#### ABSTRACT

SARS-CoV-2 virus genomes are currently being sequenced at an unprecedented pace. The choice of viral sequences used in genetic and epidemiological analysis is important as it can induce biases that detract from the value of these rich datasets. This raises questions about how a set of sequences should be chosen for analysis, and which epidemiological parameters derived from genomic data are sensitive or robust to changes in sampling. We provide initial insights on these largely understudied problems using SARS-CoV-2 genomic sequences from Hong Kong and the Amazonas State, Brazil. We consider sampling schemes that select sequences uniformly, in proportion or reciprocally with case incidence and which simply use all available sequences (unsampled). We apply Birth-Death Skyline and Skygrowth methods to estimate the time-varying reproduction number  $(R_t)$  and growth rate  $(r_t)$  under these strategies as well as related  $R_0$  and date of origin parameters. We compare these to estimates from case data derived from *EpiFilter*, which we use as a reference for assessing bias. We find that both  $R_t$  and  $r_t$  are sensitive to changes in sampling whilst  $R_0$  and the date of origin are relatively robust. Moreover, we find that the unsampled datasets, which reflect an opportunistic sampling scheme, engender the most biased  $R_t$  and  $r_t$  estimates for both our Hong Kong and Amazonas case studies. We highlight that sampling strategy choices may be an influential yet neglected component of sequencing analysis pipelines. More targeted attempts at genomic surveillance and epidemic analyses, particularly in resource-poor settings with limited sequencing capabilities, are necessary to maximise the informativeness of virus genomic datasets.

#### INTRODUCTION

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is an enveloped singlestranded zoonotic RNA virus belonging to the *Betacoronavirus* genus and *Coronaviridae* family<sup>1</sup>. It was first identified in late 2019 in a live food market in Wuhan City, Hubei Province, China<sup>2</sup>. Within a month, SARS-CoV-2 had disseminated globally through sustained human-to-human transmission. It was declared a public health emergency of international concern on the 30th of January 2020 by the World Health Organisation<sup>3</sup>. Those infected with SARS-CoV-2 have phenotypically diverse symptoms ranging from mild fever to multiple organ dysfunction syndromes and death<sup>4</sup>.

Despite the implementation of non-pharmaceutical interventions (NPIs) by many countries to control their epidemics, to date over 418 million SARS-CoV-2 cases and 5.8 million deaths have been reported worldwide<sup>5</sup>. These NPIs can vary within and between countries and include restrictions on international and local travel, school closures, social distancing measures and the isolation of infected individuals and their contacts<sup>6</sup>. The key aim of NPIs is to reduce epidemic transmission, often measured by epidemiological parameters such as the time-varying effective reproduction number ( $R_t$  at time t) and growth rate ( $r_t$ ), which both provide updating measures of the rate of spread of a pathogen (see Supplementary Table 1 for detailed definitions)<sup>7,8</sup>.

However, there is currently great difficulty in estimating and comparing epidemiological parameters derived from case and death data globally due to disparities in molecular diagnostic surveillance and notification systems between countries. Further, even if data are directly comparable, the choice of epidemiological parameter can implicitly shape insights into how NPIs influence transmission potential<sup>9,10</sup>. As such, there is a need to supplement traditional estimates with information derived from alternative data sources, such as genomic data<sup>11</sup>, to gain improved and more robust insights into viral transmission dynamics<sup>12,13</sup>.

Phylodynamic analysis of virus genome sequences have increasingly been used for studying emerging infectious diseases, as seen during the current SARS-CoV-2 pandemic<sup>14–17</sup>, recent Ebola virus epidemics in Western Africa<sup>18</sup> and the Zika epidemic in Brazil and the Americas<sup>19,20</sup>. Transmissibility parameters such as the basic reproduction number ( $R_0$ ),  $R_t$  and  $r_t$  can be directly inferred from genomic sequencing data or from epidemiological data, while

other epidemiological parameters such as the date of origin of a given viral variant or lineage can only be estimated from genomic data. This is of particular importance for variants of concern (VOC), genetic variants with evidence of increased transmissibility, more severe disease, and/or immune evasion. VOC are typically detected through virus genome sequencing and only limited inferences can be made through epidemiological data alone<sup>21</sup>.

Currently, SARS-CoV-2 virus genomes from COVID-19 cases are being sequenced at an unprecedented pace providing a wealth of virus genomic datasets<sup>22</sup>. There are currently over 8.4 million genomic sequences available on GISAID, an open-source repository for influenza and SARS-CoV-2 genomic sequences<sup>23</sup>. These rich datasets can be used to provide an independent perspective on pathogen dynamics and can help validate or challenge parameters derived from epidemiological data. Specifically, the genomic data can potentially overcome some of the limitations and biases that can result from using epidemiological data alone. For example, genomic data are less susceptible to changes at the government level such as alterations to the definition of a confirmed case and changes to notification systems<sup>24,25</sup>. Inferences from virus genomic data improve our understanding of underlying epidemic spread and can facilitate better-informed infection control decisions<sup>26</sup>. However, these advantages are not straightforward to realise. The added value of genomic data depends on two related variables: sampling strategy and computational complexity.

