Running Title: MM MRD Negativity Correlates with Stool Butyrate

Key Points

1. In MM on lenalidomide maintenance, stool butyrate concentration at 3 months was associated with higher rates of MRD negativity at 12 months.
2. Increased seafood and plant proteins, dietary flavonoids, and diversity of dietary flavonoids correlated with stool butyrate concentrations.

¹Shah U, Derkach A, Adintori P, et al. P-042: Sustained minimal residual disease negativity in Multiple Myeloma is impacted positively by stool butyrate and healthier plant forward diets. *Clinical Lymphoma, Myeloma and Leukemia*. 2021;21:S61.

Abstract

Sustained minimal residual disease (MRD) negativity is associated with long-term survival in multiple myeloma (MM). The gut microbiome is affected by diet, and in turn can modulate host immunity, for example through production of short-chain fatty acids including butyrate. We examined the relationship of dietary factors, stool metabolites, and microbial diversity with sustained MRD negativity in patients on lenalidomide maintenance. At 3 months, higher stool butyrate concentration ($p=0.037$), butyrate producers ($p=0.025$) and α -diversity ($p=0.0035$) were associated with sustained MRD-negativity. Healthier dietary proteins, (from seafood and plants), correlated with butyrate at 3 months ($p=0.009$) and sustained MRD-negativity ($p=0.05$). Consumption of dietary flavonoids, plant nutrients with antioxidant effects, correlated with stool butyrate concentration (anthocyanidins $p=0.01$, flavones $p=0.01$, and flavanols $p=0.02$). This is the first study to demonstrate an association between a plant-based dietary pattern, stool butyrate production and sustained MRD-negativity in MM; providing rationale to evaluate a prospective dietary intervention.

Statement of Significance

We demonstrate an association between diet, the gut microbiome, and sustained MRD-negativity in MM. A healthy diet, with adequate plant and seafood protein, and containing flavonoids, associates with stool diversity, butyrate production and sustained MRD-negativity. These findings suggest dietary modification should be studied to enhance myeloma control.

Introduction

Multiple myeloma (MM) remains incurable, however, sustained minimal residual disease (MRD) negativity following therapy represents the best predictor of survival.(1) Our prior studies in newly diagnosed MM demonstrated an increased relative abundance of *Eubacterium hallii* and *Faecalibacterium prausnitzii* in the stool samples collected following induction in MRD-negative patients.(2) In allogeneic hematopoietic cell transplantation, an increased abundance of *Eubacterium limosum* is associated with a lower risk of relapse and prolonged post-transplant survival.(3) These bacteria produce the short-chain fatty acid (SCFA) butyrate from dietary fiber and starch in plant foods. The SCFA butyrate can modulate systemic immunity through inhibition of NF- κ B and histone deacetylases (HDAC), producing transcriptional modulation and a reduction in proinflammatory cytokines.(4-6)

Dietary composition plays a significant role in shaping the intestinal microbiome, with enrichment of stool butyrate concentration having been reported in individuals on a plant-based diet compared with an animal-based diet(7). In addition, dietary flavonoids, (plant derived nutrients) modulate both the microbiome and intestinal immune functions.(8, 9) We hypothesized that dietary factors that affect the microbiome, in particular the abundance of butyrate-producing bacteria or stool butyrate concentration, may be associated with MM outcomes. Here, in the context of lenalidomide maintenance therapy, we evaluated the relationship of dietary factors, stool metabolites and microbial composition with sustained MRD-negativity.

Results

Baseline patient characteristics are presented in **Table 1**. Samples were available from 74 MM patients including 59 with assessment of habitual dietary patterns, and 49 with 16S sequencing of the stool microbiome. The overlap of dietary assessment and stool examination was present in 34 patients, of which 32 had stool butyrate concentration measurements (**Figure 1**). All patients had MRD status assessed at enrollment, with 42 being MRD-positive and 32 MRD-negative. Serial assessment of MRD status was performed in 68 patients at 12 months (m), 61 at 24m and 48 at 36m from enrollment. Sustained MRD-negativity was observed in 31 patients.

