25 **Keywords:** Wastewater, Variant callers, Sequencing, SARS-CoV-2

26 **Abstract**

27 Wastewater-based epidemiology (WBE) has been used extensively throughout the COVID-
28 19 pandemic to detect and monitor the spread and prevalence of SARS-CoV-2 and its
29 variants. It has proven an excellent, complementary tool to clinical sequencing, supporting
30 the insights gained and helping to make informed public health decisions. Consequently,
31 many groups globally have developed bioinformatics pipelines to analyse sequencing data
32 from wastewater. Accurate calling of mutations is critical in this process and in the
33 assignment of circulating variants, yet, to date, the performance of variant-calling algorithms
34 in wastewater samples has not been investigated. To address this, we compared the
35 performance of six variant callers (VarScan, iVar, GATK, FreeBayes, LoFreq and BCFtools),
36 used widely in bioinformatics pipelines, on 19 synthetic samples with known ratios of three
37 different SARS-CoV-2 variants (Alpha, Beta and Delta), as well as 13 wastewater samples
38 collected in London between the 15–18 December 2021. We used the fundamental
39 parameters of recall (sensitivity) and precision (specificity) to confirm the presence of
40 mutational profiles defining specific variants across the six variant callers.

41 Our results show that BCFtools, FreeBayes and VarScan found the expected variants with
42 higher precision and recall than GATK or iVar, although the latter identified more expected
43 defining mutations than other callers. LoFreq gave the least reliable results due to the high
44 number of false-positive mutations detected, resulting in lower precision. Similar results were
45 obtained for both the synthetic and wastewater samples.

46 **Introduction**

47 On March 11th, 2020, the World Health Organisation (WHO) declared a global pandemic
48 following the rapid spread of a novel coronavirus, severe acute respiratory syndrome
49 coronavirus 2 (SARS-CoV-2) [1], which causes coronavirus disease 19 (COVID-19). Since
50 then, wastewater-based epidemiology (WBE) has proven a promising tool to detect and
51 monitor SARS-CoV-2, act as a proxy for infections within certain regions/communities and
52 provide an early-warning of disease outbreaks [2]. It has been widely used across the globe to
53 complement conventional clinical surveillance, which is limited in population coverage,
54 capacity or engagement (e.g., self-testing/reporting) [3]. In this regard, it is evident that WBE
55 can be used to monitor disease prevalence in a community, allowing targeted public health
56 measures to be implemented at relative pace and geographical specificity, in combination
57 with other data. Moreover, WBE is non-invasive and less biased than clinical data, making it
58 a valuable molecular surveillance tool [4, 5].

59 Since the initial outbreak of SARS-CoV-2, several variants of concern (VOCs), variants
60 under investigation or monitoring (VUIs/VUMs) and variants of interest (VOIs) have
61 circulated globally. According to the WHO, as of May 2022, there have been five VOCs
62 (Alpha, Beta, Gamma, Delta and Omicron), eight VOIs (Epsilon, Zeta, Eta, Theta, Iota,
63 Kappa, Lambda, Mu) and two VUIs (B.1.640 and XD) [6]. While VOCs have transmitted
64 worldwide, VUIs are country-specific, with over 200 sub-lineages of the main circulating
65 variants reported by individual countries [7]. In England, the Horizon Scanning Programme,
66 part of the UK Health Security Agency (UKHSA), has been monitoring circulating variants,
67 including VOC, VUI/VUM and VOIs, identified by deep sequencing of a large cohort of
68 Covid-19 positive patients by COG-UK (Covid-19 Genomics UK) [8, 9]. Since the
69 declaration of the pandemic, this totals over 2 million patients in the UK alone [10].
70 However, the sequencing datasets generated lacked asymptomatic cases and cases not
71 sequenced.

72 The Environmental Monitoring for Health Protection programme (EMHP), part of the
73 UKHSA, has used reports produced by the Horizon Scanning Programme to monitor the
74 same variants in wastewater collected in England. However, the analysis of SARS-CoV-2
75 sequences from wastewater samples is more complicated than clinical samples obtained using
76 nasopharyngeal swabs. Discrepancies between clinical and wastewater samples have been
77 observed; in particular, the mixed strain nature of wastewater samples, the more degraded
78 nature of viral genomes and, consequently, the inability to obtain consensus genome

79 sequence for each of the samples analysed. These differences can be accounted for by the
80 nature and characteristics of the samples (wastewater vs clinical) and characteristics
81 impacting the ability to extract and analyse the samples, such as virus titre, which is
82 considerably lower in wastewater samples that, in turn, may affect variant calling such as
83 sample preparation, with additional steps such as centrifugation and filtration methods
84 required to purify the samples from chemicals and other sources of contamination and
85 platform dependent sequencing errors [11-14].

86 Several bioinformatics pipelines have been developed to specifically detect SARS-CoV-2
87 sequences and variants in wastewater samples, including ncore/viralrecon [15] and V-PIPE
88 SARS-CoV-2 [16]. However, most studies have relied heavily on the ARTIC pipeline
89 initially designed with clinical samples in mind, or, as in the case of the EMHP programme in
90 England, an adaptation of this pipeline. Common sequencing pipelines, including ARTIC,
91 involve the removal of low-quality sequencing reads, followed by read mapping and variant
92 calling to define mutations found in the sample (Single Nucleotide Polymorphisms – SNPs –
93 and INsertions/DEletions) [17]. This is performed by highly specialised tools known as
94 variant callers. The ARTIC pipeline for sequence analysis of clinical samples utilises iVar,
95 which relies on the samtools mpileup command as its variant calling function [17]. While this
96 has been well documented in clinical studies, very little is known about its performance for
97 wastewater samples. To address this knowledge gap, the EMHP programme in England
98 adapted this protocol, using VarScan as an alternative to iVar, delivering significantly
99 improved results when applied to wastewater samples [18, 19]. Before screening for sequence
100 changes, VarScan uses the BAM alignment file as the input to score each of the reads
101 produced during sequencing. If reads are found to align to multiple locations and/or are of
102 low quality, they are automatically discarded. For the remaining reads, SNPs and Indels are
103 compiled for each of the locations across the viral genome and validated depending on factors
104 such as the overall coverage, the number of reads across the site of the mutation and base
105 quality, among others.

