Abstract

Background

The vast majority of residents of high-income countries (>90%) reportedly have high access to safely managed drinking water, the highest level of service under the Sustainable Development Goal (SDG) framework. Owing perhaps to the widely held perception of near universal access to high-quality water services in these countries, the burden of waterborne disease in these contexts is understudied.

Methods

We conducted a systematic review of estimates of the disease burden attributed to drinking water in countries where >90% of the population has access to safely managed drinking water per official SDG monitoring. We searched PubMed, Web of Science, and SCOPUS for articles published before September 10, 2021.

Findings

We identified 24 studies reporting estimates for the disease burden attributable to microbial contaminants. Across these studies, the population-weighted average burden of gastrointestinal illness risks attributed to drinking water was about 3,529 annual cases per 100,000 people. Beyond exposure to infectious agents, we also identified 10 studies reporting disease burden, predominantly, cancer risks, associated with chemical contaminants. Across these studies, the pooled population-weighted average of excess cancer cases attributable to drinking water was 1.8 annual cancer cases per 100,000 people.

Interpretation

These estimates exceed WHO-recommended normative targets for disease burden attributable to drinking water and highlight that there remains important preventable disease burden in these contexts. However, the available literature was scant and limited in geographic scope, disease outcomes, range of microbial and chemical contaminants, and inclusion of subpopulations that could most benefit from water infrastructure investments. These subpopulations include rural,

low-income communities; Indigenous or Aboriginal peoples; and populations marginalized due to discrimination by race, ethnicity, or socioeconomic status. Studies quantifying drinking water-associated disease burden in countries with reportedly high access to safe drinking water, with a focus on specific subpopulations and promoting environmental justice, are needed.

Research in context

Evidence before this study

Although the burden of disease associated with unsafe drinking water in low- and middle-income countries has been subject of much research, there is uncertainty about the magnitude and nature of this disease burden in high-income countries and countries where access to safely managed drinking water is >90%. To assess the magnitude of this burden in countries with high levels of access to high quality water, we conducted a systematic review of estimates of the disease burden attributed to drinking water in countries where >90% of the population has access to safely managed drinking water as defined by the WHO/UNICEF Joint Monitoring Programme for Water Supply, Sanitation and Hygiene (JMP). We searched PubMed, Web of Science, and SCOPUS for relevant articles published before September 10, 2021. We searched for articles including "burden of disease" OR "disease burden" OR "gastrointestinal illness" anywhere in the text. From among these articles, we selected those with the terms "drinking water" OR "tap water." From this reduced set, we selected articles reporting on countries with >90% safe water access and including estimates of cases, hospitalizations, or deaths related to drinking water contamination. Additional articles were identified from consultations with subject-matter experts. Only articles in English were recovered, which may have biased our results towards specific countries.

Added value of this study

To our knowledge, this is the first global review of its kind to identify burden of waterborne disease estimates associated with microbiological contaminants as well as chemical contaminants found in drinking water, specifically in countries with reportedly high access (>90%) to safely managed drinking water. Despite the perception that high quality water is ubiquitous in these countries, we found that burden estimates in these countries exceeded WHO-recommended targets for disease burden attributable to unsafe drinking water. This review also highlighted the gaps in our understanding of waterborne disease burden across and within countries where access to high quality drinking water is common.

Implications of all the available evidence

Even though the levels of access to safely managed drinking water are high in many high-income and some middle-income countries, there remains a potentially important preventable disease burden in these high-income countries. Our review suggests that further burden research expanding the scope of contaminants, disease outcomes, geographic area, and vulnerable subpopulations within countries is necessary. Currently, available evidence is insufficient to support rational decision-making and to prioritize public investment to protect the health of marginalized communities. These groups include rural, low-income communities; Indigenous or Aboriginal peoples; and populations marginalized due to discrimination by race, ethnicity, or socioeconomic status.

1. Introduction

Since 1990, the WHO/UNICEF Joint Monitoring Programme for Water Supply, Sanitation and Hygiene (JMP) has reported on access to safe drinking water worldwide. WHO/UNICEF defines drinking water as safely managed if it comes from an improved source that is accessible on premises, available when needed, and free of fecal and priority chemical contamination. JMP data indicate that in countries classified by the World Bank as low- or middle-income (per-capita incomes <\$12,696), major gaps in safe water access remain, with 46.6% of the population unserved as of 2017.¹ These gaps manifest in high disease burdens. Recent estimates attribute unsafe drinking water as the cause of 36% of the 1.4 million annual diarrheal deaths worldwide in low- and middle-income countries (LMICs).²