As a subset of patients had undergone autologous hematopoietic cell transplantation (AHCT) prior to maintenance therapy (33/74, 45%), the timepoint for microbiome evaluation of 3m post-enrollment was chosen to allow resolution of post-AHCT reduction in microbiome diversity.(10) α -diversity of the fecal microbiome at 3m was significantly higher in those with sustained MRD-negativity (median 16.9, interquartile range [IQR] 14.8-28.0), compared with those without (median 11.9, IQR 9.9-18.6, $p=0.0035$) (**Figure 2a**). The relative abundance of predicted butyrate-producers was also significantly higher in patients with sustained MRD-negativity (median 0.093, IQR 0.072-0.100) than those without (median 0.054, IQR 0.035-0.094, $p=0.025$) (**Figure 2b**).

Stool butyrate concentration at 3m was also significantly higher in patients who achieved sustained MRD-negativity (median 18.1, IQR 10.7-29.0mM) compared to those who did not (median 10.0mM, IQR 6.6-16.2mM) ($p=0.037$) (**Figure 2c**). These associations remained significant after adjusting for AHCT and high-risk cytogenetic features (deletion 1p32, gain 1q21, t(4;14) or deletion 17p). Other stool metabolites (acetate, propanoate, valerate, heptanoate, isobutyrate, methylbutyrate, isovalerate) did not correlate with MRD-status (p -values >0.1). Collectively, these data suggest that sustained MRD-negativity in MM is associated with higher α -diversity, relative abundance of butyrate producers and concentration of stool butyrate.

Considering that dietary factors play an important role in the production of SCFA, we examined the relationship between diet composition (components of HEI-2015 score), stool butyrate concentration, and subsequent MRD-status and identified certain significant correlations (**Supplementary Table 1**). The components total protein as well as seafood and plant protein were associated with stool butyrate concentration at 3m ($R=0.5$, $p=0.004$ and $R=0.45$, $p=0.009$ respectively). Seafood and plant proteins include seafood, nuts, seeds, soy products (excluding beverages), and legumes (beans and peas). The standard for maximum score is ≥ 0.8 cup equivalent per 1,000 kcal and standard for minimum score of zero is no seafood or plant proteins. These components also correlated with sustained MRD-negativity ($p=0.01$ and $p=0.05$ respectively). To further explore the evidence supporting a plant-based diet, we measured dietary flavonoids in this cohort. Total anthocyanidins ($R=0.47$, $p=0.01$), flavones ($R=0.48$, $p=0.01$), and flavanols ($R=0.42$, $p=0.02$) correlated with stool butyrate. Additionally, the Dietary Flavonoid Diversity Index was associated with butyrate concentration ($R=0.46$, $p=0.008$) and microbiome diversity ($R=0.38$, $p=0.03$) (**Supplementary Table 2**).

Discussion

In the context of lenalidomide maintenance therapy for MM, we demonstrate for the first time an association between diet, the gut microbiome, and sustained MRD-negativity in MM. Our data show that sustained MRD-negativity among patients receiving lenalidomide is associated with higher microbial α -diversity, relative abundance of butyrate producers and concentration of stool butyrate measured after 3 months on lenalidomide maintenance. Together with our prior publication demonstrating increased butyrate producers, specifically *Eubacterium hallii* and *Faecalibacterium prausnitzii* in MRD-negative patients following induction therapy(2), this study further strengthens the hypothesis that specific microbiome features, especially butyrate levels may predict clinical outcomes in MM.

