recently been found for different primary tumors, lung  
221 (both adenocarcinoma and squamous cell), breast, colorectal, glioma, and head and neck cancer,  
222 that metabolic scaling exponents are close to  $5/4$  [8]. Following the classical reasoning of West et  
223 al. [31], one would expect metabolic exponents to be the same as growth exponents. This raises  
224 the interesting question of what the metabolic scaling of BMs would be on diagnosis, since the  
225 datasets of [8] did not include that condition. Would it be  $3/2$ , raising the question of why BMs have  
226 a different metabolic scaling than other cancers? Or would it be  $5/4$ , raising the question of why  
227 there should be a mismatch between metabolic and growth exponents in BMs? Data on metabolic  
228 scaling of BMs would be necessary to answer that question.

229 The *in silico* observation that the largest exponents  $\beta$  were achieved for combinations of slight  
230 advantages in both processes, division and migration, points out that a great advantage will not  
231 lead to a  $\beta > 1$ , as the overtaking time will be reached more quickly by the aggressive population,  
232 failing to sustain a competition throughout the time span of the BM. Another observation is that  
233  $\beta$  decreases faster with changes along the  $v_{mig}$  axis, suggesting that advantages in migration may  
234 bring more competitive advantages in division.

235 Several authors have wondered whether the interval between SRS planning and treatment is  
236 accurate [32–35]. In order to study this, they compared volumes from diagnostic imaging and  
237 radiosurgery planning MRI and extrapolated the growth linearly to the day of SRS, since only two  
238 time points were available. Progression between diagnosis and SRS is common, and some suggest  
239 that a mathematical model would be useful to individualize treatments. Our model based on three  
240 time points shows that the growth velocity of untreated BMs increases with time. Thus pointing  
241 out an inadequate prediction of the tumor volume on treatment day and a substantial benefit of  
242 reducing the interval between SRS planning and treatment.

243 The main strength of our study was that it was based on a substantial dataset of 1133 BMs  
244 treated with SRS with high-resolution data, according to the guidelines for BM clinical studies [36].  
245 Besides, each lesion was carefully segmented by the same expert and verified by a radiologist. Also  
246 it was a multicenter approach, including BMs from five different hospitals.

### 247 **Limitations of the study**

248 The main limitation was that only a subset of 82 BMs of the whole 1133 BMs could be used for the  
249 computation of  $\beta$ . Only this part of the data had the three sequential imaging studies displaying  
250 sustained growth and with no further therapeutic actions performed in that time window required  
251 to compute the growth exponents. Because of the limited size of the final dataset, the data could  
252 not be analyzed separating patients by primary histologies. It would be very interesting to look at  
253 whether any of the conclusions of our study depend on the type of primary cancer considered.

### 254 **Conclusion**

255 In summary, we studied a large BM dataset and unveiled a continuous acceleration of growth in the  
256 case of untreated lesions, due to Darwinian competition between different tumor subpopulations,  
257 as validated by *in silico* simulations using a stochastic discrete mesoscopic model. Results for mice  
258 data were in line with that. Recurrent BMs after treatment displayed slower growth, compatible  
259 with treatment-mediated reduction of tumor heterogeneity. As a result, we have highlighted the  
260 predictive value of a macroscopic variable, the evolutionary exponent, which can be used to obtain  
261 information on the microscopic status of the tumor.

## Methods & Materials

### EXPERIMENTAL MODEL AND SUBJECT DETAILS

#### Patients

Patients included were all participants in the study MetMath (Metastasis and Mathematics), a retrospective, multicenter, nonrandomized study approved by five hospitals (blinded for review). All patients were diagnosed with BM in the period 2007-2021 and followed up with MRI according to standard clinical practice. A total of 354 patients who received SRS at any time during the evolution of the disease, and with full longitudinal follow-up, were reviewed in the study, including 1133 BMs. Primary tumor histologies were mainly non-small-cell lung cancer (NSCLC), breast cancer, melanoma and SCLC.