The most popular approaches used to investigate changes in virus population dynamics include the Bayesian Skyline Plot<sup>27</sup> and Skygrid<sup>28</sup> models and the Birth-Death Skyline (BDSKY)<sup>29</sup>. These integrate Markov Chain Monte Carlo (MCMC) procedures and often converge slowly on large datasets<sup>30</sup>. As such, currently available SARS-CoV-2 datasets containing thousands of sequences become computationally impractical to analyse and sub-sampling is necessary. Although previous studies have examined how sampling choices might influence phylodynamic inferences<sup>30–34</sup>, this remains a neglected area of study<sup>35</sup>, particularly concerning SARS-CoV-2 for which sequencing efforts have been unprecedented <sup>36</sup>. To our knowledge, there are no published studies concerning SARS-CoV-2 which explore the effect that sampling strategies have on the phylodynamic reconstruction of key transmission parameters. Incorrectly implementing a sampling scheme or ignoring its importance can mislead inferences and introduce biases<sup>30,37</sup>.

This raises the important question that motivates our analysis: how should sequences be selected for phylodynamic analysis and which parameters are sensitive or robust to changes in different sampling schemes. Here we explore how diverse sampling strategies in genomic sequencing may affect the estimation of key epidemiological parameters. We estimate  $R_0$ ,  $R_t$ , and  $r_t$  from genomic sequencing data under different sampling strategies from a location with higher genomic coverage represented by Hong Kong, and a location with lower genomic coverage represented by the Amazonas region, Brazil. We then compare our estimates against those derived from reference case data. By benchmarking genomic inferences against those from case data we can better understand the impact that sampling strategies may have on phylodynamic inference, bolster confidence in estimates of genomic-specific parameters such as the origin time and improve the interpretation of estimates from areas with heterogeneous genomic coverage.

## METHODS

# Empirical Estimation of the Reproduction Number, Time-varying Effective Reproduction Number, and Growth Rate

#### Epidemiological Datasets

Two sources of data from the Amazonas region, Brazil and one source of data from Hong Kong were used to calculate empirical epidemiological parameters. For the Amazonas region, case data from the SIVEP-Gripe (Sistema de Informação de Vigilância Epidemiológica da Gripe) SARI (severe acute respiratory infections) database from the 30<sup>th</sup> of November 2020 up to 7<sup>th</sup> of February 2021 were used. Here we were interested in cases caused by the P.1/Gamma VOC first detected in Manaus, the number of P.1 cases was calculated by using the proportion of P.1/Gamma viral sequences uploaded to GISAID within each week (Supplementary Figure 1). For Hong Kong, all case data were extracted from the Centre of Health Protection, Department of Health, the Government of the Hong Kong Special Administrative region up to the 7<sup>th</sup> of May 2020. Due to lags in the development of detectable viral loads, symptom onset and subsequent testing<sup>38</sup>; the date on which each case was recorded was left shifted by 5 days within our models<sup>39</sup> to account for these delays in both datasets.

#### Basic Reproduction Number

The  $R_0$  parameter was estimated using a time series of confirmed SARS-CoV-2 cases from both Hong Kong and the Amazonas region. To avoid the impact of NPIs, only data up to the banning of mass gathering in Hong Kong (27<sup>th</sup> March 2020) and until the imposition of strict restrictions in the Amazonas region (12<sup>th</sup> January 2021) were used. Weekly counts of confirmed cases were modelled using maximum likelihood methods. The weekly case counts were assumed to be Poisson distributed and were fitted to a closed Susceptible-Exposed-Infectious-Recovered (SEIR) model (Equation 1) by maximising the likelihood of observing the data given the model parameters (Table 1). Subsequently, the log-likelihood was used to calculate the  $R_0$  by fitting  $\beta$ , the effective contact rate.

Equation 1:

$$\lambda = \frac{\beta I}{N}$$
$$\frac{dS}{dt} = -\lambda S$$
$$\frac{dE}{dt} = \lambda S - \gamma E$$
$$\frac{dI}{dt} = \gamma E - \sigma I$$
$$\frac{dR}{dt} = \sigma I$$

To generate approximate 95% confidence intervals (CIs) for  $R_0$ , non-parametric bootstrapping was used with 1000 iterations.

<b>Table 1</b> : This shows the parameter estimates used	within the deterministic SEIR model.
--	--------------------------------------

Parameter	Description	Value (source)
$R_0 = \beta \alpha$	Basic Reproduction Number	Estimated
N	Population of Hong Kong	7,481,800 persons <sup>40</sup>
	Population of Amazonas Region	4,207,714 persons <sup>41</sup>
β	Effective Contact Rate	Estimated
α	Infectious Period	0.07 day <sup>-1 42</sup>
λ	Force of Infection	Estimated
γ	Progression from E to I	5.26 day <sup>-1 43</sup>
δ	Progression from I to R	14.3 day <sup>-1 42</sup>
S	Estimated number of Susceptibles	Estimated
Е	Estimated number of Exposed	Estimated
Ι	Number of Infected	Weekly case counts
R	Estimated number of Recovered	Estimated

#### *Time-varying Effective Reproduction Number*

To estimate  $R_t$  from case line list data the *EpiFilter* method<sup>44</sup> was used. *EpiFilter* describes transmission using a renewal model; a general and popular framework that can be applied to infer the dynamics of numerous infectious diseases from case incidence<sup>45</sup>. This model describes how the number of new cases (incidence) at time *t* depends on  $R_t$  at that specified time point and the past incidence, which is summarised by the cumulative number of cases up to each time point weighted by the generation time distribution, which we assume to be known. *Epifilter* integrates both Bayesian forward and backward recursive smoothing. This improves  $R_t$  estimates by leveraging the benefits of two of the most popular  $R_t$  estimation approaches: *EpiEstim* <sup>46</sup> and the Wallinga-Teunis method<sup>47</sup>. *EpiFilter* minimises the mean squared error in estimation and reduces dependence on prior assumptions, making it a suitable candidate for deriving reference estimates. We use these to benchmark estimates independently obtained from genomic data. We assume the generation time distribution is well approximated by the serial interval (SI) distribution<sup>46</sup>, which describes the times between symptom onsets between an infector–infectee pair.

