## 30 Abstract

- 31 Aging manifests as progressive deterioration in cellular and systemic homeostasis, requiring systems-32 level perspectives to understand the gradual molecular dysregulation of underlying biological 33 processes. Here, we report systems-level changes in the molecular regulation of biological processes 34 under multiple lifespan-extending interventions in mice and across age in humans. In mouse cohorts, 35 Differential Rank Conservation (DIRAC) analyses of liver proteomics and transcriptomics show that 36 mechanistically distinct prolongevity interventions tighten the regulation of aging-related biological 37 modules, including fatty acid metabolism and inflammation processes. An integrated analysis of liver 38 transcriptomics with mouse genome-scale metabolic model supports the shifts in fatty acid 39 metabolism. Additionally, the difference in DIRAC patterns between proteins and transcripts suggests 40 biological modules which may be tightly regulated via cap-independent translation. In a human cohort 41 spanning the majority of the adult lifespan, DIRAC analyses of blood proteomics and metabolomics 42 demonstrate that regulation of biological modules does not monotonically loosen with age; instead, the regulatory patterns shift according to both chronological and biological ages. Our findings 43 44 highlight the power of systems-level approaches to identifying and characterizing the biological 45 processes involved in aging and longevity.
- 46

## 47 Introduction

48 Aging manifests as progressive deterioration in cellular and systemic homeostasis. In humans, it is 49 accompanied by an increased risk for chronic conditions such as diabetes, heart disease, neurodegeneration, and cancer<sup>1,2</sup>. Interventions targeting aging mechanisms could delay or moderate 50 51 chronic diseases and improve health and lifespan<sup>3</sup>. However, aging involves diverse chemical and 52 physiological components, posing a challenge to comprehensive understanding<sup>4</sup>. For instance, many 53 studies have demonstrated key roles of nutrient-sensing pathways in aging and longevity across 54 species, including growth hormone (GH) and insulin/insulin growth factor 1 (IGF-1), AMP-activated 55 protein kinase (AMPK), sirtuins, and mammalian (or mechanistic) target of rapamycin (mTOR) signaling pathways<sup>5-9</sup>, but these nutrient-sensing pathways are intricately interconnected with each 56 other. Given the complex and multifaceted nature of aging, systems-level approaches may provide 57 58 different perspectives from single molecule-level approaches and deepen our understanding of the 59 aging processes.

Some nutritional and pharmacological interventions consistently extend lifespan and 60 healthspan in mouse and other animal models<sup>3,10–12</sup>. Nutritional interventions include calorie 61 restriction (CR)<sup>13</sup>, methionine restriction (MR)<sup>14</sup>, and ketogenic diet<sup>15,16</sup>. While the number of possible 62 63 "geroprotectors" has been growing<sup>17</sup>, pharmacological interventions whose effects on lifespan extension were robustly confirmed by the National Institute on Aging (NIA) Interventions Testing 64 Program (ITP)<sup>18</sup> include acarbose (ACA)<sup>19–21</sup>, canagliflozin<sup>22</sup>,  $17\alpha$ -estradiol (17aE2)<sup>19,20,23</sup>, glycine<sup>24</sup>, nordihydroguaiaretic acid<sup>19,20,25</sup>, Protandim<sup>®</sup> (a Nrf2 inducer)<sup>20</sup>, and rapamycin (Rapa)<sup>26–28</sup>. Rapa is 65 66 67 the only drug found to prolong lifespan in every organism studied, including yeast, worms, flies, and mammals<sup>29,30</sup>. Rapa modulates nutrient-sensing pathways by inhibiting the activity of mTOR through 68 complex formation with FK506-binding protein 12, which globally attenuates protein translation via 69 70 mTOR complex 1 (mTORC1) and ultimately reduces inflammation, increases autophagy, and improves stem cell maintenance<sup>31,32</sup>. ACA could potentially mimic some aspects of CR<sup>19</sup>; it is an oral 71 72 antidiabetic drug which competitively inhibits the activity of  $\alpha$ -glucosidase enzymes to digest 73 polysaccharides, resulting in the deceleration of sugar uptake in the gastrointestinal tract<sup>33</sup>. ACA treatment has been shown to extend lifespan in male mice more than in female mice<sup>19-21</sup>, possibly due 74 to sex-dependent differences observed in heart, liver, and gut metabolite profiles  $^{34,35}$ . 17aE2 is a 75 76 stereoisomer of the dominant female sex hormone 17β-estradiol, having much weaker binding affinity 77 to the classical estrogen receptors, stronger affinity to the brain estrogen receptor, and neuroprotective properties<sup>36,37</sup>. 17aE2 treatment extends lifespan in male but not in female mice<sup>19,20,23</sup>, potentially due 78 79 to male-specific reduction of age-associated neuroinflammation<sup>38</sup> and sex-specific metabolomic responses observed in liver and plasma metabolite profiles<sup>39</sup>. Because these prolongevity drugs were 80 81 tested with standardized protocols in NIA ITP and because they have differences in primary mode of 82 action, comparisons of their effects on molecular regulation are valuable for our understanding of 83 aging and longevity mechanisms.

84 Differential Rank Conservation (DIRAC) method quantifies systemic variability in gene 85 expression within a module (i.e., a gene set, typically defined with an a priori network or pathway) for a given set of identically treated samples (called "phenotype")<sup>40</sup>. Briefly, for a given module, the 86 DIRAC algorithm first characterizes the rank consensus of each phenotype, which is represented by 87 88 binary value set for pairwise gene pairs (i, j) of the module to indicate whether the expression of *i*-th 89 gene is higher than that of *j*-th gene in the phenotype-sharing samples. For each sample, the DIRAC 90 algorithm next calculates the ratio of gene pairs whose relative ranking agrees with the rank consensus 91 of the corresponding phenotype. Finally, the average of this ratio within the phenotype-sharing 92 samples is a measure of how robustly the samples reflect the phenotypic gene expression pattern of 93 the module. The module is considered "tightly" regulated within a phenotype when the samples vary 94 little from their own consensus, because biological regulatory mechanisms or pressures must act 95 consistently across the samples to produce such a high conservation pattern. In contrast, the module is 96 considered "loosely" regulated within a phenotype when the samples vary considerably from their 97 consensus, indicating a lack of conservation across the samples. For instance, a previous study 98 applying DIRAC revealed the global loose regulation of BioCarta-defined modules in more malignant

phenotypes and later stages of disease progression<sup>40</sup>, indicating that a loss of tight regulation
 characterizes the dysregulation of biological processes in cancer. Hence, the DIRAC method can be
 used for identifying biological modules whose regulatory patterns are changed by prolongevity
 interventions or aging.

In this study, we report systems-level changes in the molecular regulation of biological 103 104 processes, by jointly leveraging three omics datasets of mouse cohorts including the NIA ITP-105 confirmed prolongevity interventions and two omics datasets of a human cohort spanning the majority 106 of the adult lifespan (Fig. 1). We apply DIRAC analysis to mouse liver protein abundance profiles, 107 first with predefined modules derived from Gene Ontology Biological Process (GOBP) annotations and then with unbiased modules derived from Weighted Gene Co-expression Network Analysis 108 (WGCNA)<sup>41,42</sup>, and demonstrate that three lifespan-extending drugs (ACA, 17aE2, and Rapa) 109 110 promoted tighter regulation of aging-related modules, such as fatty acid metabolism and inflammation 111 processes. As a complementary approach, mouse genome-scale metabolic model (GEM) $^{43,44}$  is developed with the three drugs-including liver transcriptomics<sup>45</sup>, and exhibits that multiple 112 prolongevity interventions shifted fatty acid metabolism. In addition, comparisons of DIRAC analyses 113 114 between the liver proteomics and transcriptomics suggest that biological modules were tightly regulated by the prolongevity interventions at different levels: transcription vs. post-transcription 115 including the cap-independent translation (CIT) of specific mRNAs<sup>46</sup>. Finally, we explore the cross-116 sectional relationship between the tight module regulation and age in humans; DIRAC analyses of 117 human plasma proteomics and metabolomics<sup>47,48</sup> reveal regulatory patterns of aging-related modules 118 according to both chronological and biological ages<sup>48</sup>. 119 120

## 121 Results

122

## Prolongevity interventions tightened the regulation of a priori proteomic modules

To compare the systems-level changes induced by different prolongevity interventions, we first 123 124 applied DIRAC analysis to a liver proteomic dataset which was generated through a mouse 125 prolongevity intervention experiment in the NIA Longevity Consortium (denoted "LC-M001 126 proteomics"; Fig. 1). In this experiment, 48 mice were either untreated (Control) or subjected to one of 127 three lifespan-extending drug treatments (ACA, 17aE2, or Rapa), and were euthanized at 12 months (n = 12 (6 female, 6 male) mice per group). The design of evaluating drug effects on healthy young adult 128 129 mice was motivated by the desire to reduce confounding effects of aging and of late-life diseases. In 130 DIRAC analysis, we pooled female and male samples per intervention to calculate robust DIRAC rank consensus from small sample size, while recognizing the false negative risks for sex-dependent 131 changes related to the sex-dependent effects of ACA and 17aE2 on lifespan extension<sup>19-21</sup>. For 132 133 biological modules used in this DIRAC analysis, we prepared 164 a priori modules which were 134 defined by the GOBP annotations mapped to the measured proteins (see Methods; Supplementary 135 Data 1).

