### <sup>33</sup>**Abstract**

<sup>34</sup>COVID-19 has demonstrated the devastating consequences of the rapid spread of an airborne 35 virus in residential aged care. We report the use of  $CO<sub>2</sub>$ -based ventilation assessment to 36 empirically identify potential "super-spreader" zones within an aged care facility, and 37 determine the efficacy of rapidly implemented, inexpensive, risk reduction measures.

<sup>38</sup>**Main Text** 

39 Outbreaks of COVID-19 in residential aged are facilities (RACF) have proven devastating. <sup>40</sup>The combination of high transmission rates and resident vulnerability has led to rates of <sup>41</sup>mortality that are higher than any other setting, including acute care hospital facilities [1]. In <sup>42</sup>response, aged care providers and public health authorities have enacted measures to reduce 43 the risk of SARS-CoV-2 exposure to prevent transmission within facilities. These measures <sup>44</sup>include social distancing, reduced visitation by family members (site lockdowns), the <sup>45</sup>wearing of personal protective equipment (PPE) by staff and visitors, and isolation of those 46 with active infection. The impact of these measures on the well-being and quality-of-life of 47 residents, more than half of whom have reduced cognitive ability or dementia [2], has been 48 considerable [3]. The need to identify less disruptive measures to protect RACF populations 49 from airborne viral transmission (including respiratory viruses other than  $SARS-CoV-2$ ) is 50 urgent.

51 Current strategies to reduce rates of indoor viral transmission can be placed into two broad 52 categories; 1) those that reduce the susceptible occupant population, including occupancy 53 limits, vaccination programs, and PPE use, and 2) those that prevent the accumulation of 54 viable viral particles within the circulating air of an RACF environment [4]. This latter group 55 of measures is more effective as it doesn't require any behaviour changes to staff or visitors. 56 It also offers long-term advantages by avoiding the need to place additional burden on facility 57 residents and staff, or the need to limit access to facilities by family members. Several

<sup>58</sup>strategies to reduce the build-up of viable viral particles can be employed, including the use 59 of high-efficiency particulate absorbing (HEPA) air-filtration, or ultraviolet C (UVC) <sup>60</sup>disinfection devices [3,4]. However, most effective approach is arguably to remove viral 61 particles through increased ventilation [5].

62 Outdoor venues are associated with a low relative risk for airborne viral transmission due to 63 the rapid clearance of virus-containing airborne particles through natural air movement. 64 Indoor spaces, where air exchange is considerably reduced, are estimated to have a SARS-<sup>65</sup>CoV-2 transmission risk that is more than 18 times higher [6]. Increasing rates of air <sup>66</sup>exchange within the built environment would reduce this transmission risk substantially. The 67 principal reason that this strategy has not been employed widely is the considerable costs <sup>68</sup>associated with heating or cooling external air [7]. Instead, many facilities, including RACFs, <sup>69</sup>typically employ high rates of air recirculation, inadvertently resulting in recirculation of the 70 virus as well  $[5]$ .

71 Increasing ventilation within facilities that house vulnerable populations has been advocated <sup>72</sup>widely during the COVID-19 pandemic [8]. However, implementation of ventilation <sup>73</sup>measures has been limited. The ability to target increases in air exchange to those zones <sup>74</sup>within facilities that carry the highest transmission risk would greatly increase the financial 75 feasibility of improving ventilation. Here we report the use of a rapid, low-cost, strategy to 76 empirically identify potential "super-spreader" zones within an RACF, and the efficacy of the 77 targeted ventilation-based risk reduction measures that were deployed in response.

78 While atmospheric  $CO<sub>2</sub>$  levels remain relatively constant, indoor  $CO<sub>2</sub>$  levels increase as a 79 result of human respiration. Elevated  $CO<sub>2</sub>$  levels have been used widely as a marker of indoor 80 air quality and, relative to occupancy, a measure of air exchange and ventilation efficiency. 81 Indeed, such measures correlate strongly with infectious disease outcomes, such as 82 absenteeism due to acute respiratory infection [9].  $CO<sub>2</sub>$  levels can be determined accurately

83 using inexpensive monitors, allowing for high transmission risk zones within facilities to be 84 identified rapidly and mitigation strategies to be enacted. We used 62 wall-mounted 85 remotely-monitored  $CO_2$  sensors (Aranet4 Pro Sensors, Radical, Australia) to monitor  $CO_2$ 86 levels over a four-week period within a two-storey 110-bed RACF in Australia. During this 87 period, all staff and visitors to the RACF were required to wear N95 face masks (or 88 equivalent), goggles or face shield, and be vaccinated against COVID-19. Deployment of 89  $CO<sub>2</sub>$  monitors covered the majority of accessible sites within the facility, including "back of 90 house" areas used by staff only  $(n=17)$  and mixed communal areas used by both staff and 91 residents ( $n=45$ ). The zones employed a range of heating, ventilation, and air-conditioning 92 (HVAC) systems, including evaporative cooling with 100% fresh ducted air, refrigerated 93 reverse cycle ducted air, refrigerated reverse cycle split system, and exhaust air. Each monitor 94 also captured temperature, humidity, and pressure, enabling data normalisation.