Butyrates have previously been shown to modulate immunity by exerting anti-inflammatory functions through inhibition of the transcription factor NF- κ B, leading to reduced formation of proinflammatory cytokines.(4, 5) They also non-competitively inhibit HDACs, acting in the same way as panobinostat, an HDAC inhibitor with activity in MM.(4, 6)

The dietary associations described in our study are consistent with prior epidemiologic data. Higher HEI-2015 scores correlated with reduced cancer risk and mortality.(11, 12) In the EPIC Oxford study, including 61,647 individuals of which 65 developed MM, those on vegetarian and vegan diets had reduced risk of development of MM compared to meat eaters (relative risk 0.23; 95% confidence interval (CI) 0.09-0.59).(13) In the Nurses' Health Study and Health Professionals Follow-up study that included 165,796 individuals with 423 MM cases and 345 deaths, those with healthier pre-diagnosis dietary pattern based on the alternative healthy eating index 2010 had lower MM mortality (hazard ratio 0.76; 95% CI 0.67-0.87).(14) The association of butyrate concentration with seafood and plant protein scores, dietary flavonoids, and dietary flavonoid diversity support the hypothesis that a diverse plant-based diet may have an impact on MM via butyrate production suggesting the potential for an underlying mechanistic basis.

Strengths of this study include the availability of simultaneous dietary, stool microbiome and metabolite assessment, as well as long term MRD data, and the consistent association between the relative abundance of predicted butyrate producers and stool butyrate levels. Limitations include the lack of untreated patient samples prior to myeloma therapy initiation, a small sample size that had all study assessments, dietary recall bias and potential confounding from other aspects of an individual's lifestyle and circumstances.

Nevertheless, our data support the hypothesis that a healthy diet, with adequate high-quality plant and seafood protein, and dietary flavonoids may have a positive impact on stool diversity, butyrate production and MM outcomes (**Figure 3**).

In conclusion, our study suggests that lifestyle modification in the form of dietary change may potentially contribute to MM control. We therefore believe that further study of prospective dietary interventions in plasma cell disorders is warranted and have initiated a prospective whole-foods plant based dietary interventional trial in MM precursor disease (NCT04920084, NUTRIVENTION).

Methods

MM patients eligible for maintenance during first-line therapy were enrolled prospectively, and received lenalidomide for up to 5 years.(15) MRD status was evaluated at enrollment then annually using a validated bone marrow-based flow cytometric assay⁽¹⁶⁾ with a sensitivity of at least 10^{-5} . Treatment responses were assessed according to International Myeloma Working Group consensus criteria(17), with sustained MRD-negativity defined as MRD-negativity at two consecutive time points 1 year apart between enrolment, 12m and 24m. Progression-free survival was not used as an endpoint given the low rate of clinical progression.

Stool samples were collected and analyzed as detailed previously(2) with identification of predicted butyrate-producing bacteria.(18) The relative abundance of predicted butyrate-producers and microbiome α -diversity were calculated from 16S microbiome profiles in

samples collected 3 months (m) from enrollment. We performed direct quantitation of stool metabolite concentrations using gas chromatography–mass spectrometry on the same stool samples.

Comparison of α -diversity (as measured by the inverse Simpson index) and relative abundance of butyrate producers were assessed using the Wilcoxon rank sum test. The association between dietary and microbiome data were evaluated by Spearman's rank correlation coefficient (R). The Kruskal–Wallis test was used to evaluate association between sustained MRD-negativity, microbiome, and dietary measurements. In this exploratory analysis we declared statistical significance at a two-sided significance level below 0.05.

Habitual dietary patterns were collected using the Block Food Frequency Questionnaire 2014 (FFQ)(19) and summarized using the United States Department of Agriculture's (USDA) Healthy Eating Index 2015 score (HEI-2015)(20) and a newly developed Dietary Flavonoid Diversity Index (*DFDI*) by NutritionQuest. The HEI-2015 is a measure of diet quality, assessing 13 nutrient and food group components, with higher scores indicating healthier diets.(20) Flavonoid nutrient values were calculated from the FFQ based on USDA data. The *DFDI* measures the diversity of flavonoid intake from foods and beverages consumed at least once per week, following the Berry-Index method(21, 22); scores range from 0-1, with higher scores indicating a greater diversity of flavonoid intake.
