Key words: P-Selectin, COVID-19, Long-COVID, SARS-CoV-2

Abstract

Background: Long-term outcomes of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) are now recognized as an emerging public health challenge - a condition termed Long-COVID. The pathophysiology of Long-COVID remains to be established. Functional P-selectin activity, implicated in COVID-19 sequelae, was measured between two convalescent COVID-19 subjects, one with (Long-COVID subject) and another without Long-COVID symptoms.

Methods: Flow adhesion of whole blood or isolated white blood cells to P-selectin (FA-WB-Psel and FA-WBC-Psel) was measured using a standardized microfluidics clinical assay; impedance aggregometry with a collagen agonist was measured using model 590 Chrono-Log impedance aggregometer; standard laboratory assays were performed to evaluate changes in blood chemistries.

Results: For both subjects, hemoglobin, WBC, platelet counts, electrolytes and ferritin were within normal reference ranges, with FA-WB-Psel significantly elevated compared to healthy controls ($p < 0.01$). *In vitro* treatment of whole blood samples with crizanlizumab (anti-p-selectin monoclonal antibody) within the clinical dose range (10 µg/ml) mL) inhibited FA-WB-Psel only in samples from asymptomatic post-COVID subject, with the Long-COVID subject sample requiring close to 5-fold elevated dose to achieve a response. Pronounced inhibition of P-selectin adhesion of isolated leukocytes was observed for both subjects in autologous platelet-poor plasma and buffer. Impedance aggregometry showed greater baseline platelet aggregation to collagen in the Long-COVID sample, although both samples responded similarly to aspirin-induced platelet inhibition.

Conclusions: Presented results suggest that elevated platelet activation in Long-COVID subject may be associated with increased P-Selectin activity. The results are discussed in terms of possible use on P-selectin inhibition therapies in treating Long-COVID.

Background

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) causes the Coronavirus disease 2019 (COVID-19), which is characterized by severe vascular complications associated with endothelial dysfunction and overproduction of inflammatory mediators, with pathology extending to the cellular level inducing a pro-coagulant state. Research efforts have focused on the acute phase of the disease; however, long-term outcomes for people recovering from COVID-19 are now recognized as an emerging public health challenge. Although most people show complete recovery within a few weeks, some continue to experience a range of symptoms long after their initial recovery which is often referred to as “Long-COVID” or post-acute sequelae of COVID-19 (PASC). While the definition of Long-COVID is still evolving, it has been suggested to include persistence of symptoms or development of related pathologies beyond 3-4 weeks from the onset of acute symptoms of COVID-19 [1-3]. Specifically, it was proposed that at least 2 periods of illness appear to be contributing to morbidity beyond acute SARS-CoV-2 infection: a post-acute hyperinflammatory illness and late inflammatory and virological sequelae. The post-acute hyperinflammatory condition manifests approximately 2 to 5 weeks after the onset of SARS-CoV-2 infection and is characterized by systemic inflammation that can occur in organs distinct from those directly affected by the virus, after host clearance of the SARS-CoV-2 infection. The pathophysiology of this multisystem inflammatory syndrome likely reflects a dysregulated host immune response [4].

The late sequelae or Long-COVID includes a wide range of cardiovascular, pulmonary, neurological, and other physiological manifestations [5]. Typically, patients with Long-COVID report different combinations of symptoms: fatigue, difficulty thinking or concentrating (sometimes called “brain fog”), headache and migraines, loss of smell or taste, hypertension, dizziness on standing, heart palpitations, chest pain, difficulty breathing or shortness of breath, cough, joint or muscle pain, depression or anxiety, hair loss, fever, symptoms that get worse after physical or mental activities. Symptoms attributed to systemic inflammation and impaired microvascular blood flow are of particular concern. These symptoms can continue for an undetermined duration, and it remains unknown to what extent these symptoms can evolve into chronic or irreversible health conditions. There is limited information about the underlying pathophysiology, disease duration, or long-term prognosis of persons affected by Long-COVID. It seems likely that individual patients with Long-COVID would manifest the symptoms through different biological drivers with suggested contributions from viral-induced injury to one or multiple organs, persistent reservoirs of SARS-CoV-2 in certain tissues, re-activation of pre-existing pathogens stimulated by COVID-

19 immune dysregulation, SARS-CoV-2 interactions with host microbiome/virome, ongoing activity of primed immune cells, and escalating autoimmunity among other possibilities [3].