A DIRAC metric, rank conservation index (RCI)<sup>40</sup>, measures consistency in the relative 136 abundance of biomolecules within a module among phenotype-sharing samples; high RCI indicates a 137 strongly shared pattern of behavior (i.e., "tight" regulation), while low RCI indicates unpatterned 138 behavior (i.e., "loose" regulation). ACA, 17aE2, and Rapa showed significantly higher RCI mean in 139 140 the examined modules than Control (Fig. 2a), suggesting general tightening of module regulation by 141 each of these prolongevity interventions. To identify the module changed (i.e., tightened or loosened) 142 by any of the interventions, we assessed the intervention effect on RCI using Analysis of Variance 143 (ANOVA) for each of the 164 modules. There were 12 significantly changed modules based on 144 "conservatively" false discovery rate (FDR)-adjusted P < 0.05 (see Methods; cf. 51 modules exhibited 145 nominal P < 0.05; Fig. 2b). Among these 12 changed modules, the post hoc RCI comparisons between 146 Control and each intervention group revealed that seven, nine, and eight modules were significantly 147 tightened by ACA, 17aE2, and Rapa, respectively (Fig. 2c), while no module was loosened. Four 148 modules were significantly tightened under all the three interventions (Fig. 2c), which were functionally related to fatty acid β-oxidation (GO:0006635, GO:0031998) or protein-transporting to 149

peroxisomes (GO:0016558, GO:0006625) (Fig. 2d, Supplementary Fig. 1c). Given that the primary
 mode of action is different between the studied drugs, this result suggests that systems-level regulation
 for these biological processes may be a general mechanism for lifespan extension.

153 Although high RCI reflects a shared pattern of relative abundances within the phenotype and 154 implies biological regulation required for the pattern, a tightly regulated module may still exhibit different relative abundance patterns under different phenotypes. Another DIRAC metric, rank 155 matching score (RMS)<sup>40</sup>, allows us to compare relative abundance patterns between phenotypes, by 156 157 measuring the similarity of each sample to the consensus pattern of a certain phenotype rather than 158 measuring the consistency to the consensus pattern of the sample's own phenotype (i.e., RCI). For 159 instance, in acetyl-CoA biosynthetic process from pyruvate (GO:0006086) where higher RCI against 160 Control was observed significantly in ACA and 17aE2 and as a tendency in Rapa (Supplementary Fig. 1a), Rapa and ACA showed significantly higher and tendentiously lower mean of RMSs, respectively, 161 162 than Control under the 17aE2 rank consensus (Supplementary Fig. 1b), suggesting that Rapa changed 163 this module similarly to 17aE2 while ACA did dissimilarly. Moreover, this Rapa's RMS mean was 164 comparable to 17aE2's RMS mean under the 17aE2 rank consensus (i.e., corresponding to 17aE2's 165 RCI) (Supplementary Fig. 1b). These DIRAC patterns suggest two modes of tight regulation for this 166 module: one under ACA and the other under 17aE2 and Rapa. Thus, using RMS under each group's 167 rank consensus, we explored the similarly tightened modules across the interventions. Among the seven, nine, and eight significantly tightened modules by ACA, 17aE2, and Rapa, three, four, and two 168 169 modules were similarly changed by the other two interventions, respectively (Fig. 2c). In particular, 170 the four consistently tightened modules across the interventions (Fig. 2c, d, Supplementary Fig. 1c) exhibited significantly higher mean of RMSs in intervention groups compared to Control under almost 171 172 all the other intervention group's rank consensus (e.g., 17aE2 and Rapa showed significantly higher 173 RMS mean than Control under the ACA rank consensus; Fig. 2e, Supplementary Fig. 1d), suggesting 174 that fatty acid  $\beta$ -oxidation and peroxisome transport were similarly tightened by mechanistically distinct prolongevity interventions and thus may be a general mechanism contributing to longevity. 175

Taken together, these results suggest that prolongevity interventions generally tightened the regulation of the examined proteomic modules and, in the modules related to fatty acid  $\beta$ -oxidation and peroxisome transport, the tightened protein expression profile was similar between different drugs.

#### 181 **Prolongevity interventions tightened the regulation of data-driven proteomic modules**

176

177

178

179

180

Given potential biases in the module definitions with GOBP terms, we inferred data-driven modules 182 using an unsupervised clustering approach, WGCNA<sup>41,42</sup>. WGCNA identifies modules of highly 183 interconnected biomolecules, relying on the overall correlation network computed from high-184 185 dimensional data. We applied WGCNA to the LC-M001 proteomics and identified nine modules, ranging in size from 66 to 839 proteins (Fig. 3a). Each WGCNA module can be characterized by the 186 "module eigengene" (i.e., the first principal component (PC) of the protein abundance matrix for the 187 module)<sup>42</sup>. To identify the module associated with any of the interventions out of the nine data-driven 188 189 modules, we assessed the intervention effect on the module eigengene for each module using ANOVA 190 model with intervention, sex, and intervention-sex interaction terms. There were no significant 191 interaction effects in any of the nine modules, and only one module, denoted Darkgreen, exhibited a 192 significant intervention effect (P = 0.00082 after the Bonferroni adjustment). The post-hoc 193 comparison revealed that 17aE2 and Rapa, but not ACA, showed significantly higher value of the 194 module eigengene than Control in the Darkgreen module (Fig. 3b, c), suggesting that the expression 195 profile of the Darkgreen module was changed specifically by 17aE2 and Rapa.

196WGCNA fits a "scale-free" network topology where the majority of nodes share relatively197few edges with other nodes, while the central nodes that have high intramodular connectivity (called198"hub" nodes) frequently take essential functions in the system<sup>49</sup>. To better understand how 17aE2 and199Rapa changed the Darkgreen module structure, we assessed the relationship between the intervention200effect on each protein in the Darkgreen module and their respective intramodular connectivity (see

201 Methods). The intervention effect on each protein showed significant positive correlation with intramodular connectivity (Spearman's  $\rho = 0.50$ ,  $P = 2.05 \times 10^{-52}$ , Fig. 3d), suggesting that 202 intramodular hub proteins were more strongly affected by the interventions than less connected 203 204 proteins. Interestingly, 18 of the top 30 hub proteins in the Darkgreen module were mitochondrial 205 proteins, involved in tricarboxylic acid (TCA) cycle metabolism and oxidative phosphorylation (Fig. 3e). Furthermore, prohibitin 1 (PHB1) and PHB2, 2 of the top 10 hub proteins, form the mitochondrial 206 PHB complex, which is known to regulate fatty acid oxidation and assembly of mitochondrial 207 respiratory complexes<sup>50,51</sup>, as well as to affect lifespan in C. elegans<sup>52</sup>. Collectively, our results from 208 209 WGCNA revealed coordinated changes in the expression profiles of mitochondrial liver proteins that 210 were limited to two (17aE2 and Rapa) of the three studied drugs.

211 We subsequently re-analyzed the LC-M001 proteomics data using the DIRAC method with seven of the nine WGCNA-identified modules (see Methods; Fig. 3a, Supplementary Data 2). ACA, 212 213 17aE2, and Rapa showed significantly higher RCI mean in the examined modules than Control (Fig. 214 3f), suggesting general tightening of module regulation by each of these prolongevity interventions, 215 consistent with the initial DIRAC result based on GOBP terms (Fig. 2a). Additionally, all the seven 216 WGCNA modules exhibited significant intervention effects on RCI in ANOVA (FDR-adjusted P < 217 0.05; Fig. 3g) and significantly higher RCI in any intervention group compared to Control in the post 218 hoc RCI comparisons (Fig. 3g, h), suggesting that all the WGCNA modules were consistently tightened across ACA, 17aE2, and Rapa. Moreover, the Darkgreen module exhibited significantly 219 220 higher mean of RMSs in intervention groups compared to Control under almost all the other 221 intervention group's rank consensus (e.g., 17aE2 and Rapa showed significantly higher RMS mean 222 than Control under the ACA rank consensus; Fig. 3i), suggesting that the tightly regulated patterns are 223 similar between the three drugs. At the same time, Rapa's RMS mean was more similar to 17aE2's 224 RMS mean than to ACA's RMS mean (e.g., 17aE2 showed higher RMS mean than ACA under the 225 Rapa rank consensus) in the Darkgreen module (Fig. 3i), implying a difference in the tightly regulated pattern between ACA vs. 17aE2 and Rapa, in line with their effects on module expression profiles 226 227 (Fig. 3b). Note that, if the tightly regulated pattern of ACA was completely different from those of 228 17aE2 and Rapa, ACA could have showed lower RMS mean than Control under the 17aE2 or Rapa 229 rank consensus (cf. Supplementary Fig. 1b).