In contrast to the situation in LMICs, JMP data suggest that in high-income countries (HICs), most of the population has safe water, with an average of <3% lacking access as of 2017 (**Table S1**). However, the JMP's national-scale data and data collection methods can mask local-scale inequities in HICs, such as in rural, low-income, and minority communities.^{3,4} They can also lead to a misconception that water problems of HICs have been solved, resulting in underinvestment in maintaining and extending water infrastructure. For example, a recent commentary on infrastructure investment needs in the United States (US) noted "Americans expect the water flowing from their kitchen faucets to be clean and safe," yet "water infrastructure is particularly vulnerable to neglect" because it "is buried underground or removed from public view, and is thus easily ignored."⁵

Improved understanding of the burden of waterborne disease in countries with high access to safely managed drinking water (most high-income and some middle-income countries) can help identify remaining contamination issues and gaps for water infrastructure investments. To support such efforts, we conducted a systematic review to identify studies estimating the disease burden attributed to contaminated drinking water in the 64 countries/territories with >90% safe water access per the JMP definition (Table S1, Figure S1). Among these countries/territories, 54 are classified as high-income; 7 are upper middle income (per-capita incomes between \$4,096 and \$12,695), and 3 are lower middle income (per-capita incomes between \$1,046 and \$4,095). The review was intended to:

- 1. identify available estimates of waterborne disease burden in countries with high access to safely managed drinking water;
- 2. evaluate and compare methods to quantify disease burden; and
- 3. identify gaps in available disease burden estimates.

2. Methods

2.1 Review Method

We followed the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) method.⁶ Table S2 documents study adherence to PRISMA guidelines.

2.2 Search Strategy

We searched PubMed, Web of Science, and SCOPUS for relevant articles published before September 10, 2021. First, we searched for articles including "burden of disease" OR "disease

burden" OR "gastrointestinal illness" anywhere in the text. From among these articles, we selected those with the terms "drinking water" OR "tap water." From this reduced set, we selected articles reporting on countries with >90% safe water access (Table S1, Figure S1). Last, 14 additional articles were identified from consultations with subject-matter experts. After removal of duplicates, 528 articles remained for screening (Figure S2). Details on the development of search criteria can be found in Text S1.

2.3 Selection Criteria

Articles in English meeting these inclusion criteria were considered:

- a) burden estimate is for a country with >90% safe water access (Table S1) and
- b) estimates cases, hospitalizations, or deaths that could be prevented if ingestion of one or more contaminants in drinking water were prevented.

Articles focusing exclusively on exposure to contaminated water via recreation (e.g., swimming in contaminated water), inhalation, or dermal uptake were excluded. At least two independent reviewers screened the 528 articles against these criteria.

2.4 Data Extraction & Synthesis

Disease burden estimates were extracted by co-authors (DL; HM; JMG) using a custom spreadsheet to record estimates, study design, population, disease type(s), contaminant type(s) (microbial or chemical), and drinking water source. To compare estimates across studies, the reported disease burden was converted to incidence per 100,000 population. For some studies, additional adjustments were made to enable cross-study comparisons; Table S3 provides details. All estimates in the custom spreadsheet were confirmed by at least two co-authors. Text S2 outlines data synthesis and visualization approaches.

3. Results

Thirty-three articles met the selection criteria. All but one of the articles focused on a single country or union of countries. Of these 32 articles, most (68.8%) burden estimates were from the United States or Canada; 12.5% were from Asia; 9.4% reported on European countries; and 9.4% from Australasia (Figure S3, Table S4). Two articles provided estimates from a middle-income country (Iran); the rest, focused on high-income countries.

3.1 Infectious Diseases

Twenty-four articles estimated gastrointestinal illness (GI) risks (Table 1). Estimates are difficult to compare across studies because some estimated total GI burden, whereas others quantified the burden only for specific pathogens or specific outcomes (e.g., hospitalization). When sufficient information was available, we scaled results to enable cross-study comparisons (Table S3).

The population-weighted average burden of GI attributable to drinking water was approximately 3,529 cases per 100,000 population (range 40–18,250 per 100,000) across studies that estimated total GI burden or that could be adjusted to estimate this burden. The highest estimate was from a 2006 study by Eisenberg *et al.*, using data from a drinking water intervention trial (Figure 1). The lowest was from a 2016 North Carolina (US) study that compared three different estimation methods; two resulted in estimates of ~40 annual cases per 100,000, while the third estimate was

 \sim 6,300 per 100,000 people. Across studies, the population-weighted standard deviation (2,535 per 100,000) was relatively low, just over half the mean.

Of the 24 studies, only five directly estimated the number of deaths attributable to microbial contaminants. These estimates were very low, averaging 1 per 100,000 people annually (range = 7.3×10^{-3} to 2.1 per 100,000).

3.2 Non-infectious Diseases

Ten articles estimated the disease burden from chemical contaminants in drinking water (Table 2).

Cancers were the most common health outcome considered, included in 7 of the 10 studies (Figure 2). Estimated cancer risks varied depending on the cancer type and contaminants considered. Across all studies with cancer risk estimates, the population-weighted average disease burden was 1.8 excess cases per 100,000 people annually (range = 0.09-2.91).