For the study of longitudinal volumetric dynamics, BMs were selected from the MetMath dataset on the basis of several inclusion criteria. First of all a minimum of three consecutive imaging studies, including a volumetric contrast-enhanced (CE) T1-weighted MRI sequence (slice thickness  $\leq 2.00$  mm, no gap) with no substantial imaging artifacts, at different time points, were required in order to allow for reliable lesion volume calculations. Secondly, an increase in tumor volume at each of the three time points was required, since it was desired to study the growth of either untreated or recurrent tumors avoiding. Next, only time points without previous SRS/WBRT treatments or with SRS/WBRT treatments received more than four months before the first imaging study were considered, in order to exclude the potential confounding effect of acute inflammatory responses seen in some patients in the first MRI after SRS. Patients with prior surgical resection of the metastasis were excluded to avoid confounding effects, such as ischemia. Brain metastases lacking relevant clinical variables and/or data on treatments received, as well as those lacking consensus in segmentations (what may lead to uncertain values of the volumes) were also excluded. Finally, patients were included regardless of their systemic treatment; however, BMs were considered as untreated for patients who were receiving chemotherapies (CTs) which are unable to cross the blood-brain-barrier

<b>Patient characteristics</b>	
Number of patients	58
Number of metastases	82
Age (years)	58.48 (33-78)
Metastases per patient	1.63 (1-19)
Sex (Male (M), Female (F))	53% M (31), 47% F (27)
<b>Primary cancer Histology</b>	
	Percentage (number of BMs)
NSCLC	54.88% (45)
Breast	26.83% (22)
Melanoma	4.88% (4)
SCLC	6.10% (5)
Others	7.32% (6)
<b>Volumetric parameters</b>	
	mean (range)
Total tumor volume (cm <sup>3</sup> )	3.45 (0.003-33.106)
CE volume (cm <sup>3</sup> )	2.77 (0.003-28.989)
Necrotic volume (cm <sup>3</sup> )	0.68 (0.000-12.452)

**Table 1.** Summary of patient and BM characteristics, histology and volumetric parameters.

(BBB) such as pertuzumab or trastuzumab [37, 38]. Those treatments target primary tumors but are known to have little or no effect on metastatic lesions due to the protecting effect of the BBB. Drugs known to cross the BBB were considered as treatments.

Each BM in our dataset was carefully revised to determine whether or not it satisfied the inclusion criteria. To do so lesion segmentation was necessary in many cases to assess its growth dynamics. Finally, 82 BMs from 58 patients were included in the study. Of these, 10 were untreated, 16 had received chemotherapy (CT), 23 WBRT or SRS (radiation therapy) and 33 received both treatments. A summary of patient characteristics used for the study is provided in Table 1.

### Imaging and follow-up

The volumetric contrast-enhanced T1-weighted MR imaging sequence used to delineate the BMs and compute their volumes was gradient echo using 3D spoiled gradient-recalled echo or 3D fast-field echo after intravenous administration of a single dose of gadobenate dimeglumine (0.10 mmol/kg) with a 6-to 8-minute delay. MRI studies were performed in the axial or sagittal plane with a 1.0 T ( $n = 5$ ), 1.5 T ( $n = 357$ ) or 3.0 T ( $n = 55$ ) MR imaging unit. Imaging parameters were no gap, slice thickness of 0.52-2.0 mm (mean 1.3 mm), 0.4-1.1 mm (mean 0.5 mm) pixel-spacing and 0.4-2.0 mm spacing between slices (mean 1.0 mm).

Typical time spacing between MRI studies for BM follow-up was about 3 months for the institutions participating in the study. In our dataset, the median time between the first two MRI studies was 3.04 months while for the second it was 2.64 months.