106 Several genomic studies have compared and highlighted the impact that variant caller choice
107 has on the analysis pipeline, including iVar [17], GATK [20], LoFreq [21], FreeBayes [22]
108 and BCFtools [23]. FreeBayes is a haplotype-based variant caller where variants are called
109 based on the sequences of reads aligned to a particular target rather than the specific
110 alignment. One of the main advantages of this method is that it bypasses the problem of
111 identical sequences that might align to multiple locations. On the other hand, GATK uses

112 HaplotypeCaller as a tool to call germline SNPs and Indels via local re-assembly of
113 haplotypes [22]. More specifically, it assembles and realigns reads to their most likely
114 haplotypes. Comparison with the reference of choice is used to calculate the likelihood of
115 each possible genotype and call possible variants. LoFreq is a high-quality and highly
116 sensitive tool to detect variants in heterogeneous samples, such as tumour samples [21]. It
117 was developed under the assumption that it is hard to distinguish true variants from
118 sequencing errors. In this regard, LoFreq is a very robust and sensitive variant caller that uses
119 base-called quality values to call variants accurately. It differs from other callers as it can
120 find SNPs and Indels at a frequency below the average sequencing error. As such, it is not
121 ideal for low-coverage genomes. BCFtools is a collection of several commands, among
122 which *call* is used for SNP/indel calling [23]. It generates the *mpileup* from the BAM
123 alignment reads and then computes the variant calling. This step is the same as VarScan,
124 which generates *mpileup* using SAMtools. iVar uses the output of the SAMtools *mpileup*
125 command to call variants as VarScan and BCFtools; however, it is not adapted for use in
126 mixed strain samples, such as those derived from wastewater where mixed populations are
127 found in the same sample [17]. [24, 25]. Indeed, it is globally acknowledged that the
128 detection of defining SNPs and Indels allows the assignment of VOCs, VUIs, VUMs and
129 VOIs to wastewater samples, thus their accurate identification is paramount for variant
130 detection in the context of WBE.

131 In this manuscript, we evaluated the performance of six different variant callers and their
132 ability to detect SNPs and indels in samples containing a mixture of synthetic SARS-CoV-2
133 control variants, as well as wastewater samples collected across Greater London during the
134 pandemic.

135

136

137 **Methods**

138 **Sample library preparation and sequencing**

139 The synthetic SARS-CoV-2 control variant dataset contained samples that consisted of a mix
140 of three variant genomes: Alpha (Control 15), Beta (Control 16) and Delta (Control 23)
141 synthesised by TWIST Biosciences, USA (Table 1). For each sample in the synthetic dataset,
142 three of these genomes were mixed in different ratios up to a total concentration of 200
143 genome copies per μ L, ranging from 0 to 100% of each synthetic genome, in quadruplicates.
144 The mutation profile of each of the synthetic genomes is provided in Supplementary Table 1.
145 Wastewater samples were collected between the 15–18 December 2021 in eight locations
146 across the city of London, UK. Most of these samples were found to be positive for both the
147 Delta and Omicron lineages using the bioinformatics pipeline developed by EMHP (data not
148 shown). Wastewater samples were clarified, concentrated and RNA extracted according to
149 the Quantification of SARS-CoV-2 in Wastewater General Protocol V1.0
150 (<https://www.cefas.co.uk/media/offhscr0/generic-protocol-v1.pdf>). Sequencing libraries (tiled
151 amplicons) were generated using the EasySeq™ SARS-CoV-2 WGS Library Prep Kit
152 (Nimagen, The Netherlands) and the Nimagen V3 (wastewater samples) and V4 (synthetic
153 samples) primer schemes, following the Wastewater Sequencing using the EasySeq™ RC-
154 PCR SARS-CoV-2 (Nimagen) V2.0 protocol [26]. The libraries were sequenced on an
155 Illumina NovaSeq 6000 (2x 150 bp) at the University of Liverpool sequencing centre
156 (synthetic samples) or an Illumina NextSeq 500 (2x 150 bp) at the University of Nottingham
157 sequencing centre (wastewater samples).

158

159 **Read pre-processing, mapping, primer trimming and variant calling**

160 The ARTIC pipeline (ncov2019-artic-nf; Illumina workflow) [27] was used to process the
161 raw Illumina reads. Briefly, amplicon reads were pre-processed using Trim Galore v0.6.5
162 [28], mapped to the reference SARS-CoV-2 genome (ENA GenBank Accession
163 MN908947.3, NCBI NC_045512.2) using BWA v0.7.17 [29], followed by primer trimming
164 using iVar v1.3 and bed files containing the genome positions of the primers used to generate
165 the amplicons (Nimagen V3 and V4 primer schemes for wastewater and synthetic samples,
166 respectively). The resulting BAM files were sorted and subsequently indexed using
167 SAMtools v1.13 [23] before analysis with six different variant callers; iVar v1.3.1, LoFreq
168 v2.1.3.1, BCFtools v1.13, GATK Haplotypecaller v3.8, VarScan v2.4.4 and FreeBayes

169 v0.9.21. To avoid introducing biases across the variant callers, only parameters common to
170 those available from VarScan were chosen. VarScan is the caller with the least number of
171 parameters as it allows to only choose from min-coverage (Minimum read depth at a position
172 to make a call), min-reads2 (Minimum supporting reads at a position to call variants), min-
173 avg-qual (Minimum base quality at a position to count a read), min-var-freq (Minimum
174 variant allele frequency threshold) and p-value (p-value threshold for calling variants). It
175 should be also noted that it is practically impossible to test all the parameters from all the
176 callers and leaving these in default is a preferred choice when performing comparison studies
177 [30-32].

178 The ARTIC pipeline outputs a list of mutations (SNPs and indels) detected for each variant
179 using iVar, but this was re-run separately after matching the common parameters across the
180 various callers being investigated. All parameters are described in Supplementary file 1. The
181 sorted, indexed and primer-trimmed BAM files were used directly to run variant calling with
182 FreeBayes, iVar, BCFtools and VarScan, while LoFreq and GATK Haplotypecaller required
183 first pre-processing of these BAM files. Since LoFreq required indel quality information in
184 the BAM file to process indel calls, we used the LoFreq command *indelqual* to insert quality
185 score for each indel, based on the dindel algorithm [33]. GATK Haplotypecaller, requires
186 reads to be grouped (using *AddOrReplaceReadGroups* from Picard) and duplicates
187 (*MarkDuplicatesSpark* from GATK) were marked before variant calling. All the variant
188 callers generated outputs in the variant call format (vcf) files except iVar, which reported
189 outputs as tsv (tab-separated values) files. A python script (*ivar_variants_to_vcf.py*) was used
190 to convert the tsv file to vcf format [15]. A python script (*ivar_variants_to_vcf.py*) was used
191 to convert the tsv file to vcf format [34].