#### Growth Rate

After  $R_t$  has been inferred, the Wallinga-Lipsitch equation for a gamma distributed generation time distribution (Equation 2) was used to estimate the exponential epidemic  $r_t^{48}$ . The SI for Hong Kong was derived from a systematic review and meta-analysis<sup>49</sup> and a study exploring SI in Brazil was used for the Amazonas datasets<sup>50</sup>. The SI was assumed to be gamma distributed. The gamma distribution is represented by gamma ( $\varepsilon$ ,  $\gamma$ ) with  $\varepsilon$  and  $\gamma$  being the shape and scale parameters respectively.

Equation 2:

$$r_t = \varepsilon (R_t^{\left(\frac{1}{\gamma}\right)} - 1)$$

#### SARS-CoV-2 Brazilian Gamma VOC and Hong Kong datasets

All high-quality, complete SARS-CoV-2 genomes were downloaded from GISAID<sup>23</sup> for Hong Kong (up to 7<sup>th</sup> May 2020) and the Amazonas state, Brazil (from 30th November 2020 up to 7<sup>th</sup> February 2021). Using the Accession ID of each sequence, all sequences were screened and only sequences previously analysed and published in PubMed, MedRxiv,

BioRxiv, virological or Preprint repositories were selected for subsequent analysis. For both datasets, sequence alignment was conducted using MAFFTV.7<sup>51</sup>. The first 130 base pairs (bp) and last 50 bps of the aligned sequences were trimmed to remove potential sequencing artefacts in line with the Nextstrain protocol<sup>52</sup>. Both datasets were then processed using the Nextclade pipeline for quality control (https://clades.nextstrain.org/). Briefly, the Nextclade pipeline examines the completeness, divergence, and ambiguity of bases in each genetic sequence. Only sequences deemed 'good' by the Nextclade pipeline were selected for. Subsequently, all sequences were screened for identity and in the case of identical sequences, for those with the same location, collection date, only one such isolate was used. Moreover, PANGO lineage classification was conducted using the Pangolin<sup>22</sup> software tool (<u>http://pangolin.cog-uk.io</u>) on sequences from the Amazonas region and only those with the designated P.1/Gamma lineage were selected for (Supplementary Figure 1).

#### Maximum Likelihood tree reconstruction

Maximum likelihood phylogenetic trees were reconstructed using IQTREE2<sup>53</sup> for both datasets. A TIM2 model of nucleotide substitution with empirical base frequencies and a proportion of invariant sites was used as selected for by the ModelFinder application<sup>54</sup> for the Hong Kong dataset. For the Brazilian dataset, a TN model of nucleotide substitution<sup>55</sup> with empirical base frequencies was selected for. To assess branch support, the approximate likelihood-ratio test based on the Shimodaira–Hasegawa-like procedure with 1,000 replicates<sup>56</sup>, was used.

#### **Root-to-tip regression**

To explore the temporal structure of both the Brazilian and Hong Kong dataset, TempEst v.1.5.3<sup>57</sup> was used to regress the root-to-tip genetic distances against sampling dates (yyyy-mm-dd). The 'best-fitting' root for the phylogeny was found by maximising the R<sup>2</sup> value of the root-to-tip regression (Supplementary Figure 2). Several sequences showed incongruent genetic diversity and were discarded from subsequent analyses. This resulted in a final dataset of N = 117 Hong Kong sequences and N = 196 Brazilian sequences. The gradient of the slopes (clock rates) provided by TempEst were used to inform the clock prior in the phylodynamic analysis.

#### Subsampling for analysis

Four retrospective sampling schemes were used to select a subsample of Amazonas and Hong Kong sequences. Each sampling period was broken up into weeks with each week being used as an interval according to a temporal sampling scheme (without replacement). This temporal sampling scheme was based on the number of reported cases of SARS-CoV-2. The temporal sampling schemes that we explored were:

- Uniform sampling: All weeks have equal probability.
- **Proportional sampling**: Weeks are chosen with a probability proportional to the value of the number of cases in each epi-week.
- **Reciprocal-proportional sampling:** Weeks are chosen with a probability proportional to the reciprocal of the number of cases in each epi-week.
- No sampling strategy applied: All sequences were included without a sampling strategy applied (equivalent to opportunistic sampling).

These sampling schemes were inspired by those recommended by the WHO for practical use in different settings and scenarios<sup>58</sup>. Proportional sampling is equivalent to representative sampling, uniform sampling is equivalent to fixed sampling whilst the unsampled data includes all sampling strategies. Reciprocal-proportional sampling is not commonly used in practice as was used as a control within this study.

#### **Bayesian Evolutionary Analysis**

Date molecular clock phylogenies were inferred for all sampling strategies applied to the Amazonas and Hong Kong dataset using BEAST v1.10.4<sup>59</sup> with BEAGLE library v3.1.0<sup>60</sup> for accelerated likelihood evaluation. For both the Amazonas and Hong Kong datasets, a HKY substitution model with gamma-distributed rate variation among sites and four rate categories was used to account for among-site rate variation<sup>61</sup>. A strict clock molecular clock model was chosen. Both the Amazonas and Hong Kong dataset were analysed under a flexible non-parametric skygrid tree prior<sup>62</sup>. Four independent MCMC chains were run for both datasets. For the Amazonas dataset, each MCMC chain consisted of 250,000,000 steps with sampling every 50,000 steps. Meanwhile, for the Hong Kong dataset, each MCMC chain consisted of 200,000,000 steps with sampling every 40,000 steps. For both datasets, the four independent MCMC runs were combined using LogCombiner v1.10.4<sup>59</sup>. Subsequently, 10% of all trees were discarded as burn in, and the effective sample size of parameter estimates were

evaluated using TRACER v1.7.2<sup>63</sup>. An effective sample size of over 200 was obtained for all parameters. Maximum clade credibility (MCC) trees were summarised using Tree Annotator<sup>59</sup>.