<sup>95</sup>Over the course of the survey period, none of the 45 mixed zones showed indications of poor 96 ventilation, with the highest peak  $CO<sub>2</sub>$  concentration being 830 ppm, which was in the 97 resident dining room during the lunch period. However, of the 17 assessed back of house 98 zones, which were only accessible to staff, 3 were identified as high transmission risk based 99 on  $CO<sub>2</sub>$  levels exceeding 1000 ppm for a period of 15 min or more (levels logged at 60 100 second intervals). These included one of the two staff lunch rooms and two of the three staff <sup>101</sup>meeting rooms (**Figure 1A**). Interventions were identified based on the zone usage, the <sup>102</sup>HVAC modality employed, and the ability to achieve improved ventilation rapidly and at low 103 relative cost.

104 *High risk zone 1:* The staff lunch room had a floor area of 19 m<sup>2</sup> with a refrigerated reverse 105 cycle split system HVAC. Despite room density restrictions of 1 person per 4  $m<sup>2</sup>$ , high, 106 regular, and prolonged  $CO<sub>2</sub>$  peaks were identified in the lunch room corresponding to meal 107 breaks (**Supplementary Figure 1**). Of note, staff were not masked while eating and CO<sub>2</sub>

108 levels did not return to baseline levels for several hours after these peak periods. To quantify 109 room ventilation, a subsequent  $CO<sub>2</sub>$  decay curve was generated over a 6-hour period, during 110 which the staff lunch room was not occupied. The resulting air changes per hour (ACH) was <sup>111</sup>0.65 (**Figure 1B**), which is 10-fold lower than the Australian Standards for ventilation in a 112 healthcare setting [10]. Discussion with the facility's environmental management team 113 identified that installation of an extraction fan at a cost of \$3400 AUD would effectively 114 ventilate the room. The fan was set to extract air at  $100$  L/s and connected to a room sensor 115 allowing usage to be limited to times of room occupancy. Retesting ventilation by  $CO<sub>2</sub>$  decay 116 curve after extraction fan installation yielded an improved ACH of 5.30 (**Figure 1B**). 117 Ongoing running costs of the extraction fan were calculated by an AC current and voltage 118 data logger to be \$40.20 AUD per year.

119 *High risk zones 2 and 3:* Two staff meeting rooms also had  $CO_2$  peaks indicative of high 120 transmission risk. The first room had a floor area of 50  $m<sup>2</sup>$  and a refrigerated reverse cycle 121 ducted air system controlled by a remote control.  $CO<sub>2</sub>$  peaks in this room were less frequent 122 than the staff lunch room, with a total of two peaks over 1000 ppm during the survey period. <sup>123</sup>It was noted by facility management that the HVAC was rarely switched on during meetings, 124 potentially explaining these  $CO<sub>2</sub>$  peaks. Intervention strategies were therefore minimal, with 125 the HVAC system programming adjusted to automatically turn on during times when the 126 room is in use. The second room had a floor area of 20  $m<sup>2</sup>$  and a refrigerated reverse cycle 127 split system HVAC. Like the first meeting room, a total of two peaks above 1000 ppm were 128 recorded in this room during the survey period. However, unlike the first meeting room, 129 existing HVAC could not be easily modified to improve ventilation. Interim protocols were 130 therefore implemented, continuing a mandated mask use and room density limit for staff 131 using this room.

<sup>132</sup>Globally, the COVID-19 pandemic has again underlined the vulnerability of those living in 133 residential aged care to airborne transmission of viral infections. In addition to COVID-19, <sup>134</sup>seasonal respiratory viruses, including seasonal influenza and respiratory syncytial virus <sup>135</sup>(RSV) represent a major cause of morbidity and mortality for residents [11]. Indeed, 136 following a period of reduced exposure, the seasonal influenza peaks in 2022 are predicted to 137 pose a significant health threat, as seen in the 2021-2022 winter in the Northern Hemisphere <sup>138</sup>[12]. Targeting effective risk reduction measures to areas that are likely to contribute 139 disproportionately viral spread could provide considerable protection.

140 In our analysis, passive and simulated  $CO<sub>2</sub>$  levels were used to identify high transmission risk 141 zones. Such approaches are simple and readily deployable, however do not account for other 142 factors affecting transmission risk, such as PPE and level of interaction [13].  $CO<sub>2</sub>$  peaks were 143 also based on levels recommended by The American Society of Heating, Refrigerating and <sup>144</sup>Air-Conditioning Engineers (ASHRAE) of less than 600 ppm above outdoor concentrations <sup>145</sup>(approximately, 420 ppm) [14]. The recommendation of these thresholds is based on 146 consideration of a number of factors, including comfort. Alignment of target levels more <sup>147</sup>closely with empirically assessed viral transmission rates would enable further protocol 148 refinements.

<sup>149</sup>The approach we describe has the potential to be applied beyond aged care. Rapid, targeted, 150 improvements in air quality management, based on empirical facility surveys, could 151 substantially reduce airborne pathogen transmission in other high-risk contexts, and warrant 152 consideration in settings such as detention facilities, hospitals, or schools.