192

193 **VCF file processing, analysis, and statistical methods**

194 QuasiModo is a tool that evaluates the results of strain resolved analyses on mixed strain
195 samples including variant calling and genome assembly [35]. It does this by taking vcf files
196 generated from the different variant callers and two genomic reference files, the first being
197 the reference against which samples were mapped in the BAM file-generating process, and
198 the second reference being a ground-truth genome known to be found in the mixed strain
199 samples. We therefore evaluated the performance of the different variant callers by
200 comparing lists of mutations identified by each of the variant callers to a second reference
201 genome (for ground truthing). The reference SARS-CoV-2 genome sequence was

202 downloaded from NCBI Genbank (Accession No. MN908947.3) and the SARS-CoV-2
203 variant genomes were obtained from GISAID: Alpha (EPI_ISL_601443), Beta
204 (EPI_ISL_678597), Delta (EPI_ISL_1544014), Omicron-England (EPI_ISL_7718520),
205 Omicron-Hong Kong (EPI_ISL_6841980), Omicron-Australia (EPI_ISL_7190366) and
206 Gamma (EPI_ISL_792683). Briefly, sequences from each sample were aligned to the
207 reference genomes using MUMmer4 [27] to identify SNPs and indels that are present in the
208 ground-truth genome and each variant call was then categorised as either a true positive (TP),
209 a false positive (FP), or a false negative (FN). A true positive is defined as one that was
210 found by the variant caller being tested in both the sample and the reference. A true negative
211 is a lack of a mutation detected by the variant caller where there is no mutation present in the
212 reference file. A false positive is a mutation reported by the variant caller but not present in
213 the original reference, while a false negative is a mutation not detected by the variant caller,
214 but that is found in the reference [35-38].

215 These values are used to calculate the recall and precision, also known as sensitivity and
216 specificity, respectively:

217
$$\text{Recall (R, fraction of truly existing variants)} = \text{TP}/(\text{TP}+\text{FN})$$

218
$$\text{Precision (P, fraction of predicted true variants)} = \text{TP}/(\text{TP}+\text{FP})$$

219 In addition, once recall and precision are calculated, a ratio of the two can be derived, known
220 as the F1 score [35]:

221
$$\text{F1} = 2 * (\text{P} * \text{R}) / (\text{P} + \text{R})$$

222

223 For the synthetic control samples, 455 vcf files (generated for 19 synthetic samples
224 (quadruplicates) from six variant callers, with one failed replicate for GATK) were analysed
225 using the MN908947.3 reference file as the mapping genome and each of the SARS-CoV-2
226 variant reference genomes (Alpha, Beta, Delta, and Gamma). Similarly, for wastewater
227 samples, we generated 77 vcf files from 13 unique samples among six variant callers, with
228 one failed sample for GATK), using the MN908947.3 reference and each of the SARS-CoV-
229 2 variant genomes (Alpha, Beta and Delta, Omicron (Hong Kong), Omicron (Australia) and
230 Omicron (England) and Gamma; Table 1). The Gamma (P1) variant reference file (Table 1)
231 served as a negative control in our bioinformatics analysis, as it was not included in the
232 synthetic mixtures nor found in the wastewater samples. We adapted the method described by
233 Deng et al. [35] to generate a table with calculated values for each of the vcf files, from

234 which recall, and precision were plotted using R v4.1.3 and ggplot2 [39]. Output from all the
235 vcf files was used by *vcfstats* from the *vcflib* package [40] to generate variant statistics for
236 each of the vcf files. *vcfstats* generates a two-column output for each vcf file, with counts for
237 SNPs, MNPs (multiple nucleotide polymorphisms), Indels and various other parameters. The
238 number of SNPs, Indels and MNPs for each vcf file were plotted using RStudio, ggplot2
239 package [39]. Frequencies of the defining mutations for each of the variant genomes were
240 extracted from the vcf files using BCFtools [23] and plotted using Rstudio, ggplot2 [39].

241 To test whether the distribution of precision, recall and F1 scores for each variant caller was
242 significantly different from another, we applied the Kruskal-Wallis one-way analysis of
243 variance test using the python scipy package v1.9.1 ([SciPy](#)). Following this, a post-hoc Dunn
244 test using scikit-posthocs package v0.7.0 ([scikit-posthocs · PyPI](#)) was performed to evaluate
245 the pairwise differences between callers. These tests were performed separately on the
246 synthetic samples, the wastewater samples and both sets of samples together, for each score.
247 Each set of quadruplicate synthetic samples were aggregated by median score before
248 applying the relevant tests.

249

250 **Results**

251 **Sensitivity and specificity of six variant callers across mixed synthetic genome samples**

252 We ran VarScan, GATK, iVar, FreeBayes, LoFreq and BCFtools across 19 mixed ratio
253 synthetic samples, in quadruplicates. Basic sequencing statistics for all the samples
254 calculating recall, precision and F1 score values are summarised in Supplementary Figure
255 7A.

256 We calculated recall and precision for each variant within the samples and plotted these
257 separately for each variant caller (Figure 1A-D, Supplementary Figure 1A-D), by also
258 highlighting the percentage of each variant in the mixed sample as described in Table 2.
259 Given that all four replicates yielded very similar results (reliable technical replicates), we
260 run the median of these for all the synthetic samples plots. As shown in Supplementary
261 Figure 2, we picked three samples which only contained 100% of one specific variant in the
262 mix, namely Alpha, Beta or Delta, (shown in Table 2 marked by *) to show the validity of the
263 replicates. They all had indeed a similar distribution of the 4 replicates.