Two studies, both in the United States, estimated adverse reproductive outcomes from nitrate in drinking water.^{7,8} In both studies, the disease burden was low on a per-capita basis. The highest burden was 1.6 low-birthweight babies per 100,000 people annually.

Surprisingly, despite the recent attention to lead in drinking water resulting from the Flint water crisis (US) and similar events elsewhere, only one study (from the Netherlands) quantified the health burden from lead.⁹ That study, published in 1999, estimated that 11 in 100,000 children were losing 1-3 IQ points as a result of neurocognitive damage from lead in drinking water.

The largest reported fatality risks from chemical contaminants were attributed to arsenic and disinfection byproducts (Figure 2b; Figure 3b), though these risks were very low. Across studies, about 0.1–1.3 premature annual deaths per 100,000 people were attributed to these contaminants. A 2017 study from North Carolina (US) attributed fewer than 0.0015 excess annual deaths per 100,000 people to gross alpha radiation, volatile organic compounds, and pesticides in drinking water.¹⁰

3.3 Comparison of Approaches Across Studies

Broadly, study methods can be classified as "top-down" or "bottom up" (Tables 1-2).

3.3.1. Top-Down Approach

Unlike foodborne illness surveillance, a robust system of waterborne illness surveillance does not exist. In the absence of such a system, some studies use overall disease surveillance data. They estimate the fraction of diseases that may be attributable to water and multiply this fraction by the total number of relevant diseases in the population. The WHO uses this method for its periodic global assessments of the contribution of various risk factors to population health.¹¹

Top-down studies have used a range of methods to estimate the attributable fraction. Some use previous epidemiologic studies, combined with estimates of the population fraction exposed to various contamination levels. As an example, Colford *et al.*¹² used data from an epidemiologic study in which participants were randomized to receive either an active or sham water treatment

system. DeFelice *et al.*¹³ obtained information on the distribution of occurrence and concentration of all regulated chemical contaminants in public water systems from state and federal water quality surveillance data. Fractions of illnesses attributable to these exposures were estimated by matching exposure concentrations to relative risks of illness from previous epidemiologic studies.

An alternative top-down method, used by Gibney *et al.*,¹⁴ relies on elicitation of expert judgments. Gibney *et al.* relied on 13 expert opinions on the fractions of illness from five different waterborne pathogens. There was wide variation in expert views. For example, for noroviruses, experts' median assessments of the attributable fraction ranged from 2% to 50%.

Another top-down approach is population intervention modeling, as illustrated in two studies by DeFelice *et al.*^{15,16} In this approach, disease surveillance data are combined with water source and water quality monitoring data, and a regression model estimating the disease incidence rate as a function of these variables (along with additional controls) is fitted. The number of cases attributable to water contamination is estimated from the regression model by comparing the baseline (observed) rate to the expected rate if water quality were improved.

3.3.2. Bottom-Up Approach

The bottom-up approach combines data on microbial or chemical contaminant exposure concentrations with dose-response information from epidemiologic or toxicologic studies. The dose-response functions are used to predict the estimated probability of illnesses for specific exposure concentrations. Those probabilities are then multiplied by the size of the exposed population. A drawback of this approach is that the estimated number of attributable cases could exceed the total number of actual cases—a potential error that the top-down approach avoids. On the other hand, in the absence of sufficiently comprehensive surveillance data, this is the only alternative.¹⁷

Among studies of the disease burden associated with microbial contamination of drinking water, the bottom-up approach was illustrated by Murphy *et al.*,¹⁸ Burch *et al.*,¹⁹ Reynolds *et al.*,²⁰ and DeFelice *et al.*¹⁶ For example, Murphy *et al.* used quantitative microbial risk assessment to estimate the disease burden from five pathogens in private wells and small community systems in Canada. Burch *et al.* used well water monitoring data for eight pathogens, along with published dose-response information, to characterize the burden from these pathogens among residents of Kewaunee County, Wisconsin (US), using private wells. Reynolds *et al.* estimated the disease burden attributable to microbial contaminants in US drinking water by making assumptions about the prevalence and concentrations of selected pathogens in different water source types and then using literature-derived dose-response information to estimate illness probabilities from these assumed exposures. DeFelice *et al.* estimated the burden of GI from three reference pathogens in North Carolina community water systems using monitoring data on the occurrence of *E. coli* and a literature review of the ratio of concentrations of each reference pathogen to *E. coli*.

The bottom-up approach is also common in studies quantifying the disease burden from chemical contaminants. Examples include studies of the disease burden from fluoride²¹ and disinfection byproducts²² in drinking water in Iran and characterization of the disease burden

from arsenic in drinking water in the US.²³ These studies begin by estimating the probability distribution of contaminant exposure across the study population, and they use a dose-response function derived from previous animal or human studies to predict the number of adverse health outcomes associated with each exposure dose.