#### **Phylodynamic Reconstruction**

*Estimation of the Basic and Time-varying Effective Reproduction Numbers* The Bayesian birth-death skyline (BDSKY) model<sup>29</sup> implemented within BEAST 2 v2.6.5<sup>64</sup> was applied to estimate the time-varying transmissibility parameter  $R_t$  (Table 2). A HKY substitution model with a gamma-distributed rate variation among sites and four rate categories<sup>61</sup> was used alongside a strict molecular clock model. The selected number of intervals for both datasets was 5, representing  $R_t$  changing every 2.5 weeks for the Hong Kong datasets and every 2 weeks for the Brazilian datasets, with equidistant intervals per step. An exponential distribution was used with a mean of  $36.5y^{-1}$  for the rate of becoming infectious, assuming a mean duration of infection of 10 days<sup>15</sup>. A uniform distribution prior was used for the sampling proportion, which models changes in case ascertainment. Four independent MCMC chains were run for 50 million MCMC steps with sampling every 5000 steps for each dataset. These MCMC runs were combined using LogCombiner v2.6.5.<sup>64</sup> and the effective sample size of parameter estimates evaluated using TRACER v1.7.2<sup>63</sup>. We obtained an effective sample size above 200 for all parameters (indicating convergence) and plotted all results using the bdskytools R package (<u>https://github.com/laduplessis/bdskytools</u>).

Parameter	Dataset	Value or prior	Rationale/Assumption
Clock rate	Brazil	4.0x10 <sup>-4</sup> (subs/site/year)	Informed by root-to-tip
	Hong Kong	1.0x10 <sup>-4</sup> (subs/site/year)	regression
Death rate	Brazil and Hong Kong	36.5 y <sup>-1</sup>	The period between infection and becoming uninfectious assumed an exponential distribution with a mean of 10 days <sup>15</sup>
Reproduction number	Brazil and Hong Kong	Lognormal (0.8, 0.5)	Median 2.2, 95% IQR 0.8 to 5.9
Time of origin	Brazil	Lognormal (-1.50, 0.4) y before present	Median 4 <sup>th</sup> December 2020, 95% IQR 25 <sup>th</sup> September 2020 to 12 <sup>th</sup> January, 2021
	Hong Kong	Lognormal (-1.75, 0.4) y before present	Median 18 <sup>th</sup> January 2020, 95% IQR 17 <sup>th</sup> November 2019 to 15 <sup>th</sup> February 2020
Sampling proportion	Brazil	Uniform (0, 0.024)	196 sequences from 8246 suspected P.1 cases as of 7 <sup>th</sup> February, 2021
	Hong Kong	Uniform (0, 0.116)	117 sequences from 1012 confirmed cases as of 7 <sup>th</sup> May, 2020

### **Table 2:** Values and priors for the parameters of the BDSKY model

#### Estimation of Growth Rates

For each dataset, a scaled proxy for  $r_t$  was obtained from the *skygrowth* method<sup>65</sup> within R. *Skygrowth* uses a non-parametric Bayesian approach to apply a first-order autoregressive stochastic process on the growth rate of the effective population size. The MCMC chains were run for one million iterations for each dataset on their MCC tree with an Exponential (10<sup>-5</sup>) prior on the smoothing parameter. The *skygrowth* model was parameterised assuming that the effective population size of SARS-COV-2 could change every two weeks. To facilitate a comparison of the scaled proxy for  $r_t$  estimated by *skygrowth* and exponential  $r_t$ estimated by *EpiFilter*, the  $r_t$  estimated by the *skygrowth* method was rescaled to the exponential growth rate. This was achieved by adding a gamma rate variable to the scaled proxy for  $r_t$ , which assumed a mean duration of infection of 10 days<sup>15</sup>, to calculate  $R_t$ . Subsequently, the Wallinga-Lipsitch equation (Equation 2) was used to convert  $R_t$  into the exponential growth rate<sup>48</sup>.

#### **Comparing Parameter Estimates from Genetic and Epidemiological Data**

To compare estimates derived from epidemiological and genetic data the Jensen-Shannon divergence  $(D_{JS})^{66}$ , which measures the similarity between two probability mass functions (PMFs), was applied. The  $D_{JS}$  offers a formal information theoretic evaluation of distributions and is more robust than comparing Bayesian credible intervals (BCIs) since it considers both the shape and spread of a given distribution. The  $D_{JS}$  is essentially a symmetric and smoothed version of the Kullback-Leibler divergence ( $D_{KL}$ ) and is commonly used in the fields of machine learning and bioinformatics. The  $D_{KL}$  between two PMFs, P and Q, is defined in Equation 3 below<sup>67</sup>.

Equation 3:

$$D_{KL}(P||M) = \sum_{x} P(x) \log\left(\frac{P(x)}{Q(x)}\right)$$

To calculate the PMF for each epidemiological parameter, the cumulative probability density function (PDF) was extracted for each model, converted to a probability density function (PDF), and a discretisation procedure then applied  $\tau$  represents the PDF and is discretized via Equation 4, where s = 0.05, 0.01....and  $\tau(v)$  is the cumulative probability density of  $\tau$  and i is the incidence.