264 Our results show that all the variant callers correctly identified each SARS-CoV-2 variant in
265 the synthetic mixes. At the time of writing, the tools we used to evaluate the presence of
266 variants in a mixed sample via evaluation of their mutational profile could not be applied for
267 mixed samples containing more than two variants or strains; therefore, we investigated the
268 correct identification of the percentage by analysing the variants independently rather than
269 confirming that all variants were found simultaneously in the same sample. Our results
270 suggest that in general, the greater the proportion of a variant (close to 100%), the greater the
271 chance it was called correctly (Figure 1). Indeed, VarScan, BCFtools and FreeBayes correctly
272 called the increased ratio of Alpha compared to the remaining variants in the mix, while iVar
273 and LoFreq had a trend line where the increased concentration of the variants could not be
274 observed as clearly as in the other callers, showing instead a lower precision and for the latter
275 also a low recall (Supplementary Figure 1A-C, 7A). As expected, our negative control P1
276 (Gamma) (Figure 1D) did not yield any significant results, with all samples having a very low
277 precision and recall for every caller assessed. Specifically, we observed that samples with a
278 ratio close to zero, thus with low concentration of a variant, tended to cluster together with
279 low recall and low precision. Those with higher ratio for a variant, and therefore with more
280 mutations to be detected across several variants, are distributed across the plot to reflect the
281 increased recall, and for some callers, higher precision. Based on this initial observation,

282 BCFtools, VarScan and Freebayes had the highest precision, followed by iVar and GATK. In
283 addition, iVar had the highest recall for each of the variants being assessed independently, via
284 count of their TPs, FPs and FNs compared to the other callers. This was supported by a
285 Dunn's test to compare the synthetic samples' precision, recall and F1 scores of each variant
286 caller. It confirmed that the differences in precision and F1 scores for LoFreq were
287 significantly different to the other callers ($p < 0.01$) and iVar performed best for recall and
288 the Dunn's test again confirmed this as statistically significant ($p < 0.01$, Supplementary
289 Figure 7A).

290

291 **Sensitivity and specificity of six variant callers across wastewater samples from London**

292 We used wastewater samples collected between the 15–18 December 2021 from Greater
293 London to assess whether the variant callers could identify the mutations with similar
294 precision and recall as observed with the synthetic samples. Table 3 shows the list of the
295 samples, dates and predicted variants known to be found in those samples and Supplementary
296 Figure 7B shows basic sequencing statistics. Samples were predicted to contain a mix of the
297 Omicron and/or Delta, AY.4.2 variants definitions (EMHP analysis based on PHE variant
298 definition, data not shown). Given the genome similarity between the Delta and AY.4.2
299 variants, we only carried out our analysis on the Delta variant mutations. Figure 2A-B shows
300 that the variant callers recognised mutations that could be identified as Delta variant for some
301 of the samples, which indeed show a higher precision and recall compared to others, while in
302 Supplementary Figure 2A-B-D we show that Alpha, Beta or Gamma variants are not
303 detected, as expected, since these were not expected to be found in the samples, compared to
304 Delta which shows to be found in some of the samples (Supplementary Figure 2C). Indeed,
305 when testing for Delta variant presence, we noticed a slight increase in the precision and
306 recall for some of those samples, which suggests that those did contain SNPs and/or Indels
307 that could be identified as being part of the Delta variant, namely S50 and S296, although the
308 latter was not called by GATK. Consistent with the data in Table 3, some of the samples were
309 found to not contain a Delta variant, such as sample S43, which indeed showed a low
310 precision and recall for all the callers, while other samples with slightly higher values
311 reflected that did contain a mix of both Omicron and Delta (samples S58, S292, S63). As
312 shown for the synthetic samples, LoFreq was the only variant caller that called with the
313 lowest precision for all the samples analysed, followed by iVar, while recall values for
314 LoFreq were sparser, yet higher than the other callers.

315 Similarly, we tested the wastewater samples for the presence of the Omicron lineage (Figure
316 3A-C). We used three different references representative of this variant, namely, England,
317 Hong Kong, and Australia. As shown in Figure 3A-C and Supplementary Figure 4A-C, all
318 three variants under analysis were found in our wastewater samples and at a higher level than
319 the one at which the Delta variant was detected for specific samples expected to have either
320 or both two variants. The degree to which each variant caller recognises the mutations varied,
321 with LoFreq again returning the lowest recall and precision values compared to the other
322 callers. This was consistent with the results obtained with the synthetic data. Based on the
323 predicted detection indicated in Table 3, the two samples identified to contain a Delta based
324 mutational profile as described above (S50 and S296), have now a low precision and recall
325 when tested against any of the Omicron lineages, suggesting that in those samples we can
326 predict to find a Delta variant rather than an Omicron. This was confirmed consistently for all
327 the callers, although we also observed again that LoFreq did have low values as shown in the
328 other plots and that GATK did not call S296. As for the synthetic samples, a Dunn's test of
329 the pairwise scores confirmed that in terms of precision, GATK, VarScan and Freebayes
330 were not significantly different from one other. However, the Dunn's test on recall showed
331 iVar to be stochastically dominant. For the combined F1 score, the same test showed that
332 only LoFreq was significantly different from each of the other tools ($p < 0.01$, Supplementary
333 Figure 7B).

334

335 **Comparison of known variant defining mutations found in synthetic and wastewater** 336 **samples across the six variant callers**

337 We calculated the total number of known SNPs, Indels and MNPs (multi nucleotide
338 polymorphisms) as described by Twist (synthetic samples) or PHE (wastewater samples) for
339 each variant and compared these with those found in our synthetic (Figure 4A-F,
340 Supplementary Figure 5A-F and Supplementary file 2) or wastewater samples (Figure 5A-F,
341 Supplementary Figure 5A-F and Supplementary file 2) by each of the callers. SNPs/Indels
342 bar plots were also shown in absence of LoFreq to show the divergence among all the callers
343 on a different scale, as shown in Supplementary Figure 6A-D. In Figure 4A-F and 5A-F we
344 used UpSet plots to show TPs for a subset of both synthetic and wastewater samples,
345 respectively. For the synthetic samples we chose the three samples with 100% of a variant
346 and one with a mix of the three (sample 12, Table 2). Among the wastewater samples, we
347 chose six samples, representative of both Omicron lineages and Delta variants (Table 3,

348 samples highlighted in bold). As shown in Figure 4A-F, and in concordance with the data
349 presented above, LoFreq did call a much higher number of mutations compared to all the
350 other variant callers in all the synthetic samples analysed, leading to a high number of FNs.
351 When looking in more detail at how many of those were the defining mutations for each of
352 the reference genomes (Table 1), we found that all callers identified the majority of the
353 expected mutations for the variants being investigated, except LoFreq which only found
354 11/28 mutations for Alpha, 14/25 for Beta, and 20/37 for Delta (Figure 4A-B-C,
355 Supplementary file 2). In addition, a set of 3 mutations was not detected by any of the variant
356 callers for Alpha and Beta variants and 4 mutations for the Delta variant. The detailed
357 number of defining expected mutations for all the callers are described in Supplementary file
358 2.