Overall, this review indicates that the lack of robust surveillance systems hinders estimation of the burden of disease attributable to drinking water contamination. A variety of approaches has been used to develop estimates in the face of limited surveillance data, but there is no single, agreed-upon approach. This methodological uncertainty complicates comparisons across geographic regions and study years.

4. Discussion

We found 23 studies that estimated the burden of infectious diseases and 9 that estimated the chemical disease burden—and one study that estimated both—from drinking water contamination in countries with reportedly high access to safely managed drinking water. Among the infectious disease burden studies, nearly all focused exclusively on GI; the average burden across the studies was approximately 3,529 excess GI cases per 100,000 people yearly (Table 1; Figure 1). Among studies of non-infectious diseases attributable to chemical contamination, the majority focused on carcinogens. The excess cancer risk across studies averaged 1.8 cases per 100,000 people yearly (ranging from less than one in one billion to two cases per 100,000 people yearly) (Table 2; Figure 2).

Overall, these results suggest that the risks of GI from drinking water contamination are low in many HICs relative to those in developing nations, but that the risks are still higher than recommended targets established by the WHO's Guidelines for Drinking Water Quality.²⁴ The Institute of Health Metrics and Evaluation estimates that globally, the burden of disease from unsafe water is 922 annual disability-adjusted life years (DALYs) per 100,000 people, with the highest burden in sub-Saharan Africa, at 2,813 annual DALYs per 100,000 people.²⁵ Using a disability weight of 0.074 for mild diarrhoea as in recent global studies,²⁶ the population-weighted average 3,529 annual GI cases per 100,000 people equates to approximately 260 annual DALYs per 100,000 people, or less than one-third the global average and about 90% less than in the most affected regions. However, the WHO defines "the tolerable burden of disease . . . as an upper limit of 10⁻⁶ DALY per person per year," equivalent to 0.1 per 100,000 people. By this measure, the burden of infectious diseases associated with drinking water contamination is still much higher than desired, even in high-income nations and even for the lowest risk estimates identified in this review (40 annual GI cases per 100,000 people, equivalent to 3 DALYs per 100,000).

Cancer risk estimates also suggest the magnitude of the disease burden associated with drinking water contamination is relatively low but still exceeds the WHO's recommendation of one excess annual cancer case per 100,000 people attributed to drinking water. Across studies, the average cancer risk was about twice this amount.

4.1. Limitations of the Available Studies

This review identified critical gaps in efforts to characterize the disease burden attributable to drinking water contamination in countries with high access to safely managed drinking water. These gaps include a lack of country representation, insufficient spatial resolution in countries with available studies, a limited scope of contaminants considered, and insufficient information to support decision-making about the best ways to decrease the disease burden. Although we attempted to recover estimates from grey literature, only two from New Zealand were found. There may be unpublished estimates that this review did not recover.

4.1.1. Limited Geographic Representation

The published disease burden studies covered only 10 of 64 countries/territories reporting >90% access to safely managed drinking water. One study covered disease burden in the European Union. More than half of studies are from the United States or Canada. As such, the results of this review may be heavily biased toward these countries.

4.1.2. Insufficient Spatial Resolution

Even in countries with available disease burden estimates, the estimates' spatial resolution is insufficient to support decision-making about allocation of resources for infrastructure improvements. Such allocation decisions typically begin at the local level and therefore require local-level estimates highlighting populations most in need of assistance. Most available studies provide estimates for large geographic regions (such as an entire country or a large political subdivision within the country), not for smaller spatial units or special subpopulations. The high risks that some populations may face are subsumed when they are averaged in with the general population receiving high-quality water services. Among studies identified in this review, only Haass *et al.*²⁷ and Beaudeau *et al.*²⁸ looked at specific vulnerable populations. Haass *et al.* examined the burden associated with communities in El Paso, Texas (US), inadequately served by water and sanitation services. Beaudeau *et al.* estimated burden in elderly populations in Massachusetts (US).

As an example, small water systems experience water quality and service delivery problems more often than larger systems due to the lack of economies of scale.^{29–31} This is of particular concern when considering that small water systems frequently serve rural, low-income communities. Allaire *et al.* found that violations of health-based drinking water standards in the US often occur in low-income rural areas.²⁹ A cross-sectional study of water quality in small and medium water systems in rural Alabama found an association between self-reported GI symptoms and the following water system characteristics: respondent-reported water supply interruption, low water pressure, lack of total chlorine in water, and detection of *E. coli* in water.³²