### Tumor segmentation

T1-weighted images were retrospectively analyzed by the same image expert (B.O.-T.) and reviewed by both an image expert with more than 6 years of expertise in tumor segmentation (J.P.-B., D.M.-G. or V.M.P.-G.) and a senior radiologist with 27 years of experience (E.A.). Segmentations were performed by importing the DICOM files into the scientific software package MATLAB (R2019b, The MathWorks, Inc., Natick, MA, USA). Each BM lesion was automatically delineated using a gray-level threshold chosen to identify the CE tumor volume. Segmentations were then corrected manually, slice by slice, using an in-house software as described in [39]. Necrotic tissue was

defined as hypointense tumor regions inside CE tissue. CE and necrotic areas of the lesions were reconstructed, the tumor interfaces rendered in 3D. Tumor volume was computed as the volume within the surface delimiting CE areas.

### Experiments in animal models

The human lung adenocarcinoma brain tropic model H2030-BrM3 (abbreviated as H2030-BrM) [40] was injected into the hearts of nude mice to induce the formation of brain metastasis from systemically disseminated cancer cells. H2030-BrM was cultured in an RPMI1640 medium supplemented with 10% FBS, 2 mM l-glutamine, 100 IU ml<sup>-1</sup> penicillin-streptomycin and 1 mg ml<sup>-1</sup> amphotericin B. Brain colonization and growth of metastasis were traced using non-invasive bioluminescence imaging, as BrM cells express luciferase. On administration of the substrate D-luciferin, bioluminescence generated by cancer cells was measured over the course of the disease. The increase in photon flux values is a well-established correlate of tumor growth in vivo [40]. The experiments were performed in accordance with a protocol approved by the Centro Nacional de Investigaciones Oncológicas (CNIO), the Instituto de Salud Carlos III and the Comunidad de Madrid Institutional Animal Care and Use Committee. Athymic nu/nu mice (Harlan) aged 4-6 weeks were used. Brain colonization assays were performed by the injection into the left ventricle of 100  $\mu$ l of PBS containing 100,000 cancer cells. Mice anaesthetized with isoflurane were injected retro-orbitally with D-luciferin (150 mg kg<sup>-1</sup>) and imaged with an IVIS Xenogen machine (Caliper Life Sciences). A bioluminescence analysis was performed using Living Image software (v.3).

### Cell culture

H2030-BrM was cultured in an RPMI1640 medium supplemented with 10% FBS, 2 mM l-glutamine, 100 IU ml<sup>-1</sup> penicillin-streptomycin and 1 mg ml<sup>-1</sup> amphotericin B.

## MATHEMATICAL AND COMPUTATIONAL METHODS' DETAILS

### VB growth model

Solving (1), with  $b = 0$  leads to

$$\frac{V(t)^{-\beta+1}}{-\beta+1} - \frac{V_0^{-\beta+1}}{-\beta+1} = \alpha(t - t_0). \quad (2)$$

Since there is information about the dynamics at three time points  $(t_0, V_0)$ ,  $(t_1, V_1)$  and  $(t_2, V_2)$  obtained by image segmentation, the two parameters  $\alpha$  and  $\beta$  can be completely determined by evaluating (2) at the times  $t_1, t_2$ , giving

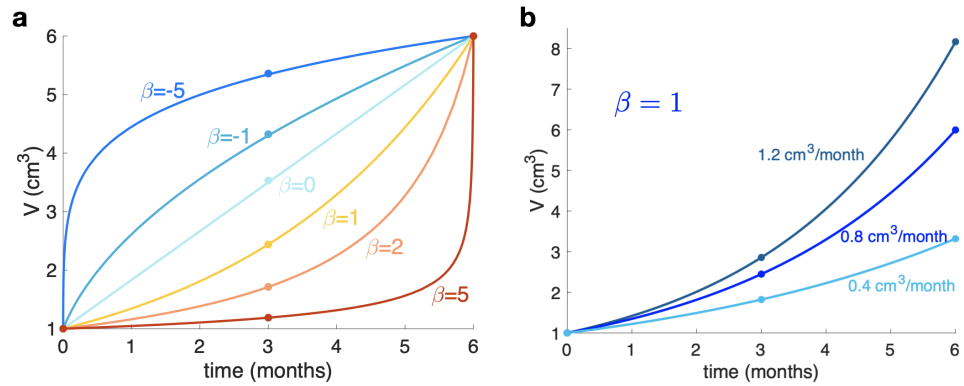

$$\frac{1 - (V_1/V_0)^{-\beta+1}}{1 - (V_2/V_0)^{-\beta+1}} = \frac{t_1 - t_0}{t_2 - t_0}. \quad (3)$$