These findings suggest that the Darkgreen module was tightly regulated across all the three interventions, while also exhibiting intervention-specific effects on protein expression profiles related to mitochondrial energy metabolism. Altogether, our results indicate that the tightening of module regulation was a general signature of the prolongevity interventions within the measured proteomic space.

## Prolongevity interventions shifted the flux regulation in fatty acid metabolism

As a complementary approach to the findings from DIRAC and WGCNA analyses, we performed in 237 238 silico analysis using the mouse GEM<sup>43</sup> to investigate metabolic shifts associated with prolongevity 239 interventions. GEM is a mathematical framework that leverages knowledge-base cataloging 240 information about biochemical reactions within a system (e.g., single cell, tissue, organ), including metabolites, genes encoding catalytic enzymes, and their stoichiometry<sup>44</sup>. Using optimization 241 techniques with large-scale experimental data (e.g., transcriptomics), the solved stoichiometric 242 243 coefficients of each reaction allow flux prediction for metabolic reactions in the system at equilibrium<sup>53</sup>. Thus, GEM has been used to investigate metabolic changes in various systems and 244 specific contexts (e.g., human cancers)<sup>54</sup>. Since the detected proteins in the LC-M001 proteomics did 245 not sufficiently cover the metabolic proteins included in the mouse GEM, we utilized a mouse liver 246 transcriptomic dataset from a previous prolongevity intervention study<sup>45</sup> (referred as "M001-related 247 248 transcriptomics"; Fig. 1), whose experimental design resembled the LC-M001 experiment and 249 contained ACA, 17aE2, and Rapa treatments as prolongevity interventions. In this M001-related 250 experiment, 78 mice were prepared for either control or one of the prolongevity interventions, 251 including two genetically modified models (the growth hormone receptor knockout mouse (GHRKO)

and the hypopituitary Snell dwarf mouse (SnellDW)), two nutritional interventions (CR and MR), and 252 four pharmacological interventions (ACA, 17aE2, Protandim, and Rapa), and were euthanized at 253 young adult ages depending on the intervention type (n = 3-12 mice per intervention group; see 254 Methods). By integrating the M001-related transcriptomics with the mouse generic GEM<sup>43</sup> for each of 255 256 78 samples, we generated 78 "context-specific" metabolic networks (i.e., GEMs constrained by each sample condition), and subsequently predicted flux values of the metabolic reactions for each context-257 258 specific GEM (see Methods). As a result, the flux values were successfully predicted for 7,930 259 reactions among the 10,612 reactions defined in the generic GEM (Supplementary Data 3).

To identify the reaction changed by any of the interventions, we assessed the intervention 260 261 effect on the flux value using Kruskal–Wallis *H*-test for each of the 7.930 reactions. To mitigate the 262 small sample size, we pooled samples per intervention in this analysis, while recognizing the false negative risks for age and sex-dependent changes related to the sex-dependent effects of ACA, 17aE2, 263 and Protandim on lifespan extension<sup>19-21</sup>. There were 1,822 significantly changed reactions based on 264 "conservatively" FDR-adjusted P < 0.05 (see Methods; cf. 2,156 reactions exhibited nominal P < 0.05265 266 0.05; Fig. 4a). Among these 1,822 changed reactions, the post hoc comparisons of flux values between each intervention group and its corresponding control group revealed that 9, 1, 730, 851, and 1,015 267 268 reactions were significantly changed by ACA, Rapa, MR, GHRKO, and SnellDW, respectively (Fig. 269 4a-c), while no reaction was significantly changed by 17aE2, Protandim, and CR. We observed that many of these changed reactions belonged to several specific "subsystems", analogous to the 270 271 functional pathways, in the GEM system. For instance, when we focused on the central energy 272 metabolism, 8 of the 10 changed reactions belonged to the fatty acid oxidation subsystem and exhibited the concordant direction of flux change across interventions (Fig. 4d). However, it was 273 274 possible that the frequency of observed subsystems in the changed reactions was merely dependent on 275 the number of mapped reactions to the subsystem, which is largely different between  $subsystems^{43}$ . 276 Hence, to interpret which subsystems in GEM were shifted by prolongevity interventions, we further 277 performed overrepresentation analysis on the significantly changed reactions of ACA, MR, GHRKO, 278 and SnellDW. Among the 5, 53, 60, and 57 tested subsystems that were annotated to any of the 279 changed reactions, 0, 5, 13, and 11 subsystems were significantly enriched in the changed reactions of ACA, MR, GHRKO, and SnellDW, respectively (FDR-adjusted P < 0.05; Fig. 4e, Supplementary Fig. 280 2a, b, Supplementary Data 4). In particular, the biotin metabolism, cholesterol metabolism, fatty acid 281 282 oxidation, and fatty acid synthesis subsystems were consistently enriched across MR, GHRKO, and SnellDW (Fig. 4e, Supplementary Fig. 2a, b), suggesting that these biological processes were shifted 283 284 at the systems level by mechanistically distinct prolongevity interventions.

285 Given that MR has been often discussed as if it was a form of CR, we addressed the 286 difference in reaction flux between CR and MR. Among the 1,822 reactions changed by any of the 287 interventions, the post hoc comparisons of flux values among CR, MR, and their corresponding 288 control groups revealed that 0, 1,081, and 1,229 reactions were significantly different in CR vs. 289 control, MR vs. control, and MR vs. CR, respectively (Supplementary Fig. 2c-f). Overrepresentation 290 analysis revealed that 11 subsystems were significantly enriched in the different reactions between CR 291 and MR (FDR-adjusted P < 0.05; Supplementary Fig. 2g), implying that MR shifted these subsystems 292 at the systems level in a different manner from CR.

In summary, our in silico analysis differentiated the metabolic effects of different
 prolongevity interventions, and implied that multiple prolongevity interventions concordantly shifted
 fatty acid metabolism at the systems level.

## Prolongevity interventions likely tightened the module regulation partly through cap independent translation

296

299To further investigate the tightening effects of prolongevity interventions on proteomic modules (Fig.3002, 3), we applied DIRAC analysis to the M001-related transcriptomics<sup>45</sup>. Again, we pooled samples301per intervention to calculate robust DIRAC rank consensus, and analyzed only three prolongevity302interventions (ACA, Rapa, and CR) and their corresponding control (Control) based on sample size (n

= 12 (6 female, 6 male) mice per group). Using 3,747 a priori modules defined by the GOBP 303 304 annotations mapped to the measured transcripts (see Methods; Supplementary Data 5), we found that 305 ACA, Rapa, and CR showed significantly higher RCI mean in the examined modules than Control 306 (Fig. 5a). This result suggests the general tightening of module regulation within the measured 307 transcriptomic space, as well as within the measured proteomic space (Fig. 2a, 3f). We next assessed the intervention effect on RCI using ANOVA for each of the 3,747 modules, and identified 1,829 308 309 significantly changed modules by any of the interventions based on "conservatively" FDR-adjusted P 310 < 0.05 (see Methods; cf. 2,107 modules exhibited nominal P < 0.05; Supplementary Fig. 3a). Among 311 these 1,829 changed modules, the post hoc RCI comparisons between Control and each intervention 312 group revealed that 828, 432, and 1,789 modules were significantly tightened by ACA, Rapa, and CR, 313 respectively (Supplementary Fig. 3a), while no module was loosened. Subsequently, using RMS under each group's rank consensus, we explored the similarly tightened modules across the interventions. 314 315 Among the 828, 432, and 1,789 significantly tightened modules by ACA, Rapa, and CR, 35, 19, and 316 12 modules were similarly changed by the other two interventions, respectively (Supplementary Fig. 3b). For instance, *ubiquitin-dependent protein catabolic process* (GO:0006511), a consistently 317 tightened module across the interventions (Supplementary Fig. 3c), exhibited significantly higher 318 319 mean of RMSs in intervention groups compared to Control under almost all the other intervention 320 group's rank consensus (e.g., Rapa and CR showed significantly higher RMS mean than Control 321 under the ACA rank consensus; Supplementary Fig. 3d), suggesting that this module was similarly tightened in transcripts by mechanistically distinct prolongevity interventions. 322