Equation 4:

$$\tau_{Rt,rt,R0} = \int_{s-0.025}^{s+0.025} \tau(v)\tau dv$$

The Jensen-Shannon distance (JSD) metric quantifies the  $D_{JS}$  by taking the square-root of the total  $D_{JS}$  and is the metric that we used to compare parameter estimations from differing sampling strategies. The JSD can be calculated using Equation 5 with P and Q representing the two probability distributions and  $D_{KL}$  as the KL divergence. A smaller JSD metric indicates that two probability distributions (P and Q) are more similar with a Jensen-Shannon distance of 0 indicating equivalence of the two distributions. The mean JSD was taken over all intervals for the BDSKY and *Skygrowth* models to obtain an overall measure of the level of estimated similarity.

Equation 5:

JSD 
$$(P||Q) = \sqrt{\frac{1}{2}D_{KL}(P||M) + \frac{1}{2}D_{KL}(Q||M)}$$
 where  $M = \frac{1}{2}(P+Q)$ 

#### Data availability

#### RESULTS

#### **Sampling Schemes**

#### Hong Kong

Hong Kong reacted rapidly upon learning of the emergence of SARS-CoV-2 in Wuhan, Hubei province, China, by declaring a state of emergency on the 25th of January 2020 and by mobilising intensive surveillance schemes in response to initial cases<sup>68</sup>. This appeared to be successful in controlling the first wave of cases. However, due to imported cases from Europe and North America, a second wave of SARS-CoV-2 infections emerged prompting stricter NPIs such as the closure of borders and restrictions on gatherings<sup>68</sup>. Following these measures, the incidence of SARS-CoV-2 rapidly decreased (Figure 1). Hong Kong has a high sampling intensity with 11.6% of confirmed cases sequenced during our study period. Further, Hong Kong has high quality case data with a high testing rate through effective tracing of close contacts, testing of all asymptomatic arriving travellers and all patients with pneumonia<sup>69</sup>.

**Figure 1.** Confirmed SARS-CoV-2 cases from Hong Kong until 7<sup>th</sup> of May 2020. The dashed lines represent policy change-times<sup>68</sup>.

The number of cases within Hong Kong for each week was used to inform the sampling schemes used within this study. This resulted in the unsampled scheme having N = 117 sequences, the proportional sampling scheme having N = 54 sequences, the uniform sampling scheme having N = 79 and the reciprocal-proportional sampling scheme having N = 84 sequences (Supplementary Figure 3).

#### Amazonas

The Amazonas state of Brazil had its first laboratory confirmed case of SARS-CoV-2 in March 2020 in a traveller returning from Europe<sup>70</sup>. After a first large wave of SARS-CoV-2 infections within the state that peaked in early May 2020 (Figure 2), the epidemic waned, cases dropped, remaining stable until mid-December 2020. The number of cases then started growing exponentially, ushering in a second epidemic wave. This second wave peaked in January 2021 (Figure 2) and coincided with the emergence of a new SARS-CoV-2 VOC, designated P.1/Gamma<sup>14</sup>.

To combat this second wave, the Government of the Amazonas state suspended all nonessential commercial activities on the 23rd of December 2020 (http://www.pge.am.gov.br/legislacao-covid-19/). However, in response to protests, these restrictions were reversed, and cases continued to climb. On the 12th of January, when local transmission of P.1/Gamma was confirmed in Manaus, capital of Amazonas state<sup>71</sup>, NPIs were re-introduced (http://www.pge.am.gov.br/legislacao-covid-19/) which seemed to be successful in reducing the case incidence in the state. However, cases remained comparatively high (Figure 4). Amazonas has a low sampling intensity with 2.4% of suspected P.1/gamma cases sequenced during our study period.

**Figure 2.** Confirmed SARS-CoV-2 cases from Amazonas state, north Brazil until 7<sup>th</sup> of February 2021. The dashed lines represent policy change-times <sup>72</sup>.

The number of cases within the Amazonas region informed the sampling schemes used within this study. This resulted in the unsampled scheme having N = 196 sequences, the proportional sampling scheme having N = 168 sequences, the uniform sampling scheme having N = 150 and the reciprocal-proportional sampling scheme having N = 67 sequences (Supplementary Figure 4).

#### **Root-to-tip Regression**

The correlation ( $\mathbb{R}^2$ ) between genetic divergence and sampling dates for the Hong Kong datasets ranged between 0.36 and 0.52 and between 0.13 and 0.20 for the Amazonas datasets (Supplementary Figure 2). This implies that the Hong Kong datasets have a stronger temporal signal. This is likely due to the Hong Kong datasets have a wider sampling interval (106 days) compared to the Amazonas datasets (69 days). A wider sampling interval can lead to a stronger temporal signal<sup>73</sup>. The gradient (rate) of the regression ranged from 1.16x10<sup>-3</sup> to 2.09x10<sup>-3</sup> s/s/y for the Hong Kong datasets and 4.41x10<sup>-4</sup> to 5.30x10<sup>-4</sup> s/s/y for the Amazonas datasets.

#### **Estimation of Evolutionary Parameters**

The mean substitution rate (measured in units of number of substitutions per site per year, s/s/y) and the time to most common recent ancestor (TMRCA) was estimated in BEAST, for both datasets, and the estimation from all sampling schemes was compared.