Eq. (3) is an algebraic equation for  $\beta$  that was solved using the MATLAB function `fzero` (which returns the root of a nonlinear function) for each set of known values  $V_0, V_1, V_2, t_0, t_1, t_2$ . A sensitivity analysis was performed to ensure the robustness of the method for the computation of  $\beta$ .

The growth exponent  $\beta$  provides information on the shape of the tumor growth curve, which cannot be directly interpreted as a growth rate, e.g. the speed of volumetric growth. Figure 6 (a) shows examples fitting the same pair of volumes and time points (initial and final), with different values of  $\beta$  while subfigure (b) shows that any fixed value of  $\beta$  (chosen there arbitrarily as  $\beta = 1$ , i.e. exponential growth), is compatible with different 'growth rates'.

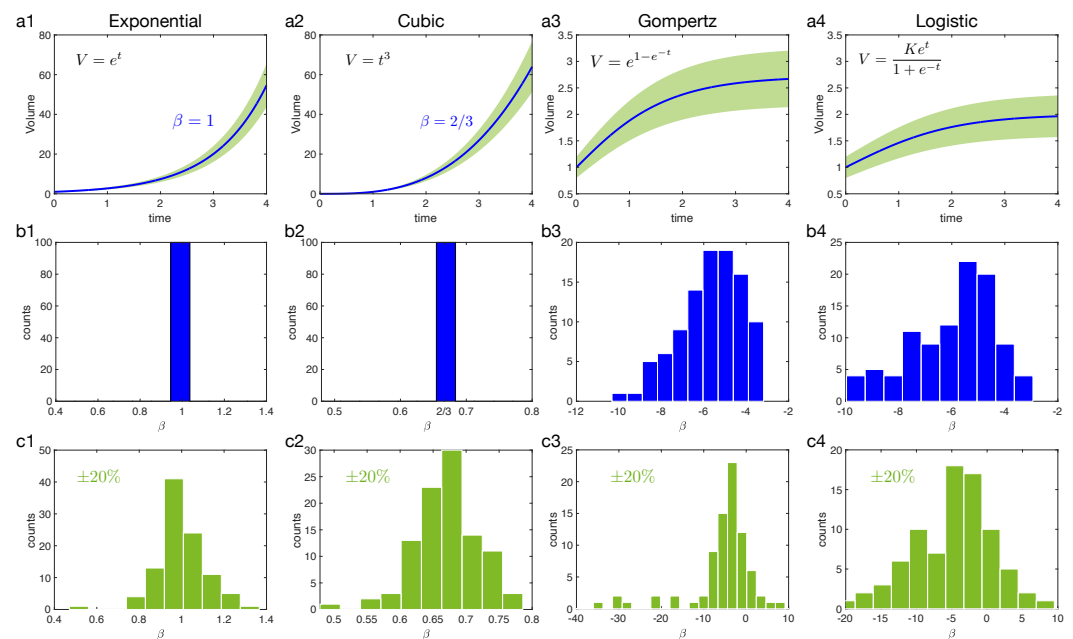

### Sensitivity analysis of the exponents calculation

To ensure the robustness of the growth exponent  $\beta$  computation, some well-known growth curves were studied: exponential, cubic, Gompertz and logistic. For each type of growth, 100 sets of points  $(t_1, t_2, t_3), (V_1, V_2, V_3)$  were randomly chosen and  $\beta$  was computed. For the exponential and cubic growths, the same value was obtained independently to the chosen points (Fig 7.b1-b2). In the case of Gompertz and logistic growths a set of  $\beta$  values was obtained (Fig 7.b3-b4). When adding a

**Figure 6. Interpretation of the growth exponent  $\beta$ .** **a.** Growth behavior for several values of the growth exponent  $\beta$  when fixing initial and final volumes and times. The growth exponent gives information about the shape of the curves. **b.** Growth behavior when fixing  $\beta$  and the initial volume, showing different growth curves with different growth rates but the same exponent.

random error from -20% to +20% to the curves, a wider range of values for  $\beta$  appears, but such values are located around the values obtained without error (Fig 7.c).