323 To directly compare the DIRAC results between the LC-M001 proteomics and the M001related transcriptomics, we focused on the two interventions (ACA and Rapa) and the 147 GOBP 324 modules that were used in both omics results (Supplementary Data 6), and re-assessed the intervention 325 326 effect on RCI using ANOVA for each of the 147 modules and each omics. There were 10 and 5 327 significantly changed modules by any of the interventions in proteins and transcripts, respectively, based on "conservatively" FDR-adjusted P < 0.05 (see Methods). Among these changed modules, the 328 329 post hoc RCI comparisons between Control and each intervention group revealed that 8, 6, 10, and 4 330 modules were significantly tightened by ACA in proteins, ACA in transcripts, Rapa in proteins, and Rapa in transcripts, respectively (Fig. 5b). Interestingly, the modules that were significantly tightened 331 332 by ACA and Rapa in both proteins and transcripts were three modules related to fatty acid  $\beta$ -oxidation 333 (GO:0006635), retrograde transport (GO:1990126), or interleukin 7 (GO:0098761) (Fig. 5b, c). This result suggests that these modules were tightened by the prolongevity interventions via transcription-334 level changes with concordant changes of proteomic profiles. At the same time, we also observed 335 336 seven modules which were tightened specifically in proteins (Fig. 5b). In particular, tryptophan 337 catabolic process to kynurenine (GO:0019441) exhibited significantly higher RCI across interventions compared to Control specifically in proteins (Fig. 5d), suggesting that this module was tightened by 338 339 ACA and Rapa in the proteomic profile but not in the transcriptomic profile. This inconsistency may 340 reflect post-transcriptional regulatory mechanisms that can affect protein profiles beyond 341 transcriptional changes. For instance, since the abundance of a protein is determined by both its 342 synthesis and degradation rates, a difference in "proteostasis", whose loss is known as an aging signature<sup>1,55</sup>, can lead to the change in protein abundance without a change in transcript abundance. 343

Likewise, CIT<sup>46</sup> can be a possible post-transcriptional mechanism to explain the inconsistency 344 between proteins and transcripts. In contrast to the standard cap-dependent translation, CIT does not 345 346 require the interaction of the eukaryotic initiation factor 4E (eIF4E) complex with 5' cap of mRNA; 347  $N^6$ -methyladenosine (m<sup>6</sup>A) modification in 5' untranslated regions of mRNA can trigger the recruitment of specific initiation and elongation factors, followed by the selective translation of m<sup>6</sup>A-348 tagged mRNAs. Previous studies have shown the upregulated translation of a subset of mRNAs via 349 CIT in long-lived endocrine mutant mice<sup>56</sup> and similar increases of CIT in mice treated with ACA, 350 17aE2, or Rapa<sup>57</sup>. We therefore tested if CIT could explain the difference in module regulation 351 352 between proteins and transcripts, by jointly applying DIRAC analysis to the LC-M001 proteomics and 353 another liver proteomic dataset which was generated through a mouse CIT experiment (denoted "LC-354 M004 proteomics"; Fig. 1). In this experiment, 16 mice were treated with either solvent (Control-2) or

4EGI-1, a synthetic small compound which inhibits the eIF4E-eIF4G interaction and thereby blocks 355 cap-dependent translation and enhances  $CIT^{58}$ , and were euthanized at young adult ages (n = 8 (4 356 female, 4 male) mice per group). To directly compare the DIRAC results across the LC-M001 and 357 358 LC-M004 proteomics, we focused on 153 GOBP modules for this analysis, which were mapped to the 359 measured proteins in both datasets (see Methods; Supplementary Data 7). Consistent with the elevated module tightness in ACA, 17aE2, and Rapa against their corresponding control (Control-1), 4EGI-1 360 361 showed significantly higher RCI mean in the examined modules compared to Control-2 (Fig. 5e), 362 implying general tightening of module regulation by the CIT enhancement. To reveal the similarity of module regulation between prolongevity interventions and 4EGI-1, we calculated RMSs under the 363 364 rank consensus of Control-2 and 4EGI-1 for the LC-M001 groups (Control-1, ACA, 17aE2, and Rapa), and assessed the intervention effect on the RMS mean using ANOVA for each of the 153 365 modules and each rank consensus. There were four and seven significantly changed modules by any 366 of the interventions under the Control-2 and 4EGI-1 rank consensus, respectively, based on 367 "conservatively" FDR-adjusted P < 0.05 (see Methods; cf. 24 and 41 modules exhibited nominal P < 0.05368 0.05, respectively). Among these seven changed modules under the 4EGI-1 rank consensus, the post 369 hoc comparisons for the RMS mean between Control-1 and each intervention group revealed that two, 370 371 one, and three modules were changed "dissimilarly" to the 4EGI-1 consensus by ACA, 17aE2, and 372 Rapa, respectively (Supplementary Fig. 3e). For instance, in RIG-I signaling pathway (GO:0039529), 373 all the ACA, 17aE2, and Rapa showed significantly lower mean of RMSs than Control-1 under the 4EGI-1 consensus (Supplementary Fig. 3f). Given that this module was similarly tightened across the 374 375 interventions in proteins (Supplementary Fig. 1e, f) while ACA and Rapa did not show the significant RCI difference from control in transcripts (Supplementary Fig. 3g), this result suggests that *RIG-I* 376 377 signaling pathway may be tightened in proteins via post-transcriptional regulation other than CIT. In 378 contrast, the post hoc RMS mean comparisons for the seven changed modules also revealed that two modules were changed "similarly" to the 4EGI-1 consensus by 17aE2 (Fig. 5f); e.g., mitochondrial 379 ATP synthesis coupled proton transport (GO:0042776) exhibited significantly higher mean of RMSs 380 381 in 17aE2 compared to Control-1 (Supplementary Fig. 3h). Because the regulatory pattern of 17aE2 in 382 transcripts was not available and because our P-value adjustment for multiple hypotheses was 383 conservative (see Methods), we also checked the 41 changed modules based on nominal P < 0.05under the 4EGI-1 rank consensus. The post hoc RMS mean comparisons for these 41 changed 384 385 modules revealed that four and three modules were changed "similarly" to the 4EGI-1 consensus by 386 17aE2 and Rapa, respectively (Fig. 5f). Remarkably, in coding region instability determinant (CRD)mediated mRNA stabilization (GO:0070934) and positive regulation of RNA polymerase II 387 transcription preinitiation complex (PIC) assembly (GO:0045899), Rapa showed significantly higher 388 389 mean of RMSs than Control-1 under the 4EGI-1 rank consensus (Fig. 5g, Supplementary Fig. 3i), while Rapa did not show the significant RCI difference from control in transcripts (Fig. 5h, 390 391 Supplementary Fig. 3j), suggesting that regulation of these processes was modified by Rapa likely via 392 CIT.

393Altogether, these findings suggest that the tightening of module regulation was a general394signature of the prolongevity interventions even within the measured transcriptomic space and that the395tightened modules in proteins were achieved through both transcriptional and post-transcriptional396regulation, potentially including augmented CIT.

397 398

## Module regulation was changed across chronological and biological ages

399 Our results observed in mice demonstrate that the molecular regulation of biological processes is 400 modifiable at the systems level. To address the systems-level dynamics through lifetime in humans, 401 we investigated the cross-sectional relationship between the tight module regulation and age by 402 applying DIRAC analysis to a plasma proteomic dataset which was collected through the Arivale program<sup>47,48</sup> (Fig. 1). This cohort consisted of community-dwelling adults ranging from 18 to 89 years 403 old, who were not screened for any particular disease, and we stratified this cohort into deciles per sex 404 by chronological age (referred as "CA10"; Supplementary Fig. 4a). Setting these CA10 groups as the 405 group unit for the rank consensus, we calculated DIRAC metrics for 19 a priori modules which were 406