Water systems serving communities of color also are more likely to experience water quality problems, with a consequent disease burden that can be masked in studies lacking sufficient spatial resolution. In Canada, boil-water advisories for systems serving indigenous communities are common—typically a result of inadequate disinfection, mechanical failure, and insufficient technical expertise of system operators.^{33–35} A scoping review of drinking water quality and health outcomes of Canadian indigenous communities found various reports of adverse health outcomes (mostly GI) associated with drinking water but highlighted the paucity of relevant research.³⁶ The remote, indigenous communities of Australia may also be at higher risk of

infection with waterborne pathogens. The water supply in many of these communities often fails to meet microbiological water quality standards,³⁷ and Ng-Hublin *et al.* found that the notification rate of cryptosporidiosis in Aboriginal people was 50 times that among non-Aboriginal people in Western Australia.³⁸ Schaider *et al.* found a positive association across the United States between the proportion of Hispanic residents and nitrate levels in drinking water.³⁹ Balasz *et al.* found a similar association in the San Joaquin Valley of California for small community water systems serving a large proportion of Latino residents.⁴⁰ A study by Nigra and Navas-Acien found that incarcerated people in the southwestern US were disproportionately at risk of exposure to arsenic in drinking water.⁴¹ MacDonald Gibson *et al.* found that in Wake County, North Carolina (US), children in households relying on private wells had higher blood lead levels than those with community water service and that these differences were especially acute in peri-urban minority communities.⁴²

4.1.3. Limited Scope of Disease Types and Contaminants

Nearly all the studies of the waterborne infectious disease burden consider only GI, overlooking other critical diseases (such as respiratory illnesses) that can be transmitted through drinking water. For example, only three studies identified in this review^{43–45} characterized the respiratory disease burden attributable to *Legionella*, even though it caused all deaths from waterborne disease outbreaks in the United States in 2013–2014.⁴⁶

More information on the comparative disease burden from chemical contaminants is especially important for developed nations since these contaminants tend to be the major focus of drinking water regulations in developed nations.^{13,47} Especially notable is the dearth of studies estimating the disease burden from lead in drinking water, despite recent water crises brought about by lead (for example, in Flint, Michigan, US), along with mounting evidence that exposure to lead in private well water may be much more prevalent than previously recognized and, in some cases, can be a source of health disparities.^{42,48} This review located only one study that quantified the burden of disease due to lead in drinking water in a developed nation, and it was completed more than 20 years ago. This finding is surprising, since lead is ubiquitous in plumbing (even in plumbing branded as "lead-free").⁴⁹ Updated estimates of lead exposure risks from drinking water and the associated disease burden are needed across developed nations.

Also needed are studies of the disease burden attributable to "emerging" chemical contaminants—that is, those for which knowledge on their potential prevalence in drinking water is relatively new. One example is per- and polyfluoroalkyl substances (PFAS), which have been reported in drinking water sources and systems globally in recent years.⁵⁰ Another example is toxins formed by aquatic fungi and algae, such as mycotoxins and cyanotoxins.⁵¹ The most recently published waterborne disease surveillance data from the US Centers for Disease Control and Prevention indicate that cyanotoxins caused 12% of reported US waterborne disease cases.⁴⁶

4.1.4. Insufficient Consideration of Causal Factors

Also lacking is information that would enable estimates of specific water system deficiencies causing preventable illness. Available estimates focus on total disease burden, not on contributing factors. These might include source water contamination, treatment system deficiencies or failures, distribution system breaches, disinfectant loss in the distribution system,

water shutoffs and low-pressure events, or release or formation of contaminants as water travels through plumbing within buildings.

5. Conclusions

This review sheds light on the dearth of research on the disease burden attributable to unsafe drinking water in countries with high access to safe drinking water. Estimating this disease burden remains difficult given the lack of a comprehensive surveillance system and gaps in drinking water quality data. JMP data suggesting the vast majority of the population has access to safely managed water can be misleading because these data mask variation in the quality of water service delivery that can have important public health consequences. Further research on the drinking water-attributed disease burden in these countries remains vital to identifying the main drivers of waterborne disease, the populations at greatest risk, and strategies for improving health outcomes related to drinking water.

Contributors

HMM, JMG, and JB designed the study. DL, JH, JMG, and HMM recovered articles, assessed article eligibility, and extracted and analyzed data from articles. DL, JMG, and HMM wrote the initial drafts of the manuscript. All authors contributed to edits of the manuscript.