**Figure 7. Growth exponent  $\beta$  for different types of growth: exponential, cubic, Gompertz and logistic.** **a.** Growth function in blue with a  $\pm 20\%$  error in green. **b.** Computed  $\beta$  from Eq (1) for the different growth without error. **c.** Computed  $\beta$  when a random error is taken into account.

### Longitudinal growth analysis: individual growth exponents for mice

In animals, more than three volumetric points were available and a different method was used to calculate the growth exponent for each mouse. Measurements at 7, 14, 18, 21, 25 and 28 days were usable from 24 mice, however at 25 and 28 days, the measured volume was close to the total brain volume and it was assumed that growth would be affected by limitations of space. Thus, to avoid confounding effects coming from mechanical constraints, the latter two time points were excluded

from the analysis. A discretization of Eq. (1) was performed, and taking logarithms on both sides

$$\ln \left( \frac{V_i - V_{i-1}}{t_i - t_{i-1}} \right) = \ln \alpha + \beta \ln V_i, \quad (4)$$

the slope of the straight line that best fits all the points for each mouse corresponds to the growth exponent  $\beta$ . Four mice were excluded because of volume decrease, leading to the use of 20 mice for  $\beta$  computation.

### Sensitivity to small changes in volume when computing beta

In order to test the sensitivity to little fluctuations in the data, a random error smaller or equal to  $\pm 5\%$  was added to each volume. For each BM, the procedure was carried out 200 times in order to compute  $\beta^*$  for each set of random errors. It was imposed that the average of the 200 calculated  $\beta^*$  have a difference less than 0.5 from the computed  $\beta$  for the measure volumes, that is to say,  $|\beta_{av}^* - \beta| < 0.5$ .

### Longitudinal growth exponents: Group calculations

An iterative method was used to automatically compute the optimum  $\beta_*$  that is, the one giving the lowest relative error to the segmented volumes for each group. A sweep was performed on  $\beta' = [0, 3]$  with 300 steps and on  $V'_0 = [0, V_1]$  and  $V'_1 = [V_0, V_2]$ , with 500 steps for each. To each  $\beta'$  and each pair  $(V'_0, V'_1)$  there corresponds a single value of  $V'_2$  from Eq. (3). Then, the sum of relative errors of the three segmented volumes for every BM  $(V_0, V_1, V_2)$  was computed using the formula:

$$\text{Relative error} = \frac{|V'_0 - V_0|}{V_0} + \frac{|V'_1 - V_1|}{V_1} + \frac{|V'_2 - V_2|}{V_2}, \quad (5)$$

the smallest is retained, that is to say, the combination of  $(V'_0, V'_1, V'_2)$  that best fits  $(V_0, V_1, V_2)$ , given each  $\beta'$  (pseudocolor plots in Fig. 3(a).) Finally, the  $\beta_*$  value for which the sum of all errors (Fig. 3(b)) is minimum and therefore corresponds to the best fit for the whole subgroup, is observed.

### Stochastic discrete mesoscopic simulator of BMs longitudinal dynamics and response to treatments

To illustrate how treatment could modulate heterogeneity and influence the  $\beta$  values obtained from BM longitudinal growth data, as well as to provide an *in silico* testbed capable of simulating the growth and evolution of BMs, an adapted version of the mesoscopic model developed in [16] was used. The mesoscopic model is a discrete stochastic simulator of tumor growth, that features clonal populations as the basic agent, instead of individual cells. The spatial domain is divided into voxels, a 3D generalization of a bi-dimensional compartment (commonly used in medical imaging). Each voxel has a given carrying capacity  $K$ , so it can harbor as much as  $K$  cells, that may belong to different clonal populations. It is assumed that cells belonging to the same clonal population and exposed to the same stimuli (microenvironment, surrounding cell density, nutrient/oxygen availability) will behave in the same way. Therefore, instead of assessing cell-by-cell the outcome of any dichotomous success/failure process that an individual cell may perform (such as division or death), the number of cells in each clonal population that succeed in performing such processes is assessed in a single step.