The interest in Long-COVID continues to increase as new reports detailing the condition continue to emerge. A number of investigators reported different prevalence of persisting complications in patients recovered from COVID-19. A study published in JAMA presented cardiac magnetic resonance imaging data showing 78% patients exhibiting cardiac involvement and 60% having an ongoing myocardial inflammation [6]. It was also reported that two-months post the infection among the adults with non-critical COVID-19, two thirds had complaints including severe dyspnea or asthenia, chest pain, palpitations, headache, myalgia, and fever [7], while a study published in BMJ reported about 10% of those who had COVID-19 experienced symptoms beyond three weeks, with an even smaller proportion experiencing them for months [2].

A recent FAIR Health study reviewed a total of 1,959,982 COVID-19 patients for the prevalence of Long-COVID condition 30 days or more after their initial diagnosis with COVID-19 and reported that about 23% had at least one Long-COVID symptom [8]. The five most common Long-COVID conditions across all ages, in order from most to least common, were pain, breathing difficulties, hyperlipidemia, malaise/fatigue, and hypertension. Long-COVID conditions were found to a greater extent in patients who had more severe cases of COVID-19, but also in a substantial share of asymptomatic patients. Of patients who were hospitalized with COVID-19, the percentage that had a Long-COVID condition was 50%, while for patients who were symptomatic but not hospitalized, 27.5%; and 19% for patients who were asymptomatic for COVID-19 [1]. Without a clear clinical picture of the underlying mechanisms, the treatment of Long-COVID syndrome is mainly limited to supportive care and symptomatic control, and its long-term impacts on quality of life of COVID-19 survivors remains unclear.

Commonly reported for COVID-19 positive patients are lymphocytopenia, as well as elevated levels of D-dimer, lactate dehydrogenase, ferritin, Von Willebrand factor, Factor VIII, and inflammatory markers like C-reactive protein, IL-6 and erythrocyte sedimentation rate [9-12]. Despite seeming trends, the reports do not present consistent picture of COVID-19-associated changes and can be hard to reconcile with existing patient-to-patient variability as the reportedly altered values in many cases remain within the normal physiological range. In other cases, both elevated and depleted biomarker values had been observed as e.g., the case of platelet counts, where both

thrombocytopenia and thrombocytosis have been reported [12]. The analysis is further complicated by biomarker significant dependence on disease severity and associated co-morbidities, as well as on wide range of possible patient clinical trajectories defined by an interplay of immunological, inflammatory, and coagulative processes.

COVID-19 association with platelet activation is well documented [13]. Typically, through binding to PSGL-1 on WBC, P-selectin overexpressed on platelets would enhance platelet aggregation and thrombus formation. Indeed, viral-induced coagulopathies including arterial thrombotic events like stroke and ischemic limbs as well as microvascular thrombotic disorders have been observed in SARS-CoV-2 infection with platelet hyperactivity suggested as the key element in disease thrombotic manifestations [14]. Clinically, in patients hospitalized with COVID-19, platelet hyperactivity had been associated with adverse events including thrombosis and death [15]. Such events are often, but not always, correlated with elevation of thrombosis biomarkers like D-dimer and fibrin/fibrinogen-degradation products. Interestingly, some studies did not observe a correlation between levels of D-dimers and platelet activation [16].

Inflammatory and coagulative sequelae are mediated by selectins including P, E, and L selectin and cell adhesion molecules (ICAM-1, VCAM-1), with P-Selectin in particular gaining attention. Located within the α -granules of platelets and the Weibel-Palade bodies of endothelial cells, P-Selectin rapidly translocate to the cell surface following activation. P-selectin in platelets interacts with P-Selectin glycoprotein ligand-1 (PSGL-1) on leukocytes promoting platelet-leukocyte aggregate formation, release of procoagulant microparticles, and upregulation of a several leukocyte cytokines. It is also involved in platelet-platelet aggregation, which is major factor in arterial thrombosis [17]. Most investigators report elevated levels of P-Selectin in SARS-CoV-2 positive patients, with seemingly larger elevation of P-selectin in more severe disease states. However, a number of studies also report comparable levels of P-selectin in COVID-19 patients and healthy controls [18].