359 For the synthetic mixed strain sample (Table 2, sample 12) we tested the presence of the
360 defining mutations for Alpha, Beta and Delta (Figure 4D-E-F, respectively and
361 Supplementary file 2) which were mixed in a 50:25:25 ratio, respectively. As summarised in
362 Supplementary file 2, GATK called the lowest number of expected mutations for all the three
363 variants, followed by VarScan and LoFreq. On the other hand, we found that iVar, FreeBayes
364 and BCFtools were the callers with the highest number of expected mutations for all three
365 variants profiled. Five mutations for the Alpha variants, 3 for the Beta and 8 for the Delta
366 variant were not detected by any of the callers.

367 Similarly, we called variants for the wastewater samples (in bold Table 3, Figure 5A-F,
368 Supplementary Figure 5B-D-F and Supplementary file 2) and observed the same pattern.
369 More specifically, we investigated how many of the Delta, Omicron BA.1 and BA.2 defining
370 mutations were detected by each of the variant callers across the samples and compared the
371 numbers. As shown in Figure 5A-F, we found that, of all the mutations detected in the
372 wastewater samples, 13/20 mutations for BA.2 were not detected by any of the variant callers
373 (Supplementary file 2), yielding to a very low number of defining mutations found by each
374 caller (up to 6 total mutations). For BA.1, who has a total of 17 defining mutations, LoFreq
375 called the least number of expected mutations for sample S58 (7/17) and S263 (6/17).
376 Overall, all the callers found between 6 to 16 defining mutations across the samples, with
377 iVar having the highest number of expected mutations compared to the other callers: it
378 detected all the 16/17 mutations for BA.1 in all samples, except 10/17 for S263 and 0/17 for
379 S296. When looking at the Delta variant defining mutations, as observed for the other
380 variants, there is a degree of difference within the same sample, e.g., iVar and LoFreq called

381 8/17 and 9/17 defining mutations, respectively for sample S63, but all the others only 3/17.
382 Overall, iVar seemed to have performed well for the Delta variant where it called the highest
383 number of expected mutations (Supplementary file 2).

384 Similarly, bar plots showing the number of total SNPs, Indels and MNPs across the samples
385 for the six variant callers were also calculated. This is shown in Supplementary Figure 5A-F,
386 for both synthetic and the real wastewater samples, and in absence of LoFreq in
387 Supplementary Figure 6A-D. Interestingly, not all the variant callers were able to recognise
388 MNPs. As shown in Supplementary Figure 5E-F only FreeBayes and iVar found this type of
389 mutations across both synthetic and real wastewater samples.

390

391 **Comparison of alternate allele frequencies across the six variant callers**

392 We extrapolated the alternate allele frequencies values from the vcf files for both the
393 synthetic and wastewater samples across the six variant callers to look if these were called
394 similarly. Degenerate codons were not plotted for any of the callers. In Figure 6A-C
395 (synthetic) and Figure 6D-F (wastewater) we plot all the defining mutations for the variants
396 of interest across all the 19 synthetic or the 13 wastewater samples. Frequencies are coloured
397 by gradient.

398 Among the synthetic samples, all the callers had the same frequency for those samples where
399 there was a high proportion of a variant (75-100%), such as samples 1 and 7 for Alpha
400 (Figure 6A), sample 2 for Beta (Figure 6B) and samples 3 and 17 for Delta (Figure 6C). For
401 the remaining samples, frequencies were similar, although iVar called more mutations than
402 others, but at very low frequency. Similarly, for the wastewater samples we plotted
403 frequencies for defining mutation for Omicron BA.1 (Figure 6D), BA.2 (6E) and Delta (6F)
404 variants. BA.1 mutation frequencies were called at the same level across all the callers. In
405 particular, samples S58, S63 and S292 were the ones with the highest number of mutations
406 detected by all callers, at the same high frequency. All three samples were found to be
407 positive for Omicron from previous data analysis (data not shown). Some mutations, such as
408 Q19E were not called by any of the callers. It is worth highlighting that at the time the
409 original samples were analysed (December 2021) there was no clear distinction between
410 BA.1 and BA.2. Frequencies for BA.2 (Figure 6E) were also similar across the callers,
411 although only a subset of these were detected, suggesting that more likely the BA.1 subgroup
412 was the one circulating at that time. As for the Delta variant, two samples, S50 and S296,

413 showed high frequency and were consistent among all the callers. Other samples were called

414 similarly, with no evident differences.

415

416 **Discussion**

417 In this paper we have analysed six variant callers commonly used in bioinformatics data
418 analysis to empirically quantify their ability to identify mutations across mixtures of synthetic
419 samples with known mutations as well as a set of wastewater samples with an unknown
420 number of mutations. We first calculated recall and precision across the full genome for all
421 the samples to define ground differences across the callers, to then focus in more detail on a
422 set of defining mutations, by comparing how many of these were found and at which
423 frequency by each of the callers. Our results suggest that the variant callers that showed the
424 highest precision when looking at all samples together (synthetic and real wastewater
425 samples) were GATK and VarScan followed by BCFtools and FreeBayes, which instead
426 showed sparser data points. LoFreq and iVar showed the lowest precision values
427 (Supplementary Figure 7C). Recall values were the lowest for GATK (and very sparse
428 values), while they were significant statistical differences among the rest of the callers (in
429 particular iVar's stochastic dominance). Overall, the F1 score confirmed that LoFreq was the
430 least sensitive (Supplementary Figure 7C), presenting numbers of mutations that are
431 magnitudes larger than the rest, and subsequently with a lower precision. On the other hand,
432 when focusing on selected mutations, iVar identified the highest number of expected defining
433 mutations across both synthetic and wastewater samples, compared to the other callers.

434 Wastewater-based epidemiology (WBE) has been used for many years to monitor key
435 pathogens such as polio [41-45]. However, it has undergone a renaissance during the SARS-
436 CoV-2 pandemic, with many tools and software specifically designed to detect the virus in
437 wastewater and being developed in the wake of WBE monitoring [46-50]. As such, tools used
438 to detect the virus in clinical samples were used as templates, but in many cases, these did not
439 reflect the composition of the wastewater samples accurately, e.g., the mixed strain nature as
440 well as degradation of the viral RNA in the environment, thus the lack of a complete genome,
441 and more importantly the lack of a consensus sequence. These nuances impact and should
442 inform downstream analysis at the bioinformatics level: sequences could only be a fraction of
443 the genome, as the samples may be highly degraded, and the lack of a consensus will affect
444 the ability to assign a variant to a sample [51, 52]. Subsequently variant analysis is limited to
445 a shorter region in some cases and variant assignment has to happen based on specific
446 mutations known to define a variant, as used for clinical cases [53]. For this reason, a variant
447 caller that adapts to the type of data available is very important as it will be expected to call
448 the mutations with higher sensitivity.