Author	Date	Location	Health Outcomes	Exposure Source	Pathogens	Approach	Burden Estimate (Per Year)
Ball et al.52	2006	New Zealand	GI cases	Drinking	Unspecified	Top down	33,743 GI cases
Beaudeau et al. ²⁸	2014	Boston, Massachusetts, USA	GI hospital admissions	Drinking (public systems)	Unspecified	Top down	153 GI hospital admissions
Burch et al. ⁵³	2021	Kewaunee County, Wisconsin, USA	GI cases	Drinking (private wells)	Adenovirus group A, <i>Campylobacter</i> , <i>Cryptosporidium</i> , enteropathogenic <i>E.</i> <i>coli</i> , <i>Giardia</i> , <i>Salmonella</i>	Bottom up	301 GI cases
Butler et al. ⁵⁴	2016	Canada	Enteric illness cases	Food, drinking, recreation, animal contact	Campylobacter, Cryptosporidium, Giardia, verotoxin- producing <i>E. coli</i> (non- 0157 and 0157)	Top down	447,459 enteric illness cases attributed to only drinking water (private wells, public water systems, bottled)
Colford et al. ¹²	2006	USA	GI cases	Drinking (public systems)	Unspecified	Top down	4.26-11.69 million GI cases
Collier et al. ⁴⁵	2021	USA	GI and respiratory cases, ED visits, hospitalizations, deaths	Drinking, recreation, inhalation	Campylobacter, Cryptosporidium, Giardia, Legionella, nontuberculous mycobacteria, norovirus, Pseudomonas, Salmonella, Shiga toxin-producing E. coli, Shigella, Vibrio, unspecified otitis externa	Top down	7.15 million waterborne illnesses, 601,000 ED visits, 118,000 hospitalizations, 6,630 deaths
DeFelice et al. ¹⁵	2016	North Carolina, USA	ED visits for GI	Drinking (public systems and private wells)	Unspecified	Top down	29,400 ED visits
DeFelice et al.55	2015	North Carolina, USA	ED visits for GI	Drinking	<i>Giardia, Campylobacter,</i> rotavirus	Top down, bottom up comparison	Varied by approach: 190, 190, and 32,000 ED visits
Eisenberg et al. ⁵⁶	2006	Iowa, USA	GI cases	Drinking (public systems)	Burden from trial data: unspecified	Top down, bottom up comparison	Burden from trial data: 1,825 cases per 10,000 population

Table 1. Estimated disease burden from waterborne microbial contaminants in high-income countries

Author	Date	Location	Health Outcomes	Exposure Source	Pathogens	Approach	Burden Estimate (Per Year)
					Burden from risk model: <i>Giardia</i> , <i>Cryptosporidium</i> , unspecified viruses		Burden from risk model: 13.9 cases per 10,000 population
Gibney et al. ¹⁴	2017	Australia	GI cases, deaths, DALYs	Drinking, recreation	Campylobacter, Cryptosporidium, Giardia, nontyphoidal Salmonella, norovirus	Top down	820,003 GI cases; 11 deaths
Haass et al. ²⁷	1996	San Elizario, El Paso County, Texas, USA	GI cases, Hepatitis A cases	Drinking, sanitation	Entamoeba histolytica, Campylobacter, hepatitis A virus, nontyphoidal Salmonella, typhoidal Salmonella, Shigella	Top down	199 GI cases, 6 hepatitis A cases
Kim et al. ⁵⁷	2018	Korea	Deaths, DALYs	Drinking, sanitation, hygiene	Unspecified GI pathogens (includes hepatitis A virus and helminths)	Top down	6 deaths
MacDonald Gibson et al. ⁵⁸	2013	United Arab Emirates	Gastroenteritis cases	Drinking	Unspecified	Top down	46,200 cases (4 deaths)
Masciopinto et al. ⁵⁹	2019	Salento Region, Italy	GI cases, hepatitis A, DALYs	Drinking (groundwater)	Adenovirus, enterovirus, hepatitis A virus, norovirus, rotavirus	Bottom up	348 GI cases; 2 hepatitis A cases (summer only)
Messner et al. ⁶⁰	2006	USA	AGI cases	Drinking	Unspecified	Top down	16.4 million cases
Moore et al. ⁶¹	2010	New Zealand	AGI cases	Drinking (noncompliant public systems)	Unspecified	Top down	35,000 cases
Morris and Levin ⁶²	1995	USA	GI cases, deaths	Drinking	Campylobacter, Cryptosporidium, E. coli, Giardia, norovirus Salmonella, Shigella	Top down (bacteria); bottom up (parasites & viruses)	7.66 million cases; 1,210 deaths
Murphy et al. ⁶³	2016	Canada	AGI cases	Drinking (public systems serving >1,000)	Unspecified	Top down	334,966 cases
Murphy et al. ¹⁸	2016	Canada	AGI cases	Drinking (private wells, small public systems)	Campylobacter, Cryptosporidium, E. coli O157:H7, Giardia, norovirus	Bottom up	103,230 cases