Studies also indicated elevated soluble P-selectin (sP-selectin) levels in plasma of COVID-19 patients [19], with such levels suggested as an early marker of thromboembolism [20]. sP-selectin predominantly originate through proteolytic cleavage of the transmembrane protein (shedding). For example, activated platelets can shed P-Selectin in hours after activation [21]. The process is mediated through leukocyte P-Selectin glycoprotein ligand-1 (PSGL-1) interaction with transmembrane P-Selectin on platelets or endothelial cells [22]. However, despite its elevated plasma concentration, mostly monomeric sP-

selectin, by itself is expected to have limited impact on P-Selectin-associated pathology, as its prior dimerization is likely required to promote inflammation and coagulation [22].

While some understanding seems to emerge regarding the active phase of COVID-19, the pathophysiology involved in persisting Long-COVID remain essentially unknown. Part of the reason is that long-term follow-up presently is too limited to reveal the full scope of all potential COVID-19 consequences. Another is the natural focus of the research community on understanding and combatting of the active phase of the infection. A recent review presents the multitude of mechanisms potentially involved in the development of Long-COVID symptoms [23]. Diversity of the proposed mechanisms underlines both the complexity of Long-COVID pathology and the need for further investigation on the resolution of this new health problem. Presently we report changes in platelet reactivity, blood cell adhesion on P-Selectin and response to *in-vitro* P-Selectin inhibition therapy in subjects after SARS-CoV-2 infection with and without severe Long-COVID symptoms.

Methods

Study Subjects and Sample Collection: Two convalescent COVID-19 subjects, one with Long-COVID symptoms (LC) and the other asymptomatic post-COVID (PC) were recruited according to the protocols FF-RBC-001 and FF-RBC-003v2 approved by Institutional Review Board of the Institute for Regenerative and Cellular Medicine. Throughout this paper, the two subjects will be referred to as , the Long-COVID subject ,(LC), and the asymptomatic post-COVID subject (PC). The blood draws were obtained via venipuncture after a 12-h fast. Whole blood was collected into EDTA tube for CBC, aggregometry, and flow adhesion assays, 3.2% sodium citrate tube for D-dimer, and serum separation tubes for interleukins, COVID-19 antibodies and for calcium, LDH, iron, TIBC and ferritin panel that were transferred to Quest Diagnostic Lab for analysis. Reference ranges are those provided by the laboratory unless specified otherwise. Both subjects consented to take part in the present study and for the results to be published.

Flow Adhesion Assays: Flow adhesion of whole blood to P-Selectin (FA-WB-Psel) and Flow adhesion of white blood cells to P-Selectin (FA-WBC-Psel) were conducted as described previously [24]. Briefly, isolated white blood cell (i-WBC) suspensions were prepared according to a standardized protocol (HetaSep™, StemCell Technologies). Whole blood samples (1:1 diluted with HBSS buffer) or i-WBC (5×10^6 cells/mL) were perfused through P-Selectin-coated microfluidic channels at 1 dynes/cm^2 for 10 or 6 minutes respectively, washed to eliminate non-adhering cells, with resultant adhesion quantified

manually by an independent trained observer to generate an adhesion index (cells/mm²) using a previously described protocol [25]. For drug treatment conditions, samples were incubated for 5 minutes with crizanlizumab at the final concentrations as required before assessment by the flow adhesion assay.

Impedance Aggregometry: Platelet aggregation in whole blood samples was tested with an impedance aggregometer (Model 590; Chrono-Log Corporation, Havertown, PA) and analyzed using Aggro/Link[®]. Whole blood samples were collected into 3.2% sodium citrate tubes, transferred at room temperature, and tested within 4 hours after the blood draw. The sample was split into control (1% DMSO treated) and aspirin treatment (100µM). Briefly, after a stable baseline (steady state) had been established, the agonist collagen (Chrono-Par, Chrono-Log Corporation, Havertown, PA) was added to the sample to a final concentration of 2µg/mL, and the aggregation was monitored for 10 minutes. Instrument normal control reference values (Table 3) are for normal donor with no previous exposure to COVID19 tested same as post-COVID subjects. Note, that sample collection in citrate tubes required for other assays could have resulted in lower overall values than would have been observed in EDTA [26].