449 The six callers analysed in this paper have many aspects in common as well as significant
450 differences. For example, of all the callers LoFreq is the only one that requires base quality
451 information to call variants, making this method much more stringent and robust than the
452 others, but similarly prone to call many more mutations than expected [21], as seen in our
453 results. In addition, it has been reported that LoFreq can efficiently recognise sequencing
454 errors from expected mutations in non-environmental samples, however, it seems that it did
455 not behave as efficiently in our wastewater samples nor with the synthetic samples. This
456 could also be a consequence that more specific combinations of parameters have to be chosen
457 for efficient performance. Although for some samples the recall was correct, the precision
458 was lower indicating the lower efficiency. Indeed, LoFreq is a fast and sensitive variant caller
459 that calls many mutations that, however, are not true positive, hence low recall and precision
460 as found in our results. We suggest that this tool is more suited for shorter viral sequences,
461 and more likely in samples with higher coverage. Similarly, GATK was designed to detect
462 genomes across a range of sample sources, but not environmental, and this is reflected in the
463 highly comprehensive set of parameters available to efficiently analyse the datasets (over 111
464 parameters) [20], but most of GATK parameters are not applicable to wastewater datasets.
465 These aspects also highlight the difficulty in using these two tools for wastewater data, in
466 contrast to FreeBayes, BCFtools or VarScan, which are functional and easy to apply in non-
467 clinical settings. Nevertheless, we found that compared to most of the callers analysed,
468 GATK did find the majority of the expected mutations (TPs) as well as overall good scores
469 for recall and precision, suggesting that applying different sets of parameters might improve
470 its functionality for environmental samples as well. This applies to LoFreq as well.

471 The selected variant callers have been extensively used in other fields for comparison
472 purposes. For example, a recent paper comparing the efficiency of different mappers and
473 callers in plant NGS data found that GATK was the best caller among those tested,
474 suggesting that the type of data greatly affects not only the results but also the choice of tools
475 used to analyse the datasets [30, 54, 55]. Although GATK was not the best of the callers in
476 our study, we suggest these results are valid given the diversity of the datasets; namely, the
477 plant genome being of better quality and not containing mixed strains compared to the
478 wastewater, secondly, the fact that not always the expected mutations are known, thus many
479 more mutations will account as TP or FP. This is independent of the pathogen studied, since
480 most of the tools are widely applicable in different fields. Similarly, another study looking at
481 exome sequencing also found that among the variant callers analysed, GATK

482 UnifiedGenotyper performed best [54]. We suggest that looking at shorter regions of a
483 genome, such as exons, has its advantage since it allows us to work with a relatively smaller
484 and highly covered region. In addition, compared to the above paper, we used GATK
485 Haplotypecaller, which is known to have a different algorithm for calling variants than
486 GATK UnifiedGenotyper.

487 It should also be noted that many of the parameters within each of these variant callers were
488 left in default in our analysis. In fact, the wide choice of parameters poses a risk on its own
489 when comparing different tools as it introduces biases. In an ideal setting, the correct
490 procedure will imply that all parameters are tested and those reflecting an outcome that is
491 expected are then chosen. In this paper we did not assume a certain output as we did not use
492 all the possible parameters and because we were not expecting similar results between the
493 callers. Indeed, a small test using FreeBayes showed us that changing certain key parameters
494 yielded many different outputs, all of them being acceptable results (data not shown).
495 Because these parameters are not shared or found in other callers, the comparison could not
496 be achieved, as it would have introduced an advantage or disadvantage for some callers. This
497 is in agreement with current literature, where on many occasions' parameters are left in
498 default [30-32]. A direct consequence of this is that many results across our data would have
499 had a different outcome. Indeed, LoFreq results might differ enormously if we had
500 considered and adjusted all the parameters accordingly, irrespective of whether these were
501 common to other variant callers.

502 It should be noted that calculating recall and precision for samples containing a mix of
503 variants (two or more), is a cumbersome task, as some mutations can be shared among the
504 variants, which will affect the ground truth. At the time of writing Deng et al., [35] designed
505 a tool, where only samples with a mix of two genomes can be used. However, as of now there
506 is no tool available for samples with a mix of three or more genomes. Wastewater are mixed
507 samples, sometimes containing more than two variants. However, this notion will only be
508 confirmed overtime, through sequencing of clinical cases. Therefore, with the aim to reflect
509 real wastewater data, we calculated recall and precision for each variant known to be
510 prevalent as it would be at that time that specific variant would have been circulating. This
511 will inevitably overestimate the number of FP in each run as it should be calculated only once
512 per sample, but it is however expected: any position not found to be a TP for one variant, will
513 show as a FP. But, by testing each of the variants separately, this will give us the correct TP

514 which are the values we have been using in our manuscript to compare the callers (defining
515 mutations).

516 **Conclusion**

517 In conclusion, we suggest that callers such as Varscan, BCFtools and Freebayes are overall
518 preferable (Supplementary Figure 7C), particularly when mutations are not known as they are
519 called with higher specificity and sensitivity.

520 However, if specific mutations are under investigation and expected in the output, such as the
521 ones we used as variant-defining, iVar performed best.

522 We also suggest that, upon choice of one variant caller for a specific study other than
523 comparison purposes, all parameters should be explored and tested to better improve the
524 calling capability.

525 In the future, tools that can analyse mixed samples without the need to run the strains
526 separately are also preferred as they will give even more accurate values of recall and
527 precision.