Author	Date	Location	Health Outcomes	Exposure Source	Pathogens	Approach	Burden Estimate (Per Year)
Payment ⁶⁴	1997	Canada	HCGI cases	Drinking (public systems)	Unspecified	Top down	4,200,000
Perz et al.65	1998	New York City, USA	GI cases	Drinking (public systems)	Cryptosporidium	Bottom up	42 cases
Reynolds et al. ²⁰	2008	USA	GI cases	Drinking (public systems)	Campylobacter, Cryptosporidium, and rotavirus (and other unspecified viruses)	Bottom up	19.5 million cases
Verhougstraete et al. ⁴⁴	2020	USA	GI cases, Legionnaires' disease, sequela and mortality	Drinking	Adenovirus, Campylobacter, Cryptosporidium Salmonella, E. coli O157:H7, Giardia, hepatitis A virus, Legionella, norovirus, and rotavirus	Top down	9 million GI cases; 13,000 Legionnaire's disease cases; 32,531 Hepatitis A cases; 0.6 million sequela; 1,470 GI deaths
Vinson ⁴³			pneumophila, Mycoplasma pneumoniae, Toxoplasma gondii and unspecified pathogens causing Gl/otitis	Top down	1.32 million GI cases		

GI- Gastrointestinal illness AGI- Acute gastrointestinal illness HCGI- Highly credible gastrointestinal illness ED- Emergency department DALYs- Disability Adjusted Life Years

Author	Date	Location	Health Outcomes	Exposure Source	Chemical Contaminant	Approach	Burden Estimate (Per Year)
Abtahi et al. ²¹	2019	Iran	Dental fluorosis	Drinking	Fluoride	Bottom up	60 cases/100,000 people (95% Cl 48- 69)
de Hollander et al. ⁹	1999	The Netherlands	Loss of 1-3 IQ points	Drinking	Lead	Bottom up	1,764 cases
DeFelice et al. ¹³	2017	North Carolina, USA	Cancer	Drinking (public systems)	20 carcinogens	Top down	53.9 (95% CI 27.8-79.4) deaths statewide; individual risk 7.2 x 10 ⁻⁶
Dobaradaran et al. ²²	2020	Bushehr Province, Iran	Cancer	Drinking, dermal, inhalation	Disinfection byproducts	Bottom up	1 (95% CI 0.32-2.8) death in Bushehr Province; 95.0 DALYs (94.7–95.2).
Evlampidou et al. ⁶⁶	2020	28 European Union countries	Cancer	Drinking	Disinfection byproducts	Top down	6,561 (95% CI 3,389, 9,537) cases across the EU
Fewtrell et al. ⁶⁷	2006	USA, United Kingdom, New Zealand	Dental and skeletal fluorosis	Drinking	Fluoride	Bottom up	Zero
Greco et al. ²³	2019	USA	Ischemic heart disease; cancer	Drinking (private wells)	Arsenic	Bottom up	500 ischemic heart disease deaths; 496 fatal cancer cases; 578 nonfatal cancer cases
MacDonald Gibson et al. ⁵⁸	2013	United Arab Emirates	Bladder and colorectal cancers	Drinking	Trihalomethanes (THMs)	Top down	154 healthcare facility visits (and 3 deaths) for bladder cancers and 328 visits (and 9 deaths) for colorectal cancers
Mathewson et al. ⁸	2020	Wisconsin, USA	Cancer; neural tube defects; low birth weight; preterm birth	Drinking	Nitrate	Top down	95 (range 46-149 very low birth weight babies; 51 (range 26-79) very preterm births; 1-2 neural tube defect births; 169 (range 111-297) cancer cases
Temkin et al. ⁷	2019	USA	Cancer; neural tube defects; low birth weight; preterm birth	Drinking	Nitrate	Top down	2,939 very low birth weight cases; 1,725 very preterm births; 41 neural tube defect births; 6,537 (range 2,300- 12,594) cancer cases

Table 2. Estimated disease burden from waterborne chemical contaminants in high-income countries

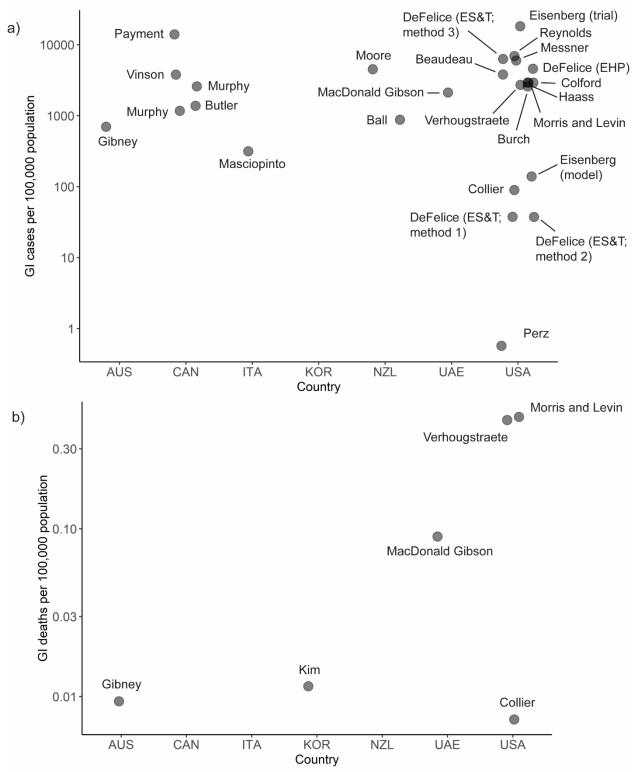

Figure 1. Summary of burden estimates (incidence per 100,000 population) for a) cases of GI illness attributed to microbiological contamination of drinking water and b) deaths from illness attributed to microbiological contamination of drinking water.