Statistical Analysis. The data is presented as mean ± standard deviation (mean ± SD) with Student t-test paired or non-paired as appropriate used for assessment of statistical significance of the differences. Results were deemed significant for comparisons where two-tailed $p < .05$.

Results

Clinical Sequelae

Post-COVID subject with severe Long-COVID symptoms: LC, is a 26-30 year old female with no history of chronic medical conditions, was not on any prescription medication, and had no prior health complaints. She was diagnosed with SARS-CoV-2 by PCR and presented with COVID-19 symptoms one week following a known exposure, including coughing, fever, difficulty breathing, cough, progressively worsening fatigue, brain fog, loss of taste and smell, and headache. In LC's own words, *"I had severe issues breathing unless I was laying down in a certain position. When I did need to sit or stand, I would have a coughing attack barely being able to breathe or be severely short of breath. My throat was extremely irritated. I was disoriented for about 3-4 days. I lost my taste and smell before the major symptoms presented but regained most of both shortly after I began to recover. I had a constant burning in my nose, almost like I had to sneeze. Headaches were nearly unbearable and remained consistent for weeks afterward, with no headache medication able to alleviate."* LC was not hospitalized, managing

symptoms at home. At most severe (10-12 days after the infection), she was on bed rest, not responsive, refusing food or drink. The symptoms started to alleviate when the fever was broken and gradually receded over the course of another week. After the resolution of the infection, LC experienced a wide range of symptoms (Table 1) typical for those reported in Long-COVID cases. While some symptoms started to alleviate to different degree over time, many of them remain quite severe even 5 months after the infection (Table 1).

Post-COVID subject with no Long-COVID symptoms: PC, is a 16-20 year old male, with no history of chronic medical conditions. He was diagnosed with COVID-19 and presented mild symptoms during the active infection lasting approximately 3-4 days. He was asymptomatic three weeks before participating in the study and remained asymptomatic 20 weeks later. He achieved full recovery with no lingering Long-COVID symptoms present at any time since infection resolution.

Clinical Chemistry

LC: Despite severe Long-COVID symptoms, clinical chemistry results of the Long-COVID subject (LC) show little deviation from the normal ranges (Table 2). As an exception, at 20 weeks after the infection with SARS-CoV-2, the subject shows slightly elevated RBC count (5.26×10^{12} cells/L), as compared to the normal reference range of $3.8 - 5.1 \times 10^{12}$ cells/L. At normal blood hemoglobin value, this slight increase in RBC count is correlated with mean cell hemoglobin concentration (MCH) at the lower end of the normal range. In parallel, metabolic panel shows a decreased total iron and Transferrin-iron saturation percentage values on the background of normal Total Iron Binding Capacity (TIBC), that could be functionally related to increased RBC counts. The values for Ferritin and LDH, often reported as elevated in COVID-19 patients, as well as bilirubin, were within the normal reference range, with the subject thus presenting no evidence of extraordinary hemolysis that could be accompanying SARS-CoV-2 infection [12, 27]. D-Dimer value was elevated compared to the reference range (1.02 vs normal value of <0.5 mcg/mL). An increase in D-Dimer associated with increased in thrombosis risk has been well documented in SARS-CoV-2 infection [28] with significant, 3- 4-fold rise in D-dimer levels (to 1.2 ± 1.4 mcg/mL) in the early stages of COVID-19 linked to poor prognosis. All other values are within the normal reference ranges at both 11- and 20-weeks post infection.

PC: Clinical chemistry parameters were within the normal reference ranges for the asymptomatic post-COVID subject (PC), with the exception of slightly elevated total bilirubin (1.3mg/dL, compared to the reference range 0.1-1.2 mg/dL) and total LDH (278 U/l, reference range 110-230 U/L). Simultaneous

elevation of LDH and bilirubin may be indicative of slightly elevated rate of hemolysis on the background of compensating erythropoietic activity and thus with no impact on RBC count or total hemoglobin values. That supposition is supported by the concurrently decreased Red Blood Cell Distribution Width (RDW), with such a decrease being potentially associated with decreased average RBC lifespan in circulation resulting in smaller contribution of older and lower volume cells to RDW [29].

Interleukin 1 Beta (IL1 β) and interleukin 4 (IL4) were in the normal reference ranges for both subjects (Table 2).