#### Hong Kong

For Hong Kong, the mean substitution rate per site per year ranged from  $9.16 \times 10^{-4}$  to  $2.09 \times 10^{-3}$  with sampling schemes all having overlapped Bayesian credible intervals (BCIs) (Supplementary table 2; Supplementary Figure 5A). This indicates that the sampling scheme did not have a significant impact on the estimation of the clock rate. Moreover, the clock rate is comparable to estimations from the root-to-tip regression and to early estimations of the mean substitution rate per site per year of SARS-CoV-2 (Duchene et al., 2020).

Molecular clock dating of the Hong Kong dataset indicates that the estimated time of the most common recent ancestor was around December 2020 (Figure 3B; Supplementary Table 2). This is a few weeks before the first confirmed case which was reported on the 18th of January 2021. Once again, all sampling strategies have overlapped BCIs and with the range in means differing by around three weeks, a relatively short time scale, suggesting that the sampling scheme does not significantly impact the estimation of the TMRCA.

#### Brazil

For the P.1 lineage in the Amazonas region, the mean substitution rate ranged from  $4.00 \times 10^{-4}$  to  $5.56 \times 10^{-4}$  s/s/y with all sampling schemes having overlapped BCIs (Figure 3D, Supplementary Table 2; Supplementary Figure 5B). This indicates that sampling strategy does not impact the estimation of the clock rate, supporting findings from the Hong Kong dataset. This also supports estimations from the root-to-tip analysis (Supplementary Figure 2).

Molecular clock dating estimated a TMRCA mean around late October to early November (Figure 3D; Supplementary Table 2). This is around five weeks before the date of the first P.1 case identified in Manaus used in our study. All sampling schemes have overlapping BCI consistent with the conclusion from the Hong Kong data that TMRCA is relatively robust to sampling.

#### **Estimation of Basic Reproduction Number**

We found that Hong Kong had a significantly lower  $R_0$  of 2.17 (95% credible interval (CI) = 1.43 - 2.83) when compared to Amazonas which had a  $R_0$  of 3.67 (95% CI = 2.83 - 4.48). All sampling schemes for both datasets were characterised by similar  $R_0$  values (Figure 3) indicating that the estimation of  $R_0$  is robust to changes in sampling scheme.

**Figure 3**. *R*<sup>0</sup> estimated from BDSKY and TMRCA for Hong Kong and Brazil. Figure 1A and B represent Hong Kong and Figure 1C and D represent the Amazonas.

#### Time-varying Reproduction number and Growth rate

We estimate  $R_t$  and  $r_t$  for local SARS-CoV-2 epidemics in Hong Kong and Amazonas, Brazil. Our main results showing these two parameters and JSD metrics are shown in figures 4-8.

#### Hong Kong

We applied the BDSKY model to estimate the  $R_t$  for each dataset subsampled according to the different sampling strategies (Figure 4). We compared these against the  $R_t$  from case data, derived from *EpiFilter*. Based on the proportional sampling scheme, which had the lowest

JSD (Figure 4E), we initially infer a super-critical  $R_t$  value, with a mean around 2, that appears to fall swiftly in response to the state of emergency and the rapid implementation of NPIs. A steady transmission rate subsequently persisted throughout the following weeks around the critical threshold ( $R_t$  = 1). This period is followed by a sharp increase in  $R_t$ , peaking at a mean value of 2.6. This is likely due to imported cases from North America and Europe<sup>68</sup>. This led to a ban on international travel resulting in a sharp decline in  $R_t$  (Figure 2). However, this decline lasted around a week with the mean  $R_t$  briefly increasing until more stringent NPIs such as the banning of major gatherings were implemented. Following this, the  $R_t$  continued its sharp decline falling below the critical threshold, with transmission becoming sub-critical (Figure 4).

These results were mirrored in the estimation of  $r_t$  (Figure 5) for which the uniform and proportional sampling schemes showed the least divergence (Figure 5E). There was an initial decline in the  $r_t$ , which steadied at a value of ~ 0, indicating that epidemic stabilisation had occurred. This stable period is followed by an increase in  $r_t$  peaking at around a 0.050 d<sup>-1</sup> (Figure 5). In response to NPIs, the  $r_t$  starts to decrease, falling below 0, indicating a receding epidemic. The rate of this decline peaks at around -0.075 d<sup>-1</sup> (Figure 5).

**Figure 5**:  $r_t$  estimated from both the *Skygrowth* and *EpiFilter* methods for Hong Kong. The bold writing represents the sampling scheme used in panels A-D. The light-shaded area represents the 95% Highest Posterior Density Interval with the darker-shaded area presenting where the BDSKY and *Skygrowth* models overlap. The solid line represents the mean  $r_t$  estimate with *Skygrowth* in red and BDSKY in blue. The dashed lines represent policy change-times. The JSD metric is ordered from best to worse in panel E.

#### Brazil

Based on the uniform sampling scheme, which had the lowest JSD (Figure 6E), we initially infer super-critical transmission ( $R_t > 1$ ) with a mean value of 3 (Figure 6). From this point, the  $R_t$  declines, although it remains above the critical threshold ( $R_t = 1$ ) for much of the study period. Sub-critical transmission ( $R_t < 1$ ) was only reached after the re-imposition of NPIs. This implies that initial restrictions, such as the suspension of commercial activities, were likely insufficient for suppressing spread. Only after more stringent restrictions were imposed did  $R_t$  become sub-critical. However, there is no evidence of a sharp decrease in  $R_t$  once restrictions were re-imposed, which may suggest limited effectiveness.