407 defined by the GOBP annotations mapped to the measured proteins (see Methods: Supplementary Data 8). The RCI median in the examined modules gradually decreased along an aging gradient in 408 409 younger groups, while this overall trend was reversed in older groups (Fig. 6a). We randomized the 410 sample-group correspondence to calculate an empirical null-hypothesis distribution, and confirmed 411 that the RCI median was significantly higher than expected in almost all the CA10 groups 412 (Supplementary Fig. 4b), suggesting that the examined modules were generally under the tight 413 regulation especially in the youngest group (Q1) and the oldest group (Q10). Next, we compared the 414 similarity of module regulation across chronological age using RMS under the O1 or O10 rank 415 consensus. The module RMS mean showed significant negative and positive correlations with the 416 quantile order of CA10 groups under the Q1 and Q10 rank consensus, respectively (Spearman's  $\rho =$ 417 -0.78 (Q1, female), -0.40 (Q1, male), 0.70 (Q10, female), 0.60 (Q10, male); Fig. 6b), suggesting that module regulation was generally more similar between closer CA10 groups and the regulatory 418 419 patterns were vastly dissimilar between Q1 and Q10. To identify the module whose regulation 420 similarity to Q1 or Q10 was associated with chronological age, we regressed the RMS under the Q1 or Q10 consensus to chronological age with Body Mass Index (BMI) and ancestry PCs as covariates for 421 422 each of the 19 modules, each rank consensus, and each sex. There were 18 and 13 modules exhibiting 423 a significant negative association under the O1 rank consensus and 17 and 18 modules exhibiting a 424 significant positive association under the Q10 rank consensus for female and male, respectively, based 425 on "conservatively" FDR-adjusted P < 0.05 (see Methods; Fig. 6c). For instance, *neutrophil* chemotaxis (GO:0030593) exhibited significant negative and positive associations of the RMS with 426 427 chronological age in both sexes under the Q1 and Q10 rank consensus, respectively (Fig. 6d), suggesting that this module was gradually changed across chronological age and its regulatory pattern 428 429 was vastly dissimilar between younger and older individuals. These results suggest that the general 430 tightness of module regulation decreased with chronological age up until midlife but then increased 431 during older stage and that the tight patterns of module regulation were different between younger and older individuals. 432

433 To validate these findings in another dimensional space, we performed DIRAC analysis on a 434 plasma metabolomic dataset of the Arivale cohort (Fig. 1). Since the dataset availability was different between participants, we re-defined CA10 groups for this analysis (Supplementary Fig. 5a). Because 435 functional annotations to define metabolite modules are limited, we used the nine data-driven 436 437 metabolomic modules identified by WGCNA (Supplementary Fig. 5b, Supplementary Data 9). Again, the RCI median in the examined modules exhibited the "U-shaped" transition with respect to CA10 438 group (Supplementary Fig. 5c), and the module RMS mean showed significant negative and positive 439 440 correlations with the quantile order of CA10 groups under the Q1 and Q10 rank consensus, 441 respectively (Spearman's  $\rho = -0.90$  (Q1, female), -0.76 (Q1, male), 0.87 (Q10, female), 0.66 (Q10, male); Supplementary Fig. 5d). Subsequently, we regressed the RMS under the O1 or O10 consensus 442 443 to chronological age with BMI and ancestry PCs as covariates for each of the nine modules, each rank 444 consensus, and each sex. All the nine modules exhibited significant negative and positive associations 445 under the O1 and O10 rank consensus for both sexes, respectively, based on FDR-adjusted P < 0.05(Supplementary Fig. 5e, f). Therefore, in line with the examined proteomic space, the similar 446 447 associations between the tightness of module regulation and chronological age were observed in the examined metabolomics space. 448

Previously, a multiomic estimate for chronological age (biological age) has been calculated 449 for the Arivale cohort<sup>48</sup>. Importantly, the difference between chronological and biological ages ( $\Delta$  age) 450 451 was a more accurate metric of wellness than chronological age (i.e., negative and positive  $\Delta$  ages indicated healthier and unhealthier conditions than chronologically expected, respectively) and 452 modifiable (i.e., lifestyle intervention decreased  $\Delta$  age). Hence, we further explored the relationships 453 454 between module regulation and health conditions by re-performing DIRAC analysis on the Arivale proteomics with  $\Delta$  age-stratified groups; we divided the Arivale cohort into tertiles per sex by 455 456 chronological age (referred as "CA3") and further stratified each CA3 group into five subgroups by  $\Delta$ 457 age (referred as "DA5"; Fig. 6e, Supplementary Fig. 4c). Under the rank consensus of the most negative  $\Delta$  age subgroup in young CA3 group (Y-subQ1) and the most positive  $\Delta$  age subgroup in old 458

459	CA3 group (O-subQ5), the module RMS mean showed significant negative and positive correlations
460	with the quantile order of DA5 subgroups in young and old CA3 groups, respectively (Spearman's $\rho$ =
461	-0.42 (Y-subQ1, young female), -0.56 (Y-subQ1, young male), 0.51 (O-subQ5, old female), 0.60 (O-
462	subQ5, old male); Fig. 6f). Moreover, these negative and positive correlations between the module
463	RMS mean and the quantile order of DA5 subgroups under the Y-subQ1 and O-subQ5 rank
464	consensus, respectively, were observed in the other CA3 groups as a tendency or with statistical
465	significance based on the Holm-Bonferroni adjustment (Fig. 6f). These results suggest that module
466	regulation was generally more similar between closer DA5 groups and the regulatory patterns were
467	vastly dissimilar between Y-subQ1 and O-subQ5. To identify the module whose regulation similarity
468	to Y-subQ1 or O-subQ5 was associated with $\Delta$ age, we regressed the RMS under the Y-subQ1 or O-
469	subQ5 consensus to $\Delta$ age with chronological age, BMI, and ancestry PCs as covariates for each of the
470	19 modules, each rank consensus, each sex, and each CA3 group. There were 11, 7, 6, 13, 1, and 4
471	modules exhibiting a significant negative association under the Y-subQ1 rank consensus and 5, 10, 9,
472	7, 1, and 10 modules exhibiting a significant positive association under the O-subQ5 rank consensus
473	for female young, female middle, female old, male young, male middle, and male old CA3 groups,
474	respectively, based on "conservatively" FDR-adjusted $P < 0.05$ (see Methods; Fig. 6g). For instance,
475	neutrophil chemotaxis (GO:0030593) exhibited significant negative and positive associations of the
476	RMS with $\Delta$ age in both sexes and all the CA3 groups, except for male middle CA3 group, under the
477	Y-subQ1 and O-subQ5 rank consensus, respectively (Supplementary Fig. 4d), suggesting that this
478	module was gradually changed across $\Delta$ age and its regulatory pattern was vastly dissimilar between
479	biologically younger and biologically older individuals. Likewise, we re-performed DIRAC analysis
480	on the Arivale metabolomics with $\Delta$ age-stratified groups, and observed the same association patterns
481	between the RMS under the Y-subQ or O-subQ5 rank consensus and $\Delta$ age (Supplementary Fig. 6).

482Altogether, these results imply that the regulatory patterns of proteomic and metabolomic483modules shifted depending on both chronological and biological ages and that the tight module484regulation representatively corresponded to a healthier state in the young stage but an unhealthier state485in the old stage.

## 487 **Discussion**

486

Studies in invertebrate organisms and mice have shown multiple ways to extend lifespan and postpone 488 age-related diseases<sup>3,10–12</sup>. Aging can be slowed, and healthspan can be extended, by mutation of 489 490 individual genes, dietary restrictions, or oral administration of compounds. Data are becoming 491 available to determine which of the many cellular and molecular traits modified by each of these 492 interventions are shared across slow-aging models and which are less universal. Elucidation of the 493 physiological and cellular mechanisms of effective interventions will provide clues for possible 494 measures to improve human health and may also give useful prognostic information. In this study, we 495 demonstrated the following key findings: (1) prolongevity interventions generally tightened the systems-level regulation of biological processes at both transcriptional and post-transcriptional layers 496 497 in mice; (2) fatty acid metabolism emerged as a common process shifted by multiple prolongevity 498 interventions; (3) the systems-level regulation of biological processes was associated with both 499 chronological and biological ages in humans.

500 By leveraging mouse omics datasets and systems-level approaches, we demonstrated that prolongevity interventions modified biological processes and metabolic reactions at the systems level 501 (Fig. 2–5). In particular, DIRAC analyses revealed that the tightening of module regulation was a 502 503 general signature of the prolongevity interventions within the measured proteomic and transcriptomic spaces (Fig. 2a, 3f, 5a). Interestingly, a previous study using DIRAC revealed the general loosening of 504 module regulation in more malignant phenotypes and later stages of cancer progression<sup>40</sup>. Given that 505 cancer resistance and longevity share commonality in mechanisms such as DNA repair and telomere 506 maintenance<sup>55,59</sup>, aging may be promoted, in part, by loss of tight regulation for pertinent modules, 507 and its tightness maintenance may be a key longevity strategy. Furthermore, we identified at least 12 508 509 proteomic modules (Fig. 2b, Supplementary Data 1), 1,829 transcriptomic modules (Supplementary

Fig. 3a, Supplementary Data 5), and 1.822 reactions (Fig. 4a, Supplementary Data 3) affected by any 510 of the prolongevity interventions. These modules and reactions included the biological processes 511 highly related to "aging hallmarks"<sup>55</sup> and "pillars of aging"<sup>1</sup>, such as amino acid regulation, fatty acid 512 regulation, TCA cycle, stress response, and inflammation, consistent with the proposed roles of these 513 processes in aging<sup>6-9,55</sup>. Therefore, our current study showed the power of systems-level approaches to 514 explore and test hypotheses about the control of aging and longevity in mammals, and provided a 515 translational implication that potential prolongevity interventions may be identified and evaluated 516 517 based on their regulatory effects on these systems.