Flow Adhesion on P-Selectin

Whole Blood

Flow adhesion of whole blood on P-Selectin (FA-WB-PSel) was significantly elevated for both Long-COVID (LC and asymptomatic post-COVID (PC) subjects (590 ± 260 and $1,100 \pm 250$ cells/mm² correspondingly) as compared to normal subjects (typically, 50 or less cells/mm² if with no significant inflammation processes).

LC: Measurements of flow adhesion of whole blood in the presence of crizanlizumab, a monoclonal antibody against P-selectin, resulted in a dose-dependent decline of adhesion to P-selectin for the asymptomatic post-COVID subject's sample. Such crizanlizumab-induced inhibition of adhesion to P-selectin reached about 60 percent at 10 μ g/mL. This dose correlates to the reported mean steady-state serum crizanlizumab concentration at 10.5 to 15.0 μ g/mL for high drug administration dose (5 mg/kg) [30]. At 60 μ g/mL of crizanlizumab, 90% of inhibition of FA-WB-PSel was reached (Figure 1A).

PC: For the Long-COVID subject with severe symptoms, supplementation of whole blood with crizanlizumab in doses up to 20 μ g/mL range did not result in any measurable inhibition of cell adhesion to P-selectin for the symptomatic patient sample. At the elevated drug doses (50-60 μ g/mL) up to 50% inhibition of adhesion P-selectin was observed, which is about half of that recorded with the asymptomatic subject at the same dose (Figure 1B).

Isolated White Blood Cells in buffer

PC&LC: Flow adhesion of isolated White Blood Cells (i-WBC) to P-selectin (FA-WBC-PSel) was similar between Long-COVID and asymptomatic post-COVID subjects, and in HBSS buffer was 1490 ± 30 and

1590 ± 110 cells/mm² correspondingly. When i-WBCs were suspended in autologous plasma (see Material and Methods), adhesion on P-selectin was decreased by 4.2- and 3.8-fold to 350 ± 20 and 420 ± 50 cells/mm² for asymptomatic post-COVID and Long-COVID subjects correspondingly (Figure 2).

PC: For the asymptomatic post-COVID subject, supplementation of buffer-suspended i-WBC with crizanlizumab resulted in a dose-dependent inhibition of WBC adhesion with the magnitude of inhibition similar to that observed in Whole Blood (the difference lacked statistical significance).

LC: For the subject with Long-COVID symptoms, supplementation of i-WBC with crizanlizumab showed nearly complete (about 95%) inhibition of cell adhesion to P-Selectin. Such un-expectantly strong adhesion inhibition had been observed event at 1 µg/mL dose of crizanlizumab, which is ten times lower than the standard clinical drug dose (Figure 3).

Isolated White Blood Cells in autologous Platelet Poor Plasma

PC&LC: Crizanlizumab supplementation of same i-WBC suspended in autologous Platelet Poor Plasma (PPP) resulted in no significant inhibition at sub-clinical crizanlizumab dose corresponding to 1 µg/mL plasma concentration and in pronounced inhibition of adhesion to P-selectin (about 80 % for asymptomatic and 65 % for symptomatic subjects, Figure 4). Similar results with adhesion inhibited by about 70-80 % were obtained when crizanlizumab-induced inhibition of adhesion was measured on i-WBC in blood-type complimentary platelet poor plasma from healthy subjects (data not shown). For the Long-COVID subject similar results had been obtained on samples collected at 11 and 20 weeks after the infection (at approximately 8 and 16 weeks after the resolution of acute COVID-19).

Whole Blood Aggregometry

PC&LC: Whole blood impedance aggregometry showed that maximum amplitude, area under the curve (AUC) and maximum rate were all elevated in post-COVID subjects, both with Long-COVID and asymptomatic, as compared to normal donors (see internal healthy control values, Table 3). Conversely, inhibition of activity induced by antiplatelet acetylsalicylic acid (ASA) was found to be more pronounced on both post-COVID subjects as compared to the instrument normal instrument control.

As compared to asymptomatic post-COVID subject, the Long-COVID subject further exhibited significantly elevated amplitude and AUC, and elevated maximum rate for the (Figure 5 and Table 3). Difference in lag time lacked significance. For both Long-COVID and asymptomatic post-COVID subjects,

in-vitro ASA supplementation resulted in marked inhibition of aggregation with the resultant similar rates and lag times. Aggregation of platelets from both post-COVID asymptomatic and Long-COVID subjects, as indicated by aggregometry, was significantly inhibited by ASA with the differences in resultant aggregation lacking statistical significance (Table 3).