528 **Author contribution**

Contributor Role	Role Definition
Conceptualisation	Ideas: formulation or evolution of overarching research goals and aims: Irene Bassano, Mathew Brown
Methodology	Development or design of methodology; creation of models: Irene Bassano, Vinoy Ramachandran, Mohammad Khalifa, Chris Lilley
Software	Programming, software development; designing computer programs; implementation of the computer code and supporting algorithms; <u>testing of existing code components</u> : Vinoy Ramachandran, Mohammad Khalifa, Irene Bassano, Chris Lilley
Validation	Verification, whether as a part of the activity or separate, of the overall replication/reproducibility of results/experiments and other research outputs: Irene Bassano, Vinoy Ramachandran, Chris Lilley, Ronny van Aerle, Hubert Denise, William Rowe, Mohammad Khalifa
Formal Analysis	Application of statistical, mathematical, computational, or other formal techniques to analyse or synthesise study data: Chris Lilley, Irene Bassano, Vinoy Ramachandran
Investigation	Conducting a research and investigation process, specifically performing the experiments, or data/evidence collection: Irene Bassano, Vinoy Ramachandran, Hubert Denise, William Rowe, Lilley Chris, George Airey, Cairns Edward, Wierzbicki Claudia, Pickwell Natalie D, Wilson Myles, Carlile Matthew, Holmes Nadine, Payne Alexander
Resources	Provision of study materials, reagents, materials, patients, laboratory samples, animals, instrumentation, computing resources, or other analysis tools: Steve Paterson, Matthew Loose, Terry Burke, Matthew Wade, Jasmine Grimsley

Data Curation	Management activities to annotate (produce metadata), scrub data and maintain research data (including software code, where it is necessary for interpreting the data itself) for initial use and later reuse: Irene Bassano, Vinoy Ramachandran
Writing – Original Draft Preparation	Creation and/or presentation of the published work, specifically writing the initial draft (including substantive translation): Irene Bassano, Vinoy Ramachandran
Writing – Review and Editing	Preparation, creation and/or presentation of the published work by those from the original research group, specifically critical review, commentary or revision – including pre- or post-publication stages: All authors
Visualisation	Preparation, creation and/or presentation of the published work, specifically visualisation/data presentation: Vinoy Ramachandran, Mohammad Khalifa, Chris Lilley
Supervision	Oversight and leadership responsibility for the research activity planning and execution, including mentorship external to the core team: Irene Bassano, Matthew Wade, Jasmine Grimsley
Project Administration	Management and coordination responsibility for the research activity planning and execution: Irene Bassano, Jasmine Grimsley

12	London 12	S305	18/12/2021	Omicron / AY.4.2 703
13	London 13	S270	18/12/2021	Omicron / AY.4.2 704

700

701 Figures and Tables legends

702 **Figure 1A-D** Point plots of precision vs recall for synthetic samples, grouped and faceted by
 703 variant caller, coloured by percentage present in the mix (dark blue, 0%, bright red, 100%). A
 704 linear regression for each plot is also present. A. is comparing the synthetic samples to the
 705 alpha variant reference, B. Beta variant reference, C. for Delta variant reference and D. for
 706 Gamma variant reference. As there was no mixed ratio for the Gamma variant which we have
 707 used as a negative control, no gradient was applied. Except for LoFreq and iVar, all the
 708 callers show a high precision and recall, and this is proportional to the percentage of the
 709 variant in the mix: indeed, samples with a high percentage of a variant (e.g., close to 100%, in
 710 red) tend to have a higher precision and recall, compared to those samples that have a lower
 711 percentage of the variant being plotted (e.g., closer to 0%, in blue) .

712

713 **Figure 2A-B** Point plots of precision vs recall for wastewater samples for the Delta
 714 variant, faceted by variant caller. A. Comparison of real wastewater samples to the Delta
 715 variant reference and B. with labelled samples to better identify which samples had low recall
 716 and low precisions (thus, not containing any Delta variant). As shown in Figure 4C, some

717 samples such as S296 and S50 are those containing a Delta variant in the mix, compared to
718 S43 seen to be negative for all the variant callers. As shown previously for the synthetic
719 data, LoFreq has the lowest recall and precision.

720

721 **Figure 3A-C** Point plots of precision vs recall for real wastewater samples for the three
722 Omicron variants, faceted by variant caller. A. Omicron England variant reference; B.
723 Omicron Hong Kong variant reference; C. Omicron Australia variant reference. Since the
724 wastewater samples are known to contain the Omicron variant, samples do show a higher
725 precision and recall compared to the negative controls used to generate Figure 4A-B-
726 D. Samples S63, S58, S42 and S292 had the highest precision and
727 recall for BCFtools, Freebayes, GATK, iVar and VarScan, while LoFreq did not call with the
728 same efficiency. S50 and S296 had the lowest precision and recall for all the callers. Notably,
729 GATK did not call S296.

730

731 **Figure 4A-F** Upset plots showing the common set of mutation found in (A) Alpha reference
732 genome and sample containing 100% alpha synthetic genome (B) Beta reference genome and
733 sample containing 100% beta synthetic genome (C) Delta reference genome and sample
734 containing 100% delta synthetic genome. (D-F) Upset plots showing common mutation
735 between sample mix (50% Alpha, 25% Beta and 25% Delta synthetic genome) and (D) Alpha
736 reference genome (E) Beta reference genome and (F) Delta reference genome for 6 different
737 variant callers. A= Alpha; B= Beta; C= Delta; D= mixed sample 12 Alpha; E= mixed
738 sample 12 Beta; F= mixed sample 12 Delta. For each A-F plot we added the variant being
739 tested at the top of the variant callers. Each mutation called by variant callers below Alpha,
740 Beta and Delta can then be compared to look at how many of the variant-defining mutations
741 are found by the variant caller. The Figures show that not all the defining mutations are found
742 by each of the caller and the additional mutations each variant caller has found. Among all
743 the callers, LoFreq is the caller with the highest number of mutations detected and much
744 fewer corresponding to the variant-defining list as shown by the variant on top of the callers.

745

746 **Figure 5A-F** Upset plots of wastewater samples showing the common set of
747 defining mutations found between Delta, Omicron BA.1 and Omicron BA.2 and wastewater
748 samples (A) S42 (B) S58 (C) S63 (D) S292 (E) 296 and (F) S263 for 6 different
749 variant callers. A=S42, B=S58, C=S63, D=S292, E=S296 – GATK failed, F=S263. As
750 described for Figure 4A-F, each mutation called by variant callers listed below Omicron
751 BA.1, Omicron BA.2 and Delta can then be compared to look at how many of the variant-
752 defining mutations are found by the variant caller. The Figure show that not all the defining
753 mutations are found by each of the caller and the additional mutations each variant caller has
754 found. As seen in the synthetic samples, LoFreq is the caller with the highest number of
755 mutations detected and much fewer corresponding to the variant-defining list as shown by the
756 variant on top of the callers. All callers also show the presence of unique mutations not found
757 by the other callers and not present in the list of the defining ones as seen under Omicron
758 BA.1, Omicron BA.2 and Delta.