518 Fatty acid  $\beta$ -oxidation is the catabolic process of fatty acid breakdown for energy production, with mitochondria and peroxisomes being the major involved organelles<sup>60</sup>. We demonstrated that fatty 519 acid β-oxidation was tightened in both proteins and transcripts consistently across mechanistically 520 distinct prolongevity interventions (Fig. 2d, 5c). We also observed that the system transporting 521 522 proteins into peroxisomes was tightened in proteins consistently across the interventions 523 (Supplementary Fig. 1c), and implied the possibility that some aspects of mitochondrial functions 524 were affected by 17aE2 and Rapa (Fig. 3e). Moreover, we showed that reactions involved in fatty acid 525 synthesis and oxidation were concordantly shifted across MR, GHRKO, and SnellDW (Fig. 4d, e, 526 Supplementary Fig. 2a, b). All these findings support the conclusion that fatty acid  $\beta$ -oxidation was directed towards tight control in a whole cellular system for longevity. At the same time, this systems-527 level control of fatty acid  $\beta$ -oxidation was observed quite possibly through different mechanisms by 528 529 each intervention. For example, the tightening pattern in acetyl-CoA synthesis, which is essentially 530 connected to fatty acid β-oxidation, was similar between 17aE2 and Rapa, but different from ACA (Supplementary Fig. 1b); 17aE2 and Rapa, but not ACA, similarly modulated expression patterns of 531 532 mitochondrial proteins (Fig. 3b); the prolongevity interventions other than MR, GHRKO, and 533 SnellDW did not show the (significant) flux changes in fatty acid  $\beta$ -oxidation (Fig. 4d). Hence, we 534 hypothesize that different prolongevity interventions lead to a similar rerouting of energy metabolism through fatty acid metabolism, albeit through different mechanisms. Although the findings from 535 536 DIRAC, WGCNA and GEM do not indicate the functional direction for cells (e.g., tight regulation can 537 be either augmentation or attenuation of a pathway), there are multiple reports about fatty acid oxidation in aging and longevity; AMPK, an essential kinase of the nutrient-sensing signaling 538 539 pathways in longevity, inhibits fatty acid synthesis and promotes fatty acid oxidation via inhibition of acetyl-CoA carboxylase 1 (ACC1) and ACC2<sup>6,61</sup>; CR increases fatty acid synthesis in adipose tissue 540 but results in enhancing whole-body oxidation<sup>62</sup>; ketogenic diet specifically upregulates the genes 541 involved in fatty acid oxidation in liver<sup>15</sup>; overexpression of fatty acid-binding protein (FABP) or 542 543 dodecenoyl-CoA delta-isomerase (DCI), corresponding to the acceleration of fatty acid  $\beta$ -oxidation, increased lifespan in *D. melanogaster*<sup>63</sup>. Therefore, tight regulation promoting fatty acid  $\beta$ -oxidation 544 could be a common signature among prolongevity strategies. On the other hand, the prominence of the 545 546 nutrient-sensing or energy-producing process from liver-derived datasets might be unsurprising 547 because the liver is a major metabolic organ. However, we also observed that prolongevity 548 interventions tightened the modules less often associated with liver and metabolism, such as RIG-I 549 signaling (GO:0039529; Supplementary Fig. 1e, f, 3f) and CD40 signaling (GO:0023035; 550 Supplementary Data 1). In the mid-life human female brain, metabolic and immune systems are shifted by chronological age: glucose metabolism and fatty acid  $\beta$ -oxidation are attenuated and 551 enhanced, respectively, and chronic low-grade innate and adaptive immune responses are enhanced<sup>64</sup>. 552 Hence, the interrelationship between fatty acid metabolism and innate/adaptive inflammation is an 553 interesting area for future investigations. 554

555Aging accompanies progressive loss of homeostasis. This intuition can be qualitatively556assessed by "allosteric load" (also known as "physiological dysregulation"), and this measure557increases with chronological age<sup>65-67</sup>. Hence, we anticipated that the tightness of module regulation558would monotonically decrease with chronological age. However, we observed the "U-shaped"559trajectory of the RCI median: the tight module regulation decreased as a function of chronological age560up to mid-life, and increased from mid-life onwards (Fig. 6a, Supplementary Fig. 5c). Our consecutive561analyses (Fig. 6b, f, Supplementary Fig. 5d, 6c) implied that the tight patterns of module regulation

were representatively characterized by a young healthy state (Y-subO1) and an old unhealthy state (O-562 subQ5). Namely, one of the interpretations is that the U-shaped trajectory was deduced from the 563 564 higher variations in health state among middle-aged individuals. These findings suggest that the binary interpretation of "dysregulation" is insufficient for understanding molecular and physiological 565 566 processes in aging. As a limitation, we cannot deny potential effects of survivorship bias on the state transition observed in older ages, which may have diminished the monotonic reduction pattern. A 567 further limitation is that we cannot deduce exactly which mechanisms are responsible for regulating 568 569 the systems entropy that we measure (i.e., rank conservation); these mechanisms are predominantly 570 under autonomous intracellular controls such as biochemical and transcriptional regulations but could 571 be affected by behavioral/neurological or external/environmental controls, which may have generated the "U-shaped" pattern. Nevertheless, we have previously reported that healthy individuals have an 572 increasingly divergent gut microbiome compositional state with  $age^{68}$ . A bacterial microbiome in D. 573 melanogaster is necessary for age-dependent changing patterns in metabolism and immune 574 575 response<sup>69</sup>. Hence, there may be a critical link between the aging patterns of module regulation and gut microbiome, especially in metabolomic space<sup>70</sup>, which lead to the tight module regulation in older 576 577 ages.

There are several limitations to this study. In DIRAC and GEM analyses, we pooled female 578 579 and male samples due to a small sample size. Hence, it is highly possible that we failed to identify sex-dependent changes, especially related to the known sex-dependent effects of ACA, 17aE2, and 580 Protandim on lifespan extension<sup>19–21</sup>. Because this study successfully validated the utility of systems-581 582 level approaches and because sex dimorphism in aging and longevity remains not fully elucidated<sup>71</sup>, we plan to address this point as a continued study by leveraging the upcoming datasets that are 583 584 generated from experiments with larger sample sizes. Additionally, there were marked differences in 585 study design between the mouse and human datasets (Fig. 1); the former addressed the systems that 586 were changed by prolongevity interventions under young adults, while the latter addressed the systems that were observed across age in an adult population. To directly link the findings from mice to 587 588 humans, one could theoretically compare the DIRAC metrics between short-lived and long-lived 589 individuals or between the individuals with or without prolongevity intervention across decades, for example, although this is not so easy in practice. In addition, the regulation for biological systems may 590 591 not be conserved between mouse liver and human blood. Moreover, there were few commonly 592 examined modules between mouse liver proteomics and human blood proteomics due to the difference in the measured proteins (Supplementary Data 1, 8). Hence, our findings in mice and humans may be 593 entirely unrelated. However, a coherent explanation may be possible to connect our mouse and human 594 595 findings. Given that the median lifespans of UM-HET3 mice in our experimental facility are 596 approximately 886 and 863 days for females and males, respectively, the mice used in this study (12 months old) completed around 42% of their potential lifespan. Assuming 80 years as a median 597 598 lifespan for humans, this would correspond to roughly 34 years-old humans. Therefore, the module state tightened by the prolongevity interventions in mice (Fig. 2, 3, and 5) may be related to the young 599 600 healthier state observed in humans (Y-subO1 in Fig. 6 and Supplementary Fig. 6), in line with the clinical anticipation that appropriate interventions (e.g., prolongevity drug administration, dietary CR) 601 602 can slow aging in humans, at least, at young or middle stage. Further investigations, including how prolongevity interventions affect older mice, are required to deepen our understanding of systems-603 604 level regulation.