Discussion

It was demonstrated that platelets from COVID-19 patients overexpress P-Selectin both basally and upon activation, associated with faster platelet aggregation and increased circulating platelet–leukocyte aggregates [31]. Significantly higher levels of the platelet activation markers including P-Selectin, had also been reported for stable hospitalized COVID-19 patients [32]. Interestingly, no changes in platelet reactivity of P-selectin expression were detected upon vaccination within 4 weeks of BNT162b2 administration, with overall activation marker expression, including P-selectin, being significantly lower than even for mild-COVID-19 patient cohort [33]. While the drivers behind platelet activation in COVID-19 remain to be determined, it is possible, that such activation occurs due to platelet interaction with the infected endothelium and/or as a result of the cytokine storm associated with SARS-CoV-2 infection [34].

Overall, the evidence seems to point to the conclusion that SARS-CoV-2 infection is indeed associated with platelet hyperreactivity, contributing to COVID-19 pathophysiology [35]. A recently completed (results are pending) Phase 2 clinical trial to test Crizanlizumab, a P-Selectin inhibiting antibody, in hospitalized COVID-19 patients (ClinicalTrials.gov Identifier: NCT04435184) highlights the attention to the hypothesized role of P-Selectin in SARS-CoV-2 infection [36].

In this work we observe that whole blood *in-vitro* treatment with P-Selectin inhibitor (Crizanlizumab) at a clinically use dose while effective in reducing P-selectin cell adhesion in an asymptomatic post-COVID subject, was ineffective in the case of a patient with severe Long-COVID symptoms. Presented results are strongly indicative of the cause being linked to persistent platelet activation with P-Selectin overexpressed on platelets essentially “scrubbing” the drug from the environment. Thus, while no adhesion inhibition was observed in whole blood of the Long-COVID subject, crizanlizumab was effective in reducing adhesion to P-selectin when used with either i-WBC in buffer or when the assay was performed in autologous platelet poor plasma (PPP). Platelet activation suggested for Long-COVID patient (LC) by the flow adhesion study was further confirmed by significantly elevated platelet activity as shown by impedance aggregometry. Such activity we equally inhibited in the presence of ASA. As

ASA inhibitory effect occurs through inhibition of cyclo-oxygenase, it would not be affected by levels of platelet P-Selectin expression [37].

Despite the mounting evidence detailing possible involvement of platelets in COVID-19, the cohesive picture of their involvement remains to be developed. Some investigations report increased platelet activation and platelet-monocyte aggregate formation in severe COVID-19 patients, but not in patients presenting mild COVID-19 syndrome [13], while other document platelet hyperactivity in COVID-19 independent of disease severity [16].

Ex vivo exposure of healthy donor platelets to plasma from severe COVID-19 patients may cause sustained control platelets activation, in terms of P-selectin expression and platelet–leukocyte aggregate formation, similar to that observed *in vivo* [38], and inducing tissue factor (TF) expression by the monocytes. Such TF expression was reduced by platelet pre-treatment with anti–P-Selectin neutralizing antibodies [13].

Platelet aggregation can be elevated in healthy women compared to men, with such sex-related difference present also after incubation with ASA [39]. A trend towards a higher platelet reactivity mainly associated with women exhibiting elevated (defined as >200 Billion cells/L) platelet counts was also reported by Ranucci et.al [40]. While gender-related factors cannot be conclusively excluded, the difference in platelet reactivity reported in this work is markedly larger than the 10% observed by Ivandic et.al [39], and likely does indicate a pathology-associated nature of the observed difference.

When tested in platelet poor plasma, adhesion on P-selectin was markedly decreased for both subjects, as compared to that in the buffer solution (see Figure 2). Such decline can be interpreted in terms of white cell PSGL-1 receptor binding with soluble P-selectin that would be present in subject’s plasma, but not in the buffer medium. Soluble P-selectin would be present in plasma in its monomeric, as opposed to oligomeric form typical for membrane bound P-selectin. However, only the lectin and epidermal growth factor domains are necessary for P-selectin interaction with PSGL-1 [41]. Thus, monomeric sP-selectin was shown to binds to high affinity ligands on leukocytes with its avidity for leukocytes enhanced when the protein is present in an oligomeric transmembrane form [42]. Significantly, the loss of surface P-selectin does not seem to prevent platelets from circulating and function, showing aggregation, adhesion, and procoagulant activity [21].