Figure 6: R<sub>t</sub> estimated from both the BDSKY and *EpiFilter* methods forAmazonas, Brazil. The bold writing represents the sampling scheme used in panels A-D. The light-shaded area represents the 95% Highest Posterior Density Interval with the darker-shaded area presenting where the BDSKY and *EpiFilter* models overlap. The solid line represents the mean R<sub>t</sub> estimate with EpiFilter in red and BDSKY in blue. The dashed lines represent policy change-times. The Jensen Shannon Distance is ordered from best to worse in panel E.

Based on the uniform sampling scheme, which had the lowest JSD (Figure 7E) we infer a steady decline in  $r_t$  which matches the pattern seen with the  $R_t$  value (Figure 7). The initial  $r_t$ implied a 0.250 d<sup>-1</sup>. Subsequently, the  $r_t$  falls over the study period.  $r_t$  falls below 0 after the re-imposition of NPIs declining at -0.030 d<sup>-1</sup> by the end of the study period. There is no evidence of any noticeable declines in  $r_t$  when interventions were introduced indicating that they might not have significantly impacted the growth rate of P.1/gamma.

The lightshaded area represents the 95% Highest Posterior Density Interval with the darker-shaded area presenting where the BDSKY and *Skygrowth* models overlap. The solid line represents the mean rt estimate with Skygrowth in red and BDSKY in blue. The dashed lines represent policy change-times. The JSD is ordered from best to worse in panel E.

#### Discussion

In this study, phylodynamic methods have been applied to available SARS-CoV-2 sequences from Hong Kong and the Amazonas region of Brazil to infer their key epidemiological parameters and to compare the impact that various sampling strategies have on the phylodynamic reconstruction of these parameters.

We estimated the basic reproductive number of SARS-CoV-2 in Hong Kong to be 2.17 (95% CI = 1.43-2.83). This supports previous estimates of the initial  $R_0$  in Hong Kong<sup>68,74</sup> which estimates  $R_0$  to be 2.23 (95% CI = 1.47-3.42). For the Amazonas region in Brazil, we estimated the  $R_0$  to be 3.67 (95% CI = 2.83 – 4.48). Whilst the population of Amazonas State may not be fully susceptible to P.1/gamma<sup>14</sup>, this should not affect the comparison among sampling schemes. We found that  $R_0$  is robust to changes in sampling schemes (Figure 3A and C).

For the Hong Kong dataset, the proportional sampling scheme was superior to all other sampling schemes in estimating  $R_t$ . It successfully predicted the initial super-critical  $R_t$ , its decline in response to rapid NPIs, and subsequent increase and decline during the second wave of infections (Figure 4B). This was in comparison to the reciprocal-proportional scheme, which provided the worst (largest) JSD (Figure 4D) and an  $R_t$  estimate that was largely insensitive to NPIs. The proportional sampling scheme, alongside the uniform sampling scheme, best estimated  $r_t$  (Figure 5B and C). In contrast, for the Amazonas dataset, the uniform sampling scheme best estimated the  $R_t$  and  $r_t$  (Figure 6C and Figure 7C). It captured both its initial super-critical  $R_t$  and high  $r_t$  alongside their subsequent decline. Our  $R_t$  estimates are consistent with previous estimates of P.1 in Amazonas state<sup>14</sup>. This contrasted with the unsampled data in which the  $r_t$  increased at the end of the period (Figure 7A). This highlights that unlike  $R_0$ , both  $R_t$  and  $r_t$  are sensitive to changes in sampling and that even related epidemiological parameters like  $R_t$  and  $r_t$  may require different sampling strategies to optimise inferences.

Molecular clock dating of the Hong Kong and Amazonas dataset has revealed that the date of origin is relatively robust to changes in sampling schemes. For Hong Kong, SARS-CoV-2 likely emerged in mid-December 2019 around 5 weeks before the first reported case on the 22<sup>nd</sup> of January 2020<sup>68</sup>. The Amazonas dataset revealed that the date of the common ancestor of the P.1 lineage emerged around late October 2020 to early November, around 5 weeks before the first reported case on the 6<sup>th</sup> of December<sup>14</sup>, with all BCI's overlapping for each

26

sampling strategy. Like the molecular clock dating, we found that the molecular clock rate was robust to changes in sampling strategies in both datasets with all sampling strategies having overlapped BCI's (Supplementary Table 2 and Supplementary Figure 5). For the Hong Kong dataset, its clock rate is comparable to early estimations of the mean substitution rate per site per year of SARS-CoV-2<sup>13</sup>. However, the clock rate estimated for the Brazilian dataset is lower than initial 8.00x10<sup>-4</sup> s/s/y which is used in investigating SARS-CoV-2<sup>75</sup> and that has been used in previous analyses of P.1<sup>76</sup>. This initial estimation of evolutionary rate was estimated from genomic data taken over a short time span at the beginning of the pandemic introducing a time dependency bias. By using a more appropriate clock rate it can improve tree height and rooting resulting in more robust parameter estimations<sup>77</sup>.

Treating sampling times as uninformative has been shown to be inferior to including them as dependent on effective population size and other parameters by several previous studies<sup>30,31,34,78</sup>. Whilst these studies did not consider the estimation of epidemiological parameters, they highlight the potential of systematic biases being introduced into the phylodynamic reconstruction by not using a sampling scheme or by assuming an incorrect model for how sampling schemes introduce information. This was supported by our results as phylodynamic inferences with no sampling strategy applied had the poorest performance for both Hong Kong and the Amazonas region. This implies that sampling has a significant impact on phylodynamic reconstruction, and that exploration of sampling strategies is needed to obtain the most robust parameter estimates.