#### 606 Methods

#### 607 Mouse liver proteomic datasets

Liver samples from mice fed with lifespan-extending drugs were collected as previously described<sup>57</sup>. 608 Briefly, 12 (6 female and 6 male) genetically heterogeneous UM-HET3 mice were prepared for each 609 610 sample group: control, acarbose (ACA),  $17\alpha$ -estradiol (17aE2), and rapamycin (Rapa). The drugs were treated via daily feeding of the Purina 5LG6 diet with ACA  $(1,000 \text{ mg kg}^{-1})$ , 17aE2 (14.4 mg 611 612  $kg^{-1}$ ), or Rapa (14 mg kg<sup>-1</sup>) starting at 4 months. At 12 months, the mice fasted for 18 h and were 613 euthanized for liver sampling. Excised livers were washed in phosphate-buffered saline (PBS) and snap-frozen for proteomic analysis. All procedures followed the methods recommended by the 614 National Institute on Aging (NIA) Interventions Testing Program (ITP)<sup>18</sup>. Hereinafter, this experiment 615 616 is called "LC-M001".

617Liver samples from 4EGI-1-treated mice were collected as previously described<sup>56</sup>. Each618group, control and 4EGI-1, consisted of 4 female and 4 male UM-HET3 mice aged 6 to 8 months old.619Controls received an intraperitoneal injection of 15  $\mu$ L dimethyl sulfoxide (DMSO) daily for 5 days,620and treated mice received DMSO containing 4EGI-1 at 75 mg per kg body weight. After the last621injection, the mice were fasted for 18 h prior to euthanasia. Excised livers were washed in PBS and622snap-frozen for proteomic analysis. Hereinafter, this experiment is called "LC-M004".

623 The frozen livers were dissected, processed with lysis and trypsin digestion, and analyzed by 624 mass spectrometry (MS) for quantitative protein abundance. Liver sections were placed in lysis buffer (50 mM tris(hydroxymethyl)aminomethane (Tris)-HCl pH 8.0 and 5% sodium dodecyl sulfate (SDS)) 625 and homogenized using a Precellys<sup>®</sup> 24 tissue homogenizer (Bertin Technologies SAS, Montigny-le-626 Bretonneux, France). For each sample, protein concentrations were determined by a bicinchoninic 627 acid (BCA) assay. 300 µg of solubilized protein extract in 5% SDS was purified to remove SDS using 628 629 Midi-S-Trap<sup>™</sup> sample processing technology (ProtiFi, New York, USA), and digested with trypsin at 630 37 °C for 4 h. The extracted tryptic peptides were subjected to reverse phase liquid chromatography tandem mass spectrometry (LC-MS/MS), using an Easy-nLC 1000 (Thermo Fisher Scientific, 631 Massachusetts, USA) with a 50 cm fused silica capillary (75 µm inner diameter) packed with C18 632 633 (ReproSil-Pur 1.9 um; Dr. Maisch GMBH, Ammerbuch, Germany) heated to 45 °C. The mobile phase gradient consisted of 5–35% acetonitrile and 0.1% formic acid over 3 h for the LC-M001 samples or 634 over 2 h for the LC-M004 samples. The LC-M001 samples were analyzed on a Q Exactive-HF mass 635 spectrometer (Thermo Fisher Scientific) in data-dependent acquisition (DDA) mode with an MS scan 636 mass range of 375-1375 m/z and a resolution of 60,000. MS/MS scans were acquired with TopN = 15 637 638 using 15,000 resolution, with an isolation width of 1.8 m/z, AGC set to 100,000, and 100 ms injection time. NCE was set to 27, and dynamic exclusion was set to 20 s. The LC-M004 samples were 639 640 analyzed on an Orbitrap Fusion Lumos (Thermo Fisher Scientific) in DDA mode with an MS scan mass range of 375-1375 m/z and a resolution of 60,000. MS/MS scans were acquired with TopN = 12 641 using 15,000 resolution with an isolation width of 1.8 m/z, AGC set to 40,000, and 30 ms injection 642 time. NCE was set to 30, and a dynamic exclusion was set to 30 s. 643

644MS data analysis was conducted using the Trans-Proteomic Pipeline<sup>72</sup>. Peptide identification645was performed by database searching with Comet<sup>73</sup> using the mouse reference proteome646UP000000589 (UniProt, downloaded on June 11, 2019) filtered to one protein sequence per gene.647Peptide sequences were validated with PeptideProphet<sup>74</sup> and iProphet<sup>75</sup>. Protein inference was648performed with ProteinProphet<sup>76</sup>. Protein quantification was performed using the top-3 method<sup>77,78</sup> on649quantities obtained from the extracted ion chromatograms of the precursor signals of the identified650proteotypic peptides.

652 Mouse liver transcriptomic dataset

653The processed dataset of mouse liver transcriptomics was kindly provided by Vadim N. Gladyshev654(Harvard Medical School). Complete descriptions are found in the original paper<sup>45</sup>. Briefly, the655original experiment was designed to investigate eight prolongevity interventions: two genetically

modified models (the growth hormone receptor knockout mouse (GHRKO) and the hypopituitary 656 Snell dwarf mouse (SnellDW)), two nutritional interventions (calorie restriction (CR) and methionine 657 658 restriction (MR)), and four pharmacological interventions (ACA, 17aE2, Protandim<sup>®</sup>, and Rapa). Three 5 months-old male mice were prepared for each sample group in genetically modified models: 659 660 SnellDW control (SnellWT), SnellDW, GHRKO control (GHRWT), and GHRKO. Three UM-HET3 mice were prepared for each of the 22 sex- and age-distinguished sample groups in nutritional and 661 pharmacological interventions: 6 months-old female of control, CR, ACA, 17aE2, Protandim, and 662 663 Rapa: 12 months-old female of control, CR, ACA, and Rapa: 6 months-old male of control, CR, ACA, 17aE2, Protandim, and Rapa; 12 months-old male of control, CR, ACA, and Rapa; 14 months-old 664 male of MR control and MR. The nutritional and pharmacological interventions were treated via daily 665 feeding of the Purina 5LG6 diet with CR (40% less than control) starting at 4 months, with MR 666 (0.12% w/w methionine; cf. 0.86% w/w methionine in MR control) starting at 2 months, or with ACA 667  $(1,000 \text{ mg kg}^{-1})$ , 17aE2 (14.4 mg kg<sup>-1</sup>), Protandim (1,200 mg kg<sup>-1</sup>), or Rapa (42 or 14 mg kg<sup>-1</sup> for 6 668 669 or 12 months-old, respectively) starting at 4 months. The liver samples were processed for paired-end RNA sequencing using NovaSeq 6000 sequencing system (Illumina, California, USA). The processed 670 reads after the quality filtering and adapter removal were mapped to gene and counted. After filtering 671 out genes with low number of reads, the count data of the filtered genes was passed to the relative log 672 673 expression (RLE) normalization.

674 675

## Human plasma proteomic and metabolomic datasets

The original human plasma proteomic and metabolomic datasets relied on a cohort consisting of over 676 677 5,000 individuals who participated in the Arivale Scientific Wellness program (Arivale, Washington, USA). Complete descriptions are found in the previous papers<sup>47,48,70</sup>. Briefly, an individual was 678 eligible for enrollment if the individual was over 18 years old, not pregnant, and a resident of any US 679 state except New York; participants were primarily recruited from Washington, California, and 680 681 Oregon. In this program, multionic data was collected, including human genomes, longitudinal 682 measurements of clinical lab tests, proteomics, metabolomics, gut microbiomes, and wearable devices, 683 and health/lifestyle questionnaires. Peripheral venous blood draws for all measurements were performed by trained phlebotomists at LabCorp (Laboratory Corporation of America Holdings, North 684 Carolina, USA) or Quest (Quest Diagnostics, New Jersey, USA) service centers. Proteomic data was 685 generated using proximity extension assay (PEA) for plasma derived from whole blood samples with 686 several Olink Target panels (Olink Proteomics, Uppsala, Sweden), and measurements with the 687 Cardiovascular II, Cardiovascular III and Inflammation panels were used in the present study since the 688 689 other panels were not necessarily applied to all samples. Metabolomic data was generated using ultrahigh-performance liquid chromatography-tandem mass spectrometry (UHPLC-MS/MS) for plasma 690 691 derived from whole blood samples by Metabolon (North Carolina, USA). This study was conducted 692 with deidentified data of the participants who had consented to the use of their anonymized data in 693 research. All procedures were approved by the Western Institutional Review Board (WIRB) with Institutional Review Board (IRB) (Study Number: 20170658 at Institute for Systems Biology and 694 695 1178906 at Arivale).