Higher activation status of platelets for the Long-COVID subject along with decreased efficacy of P-selectin adhesion inhibition described above, would seem to imply higher sP-selectin levels in Long-COVID autologous plasma [43]. However, sP-selectin plasma pool would also include sP-selectin originated from vascular endothelial cells and the significance of platelet contribution to it had not been assessed in this work. Evaluation of the role and significance of sP-selectin in mediation of whole blood and plasma response to P-Selectin inhibition therapy would be the subject of future research.

In-vitro treatment with crizanlizumab of i-WBC suspended in the autologous PPP resulted in comparable inhibition of flow adhesion (see Figure 4). However, in the same assay performed in buffer solution, i-WBC from the subject with severe Long-COVID symptoms showed much faster and stronger response, with close to complete inhibition of P-selectin adhesion even at sub-clinical crizanlizumab dose (see Figure 3). This seems to indicate either decreased PSGL-1 expression or more likely, a decrease in activation-dependent post-translational PSGL-1 modification. It is known that expression of the native protein is insufficient for selectin binding, and activation-associated post-translational modifications by sialic acid (SiA) and fucose are required to enable PSGL-1 binding to P-Selectin with high affinity [44]. Significantly, O-glycan modification involved in PSGL-1 activation was shown to regulate blood cell activity by influencing the balance between selectin-mediated cell rolling and cellular response to the chemotactic cues used in steady state T-cell traffic, reflecting platelet role as effector cell involved in both hemostasis and in pathological thrombosis [45].

Interestingly, SiA that is critically involved in PSGL-1 posttranslational modifications, is an established target for binding activity by many coronaviruses [46]. Comparing to influenza virus family which uses Hemagglutinin, a glycoprotein coat protein, to target SiA on host cell membranes, SARS-CoV-2, seems rely on more specific interactions facilitated by the virus S-protein. It is present on ACE2 receptors and is an integral part of, which present glycosphingolipid with one or more SiA molecule(s) linked to the sugar chain. On a cellular level, the entry pathway for SARS-CoV-2 was suggested to be through SiA-mediated interactions with the receptor-binding domain of the viral spike protein [47]. It was suggested that diverse clinical presentation of COVID-19 and specifically differences in age and gender associated severity may, in part, be explained through age and gender-related variability of sialome among the patients [48]. Overall, the clinical importance of SiA-mediated interactions between the host cell and virus certainly require further investigation [49].

SiA receptor-destroying enzymes like Neuraminidase (NEU) in influenza or hemagglutinin-esterase (HE) in some coronaviruses, mediate cleavage of surface SiA-containing cell receptors promoting viral

particles release from infected cells. Endogenous cell NA activity plays a role in shedding of cell surface SiA, plays a key role in activation of both platelets [50] and neutrophils [51]. While SARS-CoV-2 seem to be lacking HE gene [52], samples from COVID-19 patients revealed an overexpression of NEU in infected neutrophils and treatment with NEU inhibitors led to decreased host NEU-mediated shedding of cell SiA and reduced overactivation of neutrophils [53]. The limitation of this discussion is that the possibility of leukocyte-platelet aggregates co-purifying during i-WBC isolation cannot be completely ruled out.

It remains uncertain whether SARS-CoV-2 is capable of established a persistent and stable chronic infection in human tissues like other SARS coronaviruses [54]. Nevertheless, viral RNA is known to persist in human body well past the resolution of the active infection [3] and SARS-CoV-2 RNA had been identified in samples from patients long time after the resolution of the active infection [55-57].

Considering that SARS-CoV-2 RNA present in the blood stream was associated with platelet hyperactivity [58, 59], a similar mechanism for platelet activation can be suggested for Long-COVID case. The key limitation of such a hypothesis would derive from the fact that the above studies observed SARS-CoV-2 RNA up to a maximum of 3 months after the infection, while in the presented case, the Long-COVID patient (LC) presented platelet hyperactivity at 20 weeks and experienced severe Long-COVID symptoms even at 28 weeks after the resolution of active COVID-19 disease. In that regard, the potential for persistent SARS-CoV-2 or presence of active viral RNA in patient body more than half a year post resolution had not been fully assessed. The uncertain potential for disease resurgence and/or spread gives this question extra importance and urgency.