If the outcome of each individual process  $i$  performed by a cell is considered as a random variable following a Bernoulli distribution  $X_i \sim \text{Bernoulli}(P_i)$ , with a probability  $P_i$  associated to that process, then the joint outcome of an entire clonal population of  $N$  identical cells performing such process can be considered as a random variable following a binomial distribution  $X'_i \sim \text{B}(N, P_i)$ . In this way, by knowing the number of cells  $N$  attempting to perform a process  $i$ , and the probability  $P_i$  of successfully performing that process, updating the number of cells in a clonal population is done by sampling the binomial distribution associated with that process.

<b>Spatial and time domain parameters</b>		
Time step length ( $\Delta t$ )	4	hours
Number of voxels per dimension	80	
Voxel size	1	mm
Voxel volume	1	mm <sup>3</sup>
Carrying capacity ( $K$ )	$2 \cdot 10^5$	mm <sup>3</sup>
<b>Initial and final conditions for simulation</b>		
Initial cell number	10	
Limit volume of virtual BM	10	cm <sup>3</sup>
<b>Characteristic rates of each cellular process</b>		
Division rate	0.36	days <sup>-1</sup>
Death rate	0.144	days <sup>-1</sup>
Migration speed	2.88	mm <sup>2</sup> days <sup>-1</sup>
<b>Advantage coefficients</b>		
Advantage in division ( $v_{div}$ )	0.2-0.9	a.d.
Advantage in migration ( $v_{mig}$ )	0.2-0.95	a.d.

**Table 2.** Summary of the most relevant parameters used for simulations of the BM mesoscopic model.

The processes considered in this version of the model are division, death and migration. Note that mutations or phenotypic transitions are disregarded, as cells are not allowed to change from a given population to another. This assumption is grounded in the short time scale of evolution of BMs. At each time step, the cell number in each voxel is updated in a synchronous way (using swapping matrices) by random sampling the binomial distributions corresponding to each process, voxel and clonal population. The probabilities associated with these binomial distributions were defined in the same way as in the original work [16]. The version of the model used in this paper is adapted to simulate BMs. It considers only two clonal populations, with different traits and characteristic rates. The rates of division, death and migration were fitted (using ABC rejection algorithm [41]) to mimic the lifespan and volume dynamics of an actual BM.

One of these clonal populations is more aggressive than the other; this is implemented by faster division and migration rates. Namely, the advantage associated with the division process will be  $v_{div} \in (0, 1]$ , while the advantage associated with the migration process will be  $v_{mig} \in (0, 1]$ . These coefficients represent the ratio between the characteristic time in which the aggressive cells carry out the considered process, versus the characteristic time of the other cell type. Hence, the lower their value, the greater the advantage associated with the aggressive population. The range of parameter values used in the model to perform simulations can be seen in Table 2. A cohort of 720 simulations was produced for the parameter exploration performed in Fig. 5.

The adapted version of the mesoscopic model for BMs was coded in Julia (v. 1.1.1). Data processing and visualization of simulation files was performed in Matlab (v. 2018b).

## QUANTIFICATION AND STATISTICAL ANALYSIS

### Statistical analyses

Statistical analyses were performed using the MATLAB software, and also SPSS (Statistical package for the Social Sciences, v24.00 IBM) software. The normality of the variables was assessed via the Kolmogorov-Smirnov test. The Kruskal-Wallis test was conducted with adjustment for multiple comparisons, to determine statistically significant differences for non-parametric data (the scaling law growth factor,  $\beta$ ). P-values smaller than 0.05 were considered to be statistically significant.