759

760 **Figure 6A-F** Alternate allele frequencies of the defining mutations for Alpha (A), Beta (B)
761 and Delta (C) variants were plotted for the 19 selected synthetic datasets for six different
762 variant callers. Similarly, the alternate allele frequencies of the defining mutations of
763 Omicron BA.1 (D), Omicron BA.2 (E) and Delta (F) were plotted for 13 wastewater samples
764 for six different variant callers. The data points were coloured based on the 4-color rainbow
765 gradient from red (0%) to purple (100%). Degenerate codons were not plotted.

766

767 **Supplementary Figure 1A-D** Point plots of precision vs recall for synthetic samples,
768 grouped and coloured by variant caller and a linear regression for each. A, Alpha variant
769 reference, B. Beta variant reference, C. Delta variant reference and D. Gamma variant
770 reference. The figure shows the low precision recorded by LoFreq compared to the rest of the
771 variant callers while is higher for VarScan, FreeBayes, BCFtools and GATK. Interestingly,
772 trend lines overlap for Freebayes and BCFtools.

773

774 **Supplementary Figure 2** Plot of F1 score vs callers for three synthetic samples (1) 100%
775 alpha (2) 100% Beta and (3) 100% Delta as listed in Table 2 (samples with *). Each plot
776 represents caller in relation to either the precision or the recall, expressed as the F1 score. The
777 figure shows that all the replicates (filled circle) have similar recall and precision, suggesting
778 that no major differences are observed. As shown in Figure 1 and 2, LoFreq shows the lowest
779 F1 score compared to the rest of the callers, followed by iVar. FreeBayes and VarScan,
780 showed similar results, while GATK had the highest F1 score, followed by BCFtools.

781

782 **Supplementary Figure 3A-D** Point plots of precision vs recall for wastewater samples,
783 coloured by variant caller. A, Alpha variant reference, B. Beta variant reference, C. Delta
784 variant reference and D. Gamma variant reference. The figure shows that variants not found
785 in the mix such as Alpha, Beta and Gamma have low precision and recall. Some of the
786 samples are known to be positive for the Delta variant therefore the latter will have a
787 higher precision and/or recall.

788

789 **Supplementary Figure 4A-C** Point plots of precision vs recall for wastewater samples for
790 the Omicron variant, grouped and coloured by variant caller and a linear regression for each.
791 A, Omicron England variant reference, B. Omicron Hong Kong variant reference, C.
792 Omicron Australia variant reference. Since the wastewater samples are known to contain the
793 Omicron variant, samples do show a higher precision and recall compared to the negative
794 controls used to generate Figure 4 A-B-D.

795

796 **Supplementary Figure 5A-F** SNPs, Indels, MNVs bar plots for synthetic and
797 real wastewater samples.

798 A. Number of SNPs calculated for each of the 19 synthetic samples (mean of replicates). The
799 figure clearly identifies LoFreq as the caller with the highest number of SNPs detected, while

800 the rest of the callers do show a similar pattern. Detailed differences excluding LoFreq can be
801 appreciated in Supplementary Figure 2A-B.

802 B. Number of SNPs calculated for each of the 13 wastewater samples with variable results
803 among the callers. In comparison to other callers, LoFreq still calls more SNPs than expected
804 in some of the samples, namely S296, S292, S42, S50.

805 C. Number of Indels calculated for each of the 19 synthetic samples (mean of replicates). As
806 seen for the SNPs bar plots, LoFreq calls the highest number of Indels detected, while the rest
807 of the callers do show a similar pattern. Detailed differences excluding LoFreq can be
808 appreciated in Supplementary Figure 2C-D.

809 D. Number of Indels calculated for each of the 13 wastewater samples with variable results
810 among the callers. In comparison to other callers, LoFreq still calls more Indels than expected
811 in some of the samples, namely S296, S292, S305, S42, S50, S58 and S63. Notably, we were
812 not able to verify the presence of Indels for GATK for sample S296.

813 E. Number of MNPs calculated for each of the 19 synthetic samples (mean of replicates).
814 Only Freebayes and iVAR had detectable values to be plotted, while the rest of the callers did
815 not call this type of base variation.

816 F. Number of MNPs calculated for each of the 13 wastewater samples. As seen for the
817 synthetic samples, only Freebayes and iVAR detected the presence of MNPs.

818

819 **Supplementary Figure 6A-F** SNPs, Indels, MNVs bar plots for synthetic and
820 real wastewater samples without plotting LoFreq values. A. Number of SNPs calculated for
821 each of the 19 synthetic samples (mean of replicates). B. Number of SNPs calculated for each
822 of the 13 wastewater samples. C. Number of Indels calculated for each of the 19 synthetic
823 samples (mean of replicates). D. Number of Indels calculated for each of the 13 wastewater
824 samples. E. Number of MNPs calculated for each of the 19 synthetic samples (mean
825 of replicates). F. Number of MNPs calculated for each of the 13 wastewater samples.

826

827 **Supplementary Figure 7A-C** Statistical analysis of recall, precision and F1 score across the
828 six variant callers for synthetic and wastewater samples. The figure shows boxplots showing
829 variant caller scores for wastewater samples. For each figure, Top: Precision. Middle: Recall.
830 Bottom: F1 Score. A. Boxplots showing variant caller scores for synthetic samples. Right:
831 Post-hoc Dunn's test p-values, highlighted where $p < 0.05$ indicating significant difference
832 between the distribution of scores of that caller with another. LoFreq is stochastically
833 dominated by the others when evaluating precision and F1 scores. iVar is stochastically
834 dominant for recall. B. Left: Boxplots showing variant caller scores for wastewater samples.
835 Right: Post-hoc Dunn's test p-values, highlighted where $p < 0.05$ indicating significant
836 difference between the distribution of scores of that caller with another. LoFreq is
837 stochastically dominated by the others when evaluating precision and F1 scores. iVar is
838 stochastically dominant for recall but is dominated by all callers except LoFreq for precision.
839 C. Left: Boxplots showing variant caller scores for synthetic and wastewater samples
840 combined. Right: Post-hoc Dunn's test p-values, highlighted where $p < 0.05$ indicating
841 significant difference between the distribution of scores of that caller with another. LoFreq is

842 stochastically dominated by the others when evaluating precision and F1 scores. iVar is
843 stochastically dominant for recall but is dominated by all callers except LoFreq for precision.