The clear limitation of this work is the observation of a single Long-COVID patient, even if contrasted with an asymptomatic post-COVID subject. Moreover, it is not known to what extent *in-vitro* observations would translate to *in-vivo* treatment efficacy, especially to its long-term effects, with the treatment-related changes to cell function accumulating over time. Additionally, interaction of P-selectin inhibitors with overexpressed P-selectin on platelets of Long-COVID patients can potentially alter platelet function leading to possible clinical effects not directly observable through or related to cell adhesion to P-selectin. There could be significant potential differences in efficacy of P-selectin inhibitors drugs in terms of their action on the protein expressed on blood cells (likely, mostly platelets) as opposed to drugs' impact on flow-mediated interaction with endothelially expressed immobilized P-selectin. However, relative significance of these two mechanisms of action to drug clinical efficacy still remains to be elucidated.

It also remains presently unknown to what extent the observed cell function alterations in severe Long-COVID case are indeed a general feature of the condition or a feature of clinical presentation in that particular patient. Clinical presentation reported for SARS-CoV-2 infection is highly variable, and such is likely to extend to Long-COVID sequelae. Individual variability could be expected to play a significant role, likely on a background of certain common condition-associated factors, potentially including platelet hyperactivity with P-Selectin overexpression and alteration in functionality of PSGL-1 leukocyte receptor reported here. Where such are general features of Long-COVID or a singular individual response, may be an important question affecting the scope of utility of P-selectin inhibitor drugs in Long-COVID treatment. Further work is warranted to expand our understanding on mechanisms defining altered cell functionality in Long-COVID.

Conclusions

- Severe Long-COVID subject presented platelet hyperactivity associated with increased P-Selectin activity and seemingly with alteration in functionality of PSGL-1 leukocyte receptor, while the asymptomatic post-COVID subject did not present similar alterations of blood cell function.
- The data suggests significantly higher levels of p-selectin activity in Long-COVID, suggesting P-selectin activity as a potential driver of Long-COVID pathology.
- At similar concentrations, crizanlizumab, a p-selectin inhibitor, was significantly less effective in elucidating a response in Long-COVID patient as compared to asymptomatic post-COVID subject with several-fold larger dose was required to generate a moderate response in Long-COVID subject based on cell adhesion to immobilized P-selectin.

Conflict of interest statement

B. Hannan, M. Ferranti, S. Mota and A. Zaidi are employees, and X. Gao, P. Hines, and M. Tarasev are employees and shareholders of Functional Fluidics Incorporated, a company developing and commercializing assays for assessment of blood cell functions.

Table 1

Subject (LC) Long-COVID symptoms development

Symptom ¹	Time after SARS-CoV-2 exposure, weeks			Comment
	11	20	28	
Brain fog	8	8	6	Frequent random moments of forgetfulness and fog that started only after the recovery from SARS-CoV-2 infection
Headaches	7	6	5	Ongoing dull headaches: by 28 weeks after the exposure decreased in frequency to 2-4 times a week, but not responding to treatment by normal headache medication
Fatigue	8	8	7	Subject commented that at 28 weeks “Fatigue has begun to wear off, but still hits hard at different times”
Hair Loss	9	8	1	Was ongoing, but stopped at about around 24 weeks
Burning in the nose	8	7	3	Added and highlighted by the subject. Described as an ongoing sensation ‘burning in the nose like I have to sneeze”
Menstrual cycle	+++	++	+	Cycle regular during the active infection with a 3-weeks additional delay after the recovery. About 5 weeks cycle afterwards (+++) slowly moving back to normal after 3 months post exposure (++) , normalizing at about 28 weeks after the infection

¹Self-reported severity of symptoms is shown with 0 being barely ever and 10 being very bad/frequent

Table 2

Weeks past the resolution of SARS-CoV-2 infection	Post-COVID subject (male)	Long-COVID subject (female)		Reference range ¹	Average reported values (mean ± SD)
	2.5 weeks	11 weeks	20 weeks		During active COVID-19