While our results provide a rigorous underpinning and insight into the dynamics of SARS-CoV-2 and the impact of sampling strategies in the Amazonas region and Hong Kong, there are limitations. The *Skygrowth* and BDSKY models do not explicitly consider imports into their respective regions. This is particularly relevant for Hong Kong as most initial sequences from the region were sequenced from importation events<sup>79</sup> which can introduce error into parameter estimation. However, as the epidemic expanded, more infections were attributable to autochthonous transmission<sup>79</sup>, and the risk of error introduced by importation events decreased. Moreover, while sampling strategies can account for non-random sampling approaches in either the BDSKY or *Skygrowth* models<sup>80</sup>. It is unclear how network-based sampling may affect parameter estimates obtained through these models<sup>81</sup> presenting a key

challenge in molecular and genetic epidemiology. Spatial heterogeneities were also not explored within this work. This represents the next key step in understanding the impact of sampling as spatial sampling schemes would allow the reconstruction of the dispersal dynamics and estimation of epidemic overdispersion (k), a key epidemiological parameter.

Finally, we compared our phylodynamic estimates against epidemiological inferences derived from case data from Hong Kong and Amazonas state, two settings with very different diagnostic capacity. While Hong Kong has high quality case data with a high testing rate through<sup>69</sup>, there is a large underreporting of SARS-CoV-2 cases in the Amazonas state<sup>72,82</sup>. Future epidemiological modelling work is needed to compare parameter estimates obtained from case data, death data and excess death data across different settings.

This work has highlighted the impact and importance that applying temporal sampling strategies can have on phylodynamic reconstruction. Whilst more genomic datasets from a variety of countries and regions with different sampling intensities and proportions are needed to create a more generalisable sampling framework and to dissect any potential cofounders, it has been shown that genomic datasets with no sampling strategy applied can introduce significant uncertainty and biases in the estimation of epidemiological parameters. This finding identifies the need for more targeted attempts at performing genomic surveillance and epidemic analyses particularly in resource-poor settings which have a limited genomic capability.

## **Supplementary Figures and Tables**

Parameter	Definition
Basic reproduction number	Average number of individuals infected by a single infected
$(R_0)$	person in a fully susceptible population
Time-varying or effective reproduction number $(R_t)$	Average number of secondary infections generated per effective primary case at a certain time point and in the presence of susceptible depletion or interventions
Growth rate $(r_t)$	Rate of change of the logarithm of the number of new cases per unit of time
Incubation period	Time between infection and symptom onset
Infectious period	Period in which an infectious host can transmit infectious agents to a susceptible individual
Generation interval	Time between infection events in an infector-infectee pair
Date of origin	Date in which viral variant is thought to have emerged
Serial Interval	Time between symptom onsets in an infector-infectee pair

### **Supplementary Table 1**: Key parameters and definitions for SARS-CoV-2

Supplementary Figure 1: The proportion of P.1 sequences compared to non-P.1 sequences found on GISaid (Shu and McCauley, 2017).

Supplementary Figure 2: Root-to-tip genetic distances to sample collection dates for the SARS-CoV-2 genome datasets used in this study: A-D represents Hong Kong and E-H represent Amazonas State. Plots are based on the maximum likelihood trees rooted by maximising R<sup>2</sup>. The linear regression trend lines are shown to data points, corresponding to the genome sequences (represented with black dots).

**Supplementary Figure 3:** Number of sequences for each week and sampling scheme for Hong Kong dataset.

**Supplementary Figure 4:** Number of sequences for each week and sampling scheme for Amazonas dataset.

Supplementary Table 2: TMRCA and mean substitution rate both with 95% BCI for each sampling strategy for Hong Kong and Amazonas datasets alongside the Jensen-Shannon distance. Full posterior distribution of the TMRCA and substitution rates obtained under the different sampling strategies can be found in Figure 3B and D and Supplementary Figure 5.

Sampling Strategy	Dataset	TMRCA (95% BCI)	Mean Substitution Rate (95% BCI, subs/site/year, s/s/y)
Unsampled	Hong Kong	2 <sup>nd</sup> December 2019 (10 <sup>th</sup> November 2019 – 24 <sup>th</sup> December 2019)	1.12x10 <sup>-3</sup> (9.16x10 <sup>-4</sup> – 1.35x10 <sup>-3</sup> )
Chisampieu	Brazil	30 <sup>th</sup> October 2020 (8 <sup>th</sup> October 2020 – 13 <sup>th</sup> December 2020)	4.58x10 <sup>-4</sup> (3.69x10 <sup>-4</sup> – 5.56x10 <sup>-4</sup> )
Proportional	Hong Kong	24 <sup>th</sup> December 2019 (21 <sup>st</sup> November 2019 – 11 <sup>th</sup> January 2020)	1.39x10 <sup>-3</sup> (9.28x10 <sup>-4</sup> - 2.48x10 <sup>-3</sup> )
	Brazil	30 <sup>th</sup> October 2020 (25 <sup>th</sup> August 2020 – 29 <sup>th</sup> November 2020)	4.60x10 <sup>-4</sup> (3.70x10 <sup>-4</sup> – 5.56x10 <sup>-4</sup> )
Uniform	Hong Kong	13 <sup>th</sup> December 2019 (18 <sup>th</sup> November 2019 – 4 <sup>th</sup> January 2020)	1.64x10 <sup>-3</sup> (1.22x10 <sup>-3</sup> – 2.09x10 <sup>-3</sup> )