<u>Countries</u>: AUS=Australia, CAN=Canada, ITA=Italy, KOR=Republic of Korea, NZL=New Zealand, UAE=United Arab Emirates, USA=United States of America

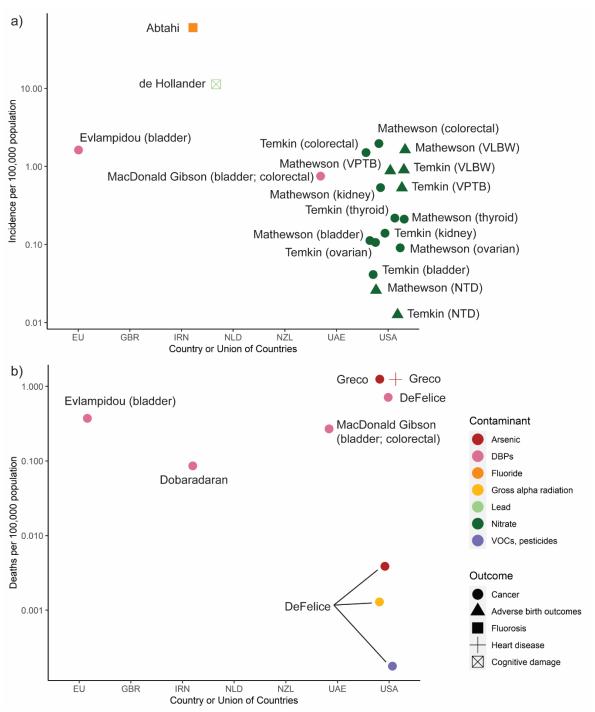

Figure 2. Summary of burden estimates (incidence per 100,000 population) for a) cases of illness attributed to chemical contamination of drinking water, and b) deaths from illness attributed to chemical contamination of drinking water.

Note: Estimates of zero cases (per 100,000 population) of fluorosis in USA, GBR (UK), NZL by Fewtrell et al. were excluded

<u>Countries</u>: EU=European Union, GBR=United Kingdom, IRN=Iran, NLD=The Netherlands, UAE=United Arab Emirates, USA=United States of America

<u>Contaminants</u>: DBPs=Disinfection by-products, VOCs=Volatile Organic Compounds <u>Outcomes</u>: VLBW=Very low birth weight, VPTB=Very preterm birth, NTD=Neural tube defects

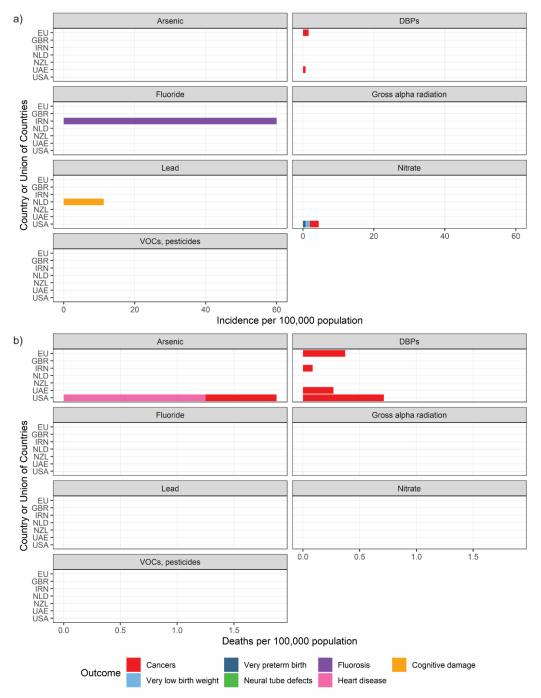

Figure 3. Summary of a) cases and b) deaths by chemical contaminant and country. For countries where disease burden estimates were available through multiple studies, disease outcome estimates from different studies were averaged to produce country-specific estimates. For cancers, specific cancer estimates (e.g. bladder cancer, liver cancer) were summed to produce an overall cancer estimate. <u>Note</u>: The burden of neural tube defects in the United States is not visible due to its relatively low level (0.02 cases per 100,000)

<u>Countries</u>: EU=European Union, GBR=United Kingdom, IRN=Iran, NLD=The Netherlands, UAE=United Arab Emirates, USA=United States of America

<u>Contaminant</u>: DBPs=Disinfection by-products, VOCs=Volatile Organic Compounds