In this study, we selected the participants for whom the multiomic biological age<sup>48</sup> and 696 697 general covariates (Body Mass Index (BMI) and ancestry principal components (PCs)) had been 698 calculated, and retrieved the baseline proteomic or metabolomic dataset (i.e., the first time point 699 measurement for each participant). Analytes which were missing in more than 10% of participants 700 were removed, and participants who had missing values for more than 10% of the remaining analytes were removed. Missing values were imputed with random forest using Python missingpy library 701 702 (version 0.2.0). Some proteins were measured on multiple Olink panels; these values were averaged to 703 produce one value per protein. The final preprocessed proteomic and metabolomic datasets were 263 704 proteins × 2,714 participants and 739 metabolites × 1,899 participants, respectively. 705

706 Weighted Gene Coexpression Network Analysis

707 Weighted Gene Coexpression Network Analysis (WGCNA) was performed using R WGCNA package (version 1.69) according to the WGCNA methodlogy<sup>42</sup>. Analytes were initially filtered based 708 on missing values with the default threshold setting (50%), and the remained analytes were used to 709 710 generate the coexpression network. Network generation was performed using Spearman's correlation 711 and the signed-hybrid approach within the WGCNA package. The  $\beta$  parameter to approximate a scalefree topology was defined with 7 for the LC-M001 proteomics and 11 for the Arivale metabolomics, 712 using the pickSoftThreshold function. Module identification was subsequently performed using the 713 714 topological overlap matrix and the default hierarchical clustering approach with dynamic tree cut. 715 Consequently, nine modules were identified for the LC-M001 proteomics (Fig. 3a) and the Arivale 716 metabolomics (Supplementary Fig. 5b). The identified modules were summarized with "module eigengene": the *q*-module eigengene  $E^{(q)}$  corresponds to the first PC of the expression matrix of 717 proteins in that module. In addition, intramodular connectivity (i.e., the sum of the adjacency to the 718 719 other nodes within the module) was calculated for each protein of the modules. 720

- 721 Differential Rank Conservation analysis
- 722 Preprocessing

723 To apply Differential Rank Conservation (DIRAC) analysis, missingness in the mouse datasets was conservatively resolved by filtering out the analytes that were not detected in one or more samples; the 724 725 final number of analytes was 2,231 proteins for DIRAC analysis of the LC-M001 proteomics, 2,112 726 proteins for DIRAC analysis of the LC-M001 and LC-M004 proteomics, and 11,192 transcripts for DIRAC analysis of the M001-related transcriptomics. Missingness in the human datasets was resolved 727 by imputation during the aforementioned cohort-defining pipeline. In this study, the analyte values 728 729 were normalized using "robust Z-score" (i.e., Z-score using median and median absolute deviation 730 (MAD) instead of mean and SD, respectively) for each sample, and further normalized using robust Z-731 score for each analyte based on the median and MAD of the control group (mouse datasets) or the 732 whole population (human datasets). In mouse datasets, samples with different conditions in sex and 733 age but the same intervention were handled as a single sample group to calculate robust DIRAC rank consensus from small sample size, while recognizing the false negative risks for potential sex or age-734 dependent changes. 735

#### 736 – Module set preparation

For each protein in the preprocessed datasets, the Gene Ontology Biological Process (GOBP) 737 738 annotations were retrieved using the European Molecular Biology Laboratory's European 739 Bioinformatics Institute (EMBL-EBI) QuickGO application programming interface (API) with a 740 query of UniProt ID (January 26, 2021 for mouse datasets; June 1, 2022 for human dataset). For each gene in the preprocessed dataset, the GOBP annotations were retrieved using R org.Mm.eg.db 741 package (version 3.12.0) with a query of the Ensembl ID. Each GOBP term defines a priori module 742 743 consisting of all annotated proteins/genes in the corresponding species (i.e., backgrounds). To 744 maintain the biological meaning of annotation, the modules were further selected if at least half of the 745 members in the module, with a minimum of four members, were quantified in the preprocessed 746 datasets; the final a priori module set was 164 modules for DIRAC analysis of the LC-M001 747 proteomics (Supplementary Data 1), 153 modules for DIRAC analysis of the LC-M001 and LC-M004 748 proteomics (Supplementary Data 7), and 3,747 modules for DIRAC analysis of the M001-related 749 transcriptomics (Supplementary Data 5). Due to the small number of quantified proteins in the 750 preprocessed Arivale proteomics, the selection criterion was relaxed to 30% of the proteins in each module but still at least four proteins; the final a priori module set was 19 modules for DIRAC 751 752 analysis of the Arivale proteomics (Supplementary Data 8).

753Data-driven modules were prepared by applying WGCNA to each of the LC-M001754proteomics and the Arivale metabolomics, as described above. Because missingness was differently755handled between DIRAC analysis and WGCNA, each WGCNA-identified module could have the756analytes that were not retained in the preprocessed datasets for DIRAC analysis (Fig. 3a,

Supplementary Fig. 5b). Hence, the WGCNA modules were further selected if at least half of the
members in the module, with a minimum of four members, were retained in the preprocessed datasets;
the final data-driven module set was seven modules for DIRAC analysis of the LC-M001 proteomics
(Supplementary Data 2) and nine modules for DIRAC analysis of the Arivale metabolomics
(Supplementary Data 9).

## 762 – **DIRAC calculation**

776

796

The DIRAC algorithm<sup>40</sup> was reimplemented in Python (version 3.7.6 or 3.9.7). Briefly, pairwise 763 comparisons of analyte values within a module are initially performed for each sample, generating a 764 765 "ranking/ordering dataframe" which contains binary values about whether analyte, value is larger than 766 analyte, value. Next, consensus of the binary values is calculated per analyte, analyte, pair for each sample group (called "phenotype" in the original paper) by majority vote, generating a binary 767 "ranking/ordering template dataframe" which corresponds to the "rank" consensus in the DIRAC 768 769 algorithm. Then, each analyte<sub>i</sub>-analyte<sub>i</sub> pair in the ranking/ordering dataframe is judged whether it 770 matches or mismatches with a consensus in the ranking/ordering template dataframe. Rank matching 771 score (RMS) for each module against each consensus is obtained per sample by calculating a ratio of 772 the number of matched pairs. Finally, RMSs for each module against each consensus is summarized with the arithmetic mean per sample group. When the mean of RMSs in a sample group is based on 773 774 the consensus of the sample group itself, it corresponds to rank conservation index (RCI); that is, RCI is a special case of the RMS mean. 775

#### 777 Genome-scale metabolic model reconstruction

778 For each of the samples in the M001-related transcriptomics, a "context-specific" (i.e., samplespecific) metabolic network model was reconstructed from a mouse genome-scale metabolic model 779 (GEM), iMM1865<sup>43</sup>, which is a knowledge-based multi-compartment model consisting of 1,865 780 metabolic genes, 10,612 reactions, and 5,839 metabolites. According to the gene-protein-reaction 781 782 (GPR) associations, the RLE values were integrated with the generic iMM1865 for each sample using the integrative metabolic analysis tool (iMAT) algorithm<sup>79</sup>. Subsequently, to predict the flux values of 783 784 reactions at steady state, flux variability analysis (FVA) was performed for each context-specific GEM using the COBRA toolbox (version 3.0)<sup>80</sup>. FVA evaluates the flux range for each reaction by 785 optimizing all the potential flux distributions to minimize or maximize a pre-defined objective 786 function under the solution space (i.e., under the context-specific constraints), which is known as the 787 788 LP (Linear Programming) and MILP (Mixed Integer Linear Programming) problems. In this study, the 789 biomass reaction (BIOMASS reaction) defined in the generic iMM1865 was used as the objective 790 function to be maximized, and FVA was performed for 90% of the optimal solution using the fastFVA 791 function. COBRA toolbox was implemented in MATLAB (R2019a), and academic licenses of Gurobi 792 optimizer (version 7.5) and IBM CPLEX (version 12.7.1) were used to solve LP and MILP. As a 793 result, the flux ranges were successfully predicted for 7,930 reactions among the 10,612 reactions 794 defined in the generic GEM, and the maximum value was representatively used as the predicted flux 795 value in this study (Supplementary Data 3).

## 797 Statistical analysis

Almost all processing and null hypothesis testing were performed using R (version 4.1.1) with R 798 799 tidyverse (version 1.3.1), multcomp (version 1.4.19), dunn.test (version 1.3.5), and clusterProfiler (version 4.2.2)<sup>81</sup> packages, while correlation tests, ordinary least squares (OLS) regression analyses, 800 and preprocessing for them were performed using Python (version 3.7.6 or 3.9.7) with Python NumPy 801 802 (version 1.18.5 or 1.21.3), pandas (version 1.0.5 or 1.3.4), SciPy (version 1.4.1 or 1.7.1) and statsmodels (version 0.11.1 or 0.13.0) libraries. P < 0.05 was considered statistically significant in all 803 804 analyses. Group statistics (e.g., sample size, mean, SEM) and test summary (e.g., test statistic, exact 805 *P*-value) are found in Supplementary Data 1–9.

For comparing overall RCI distributions, differences in the mean of RCIs between control and 806 each intervention were assessed using two-sided Dunnett's test (Fig. 2a, 3f, 5a) or repeated two-sided 807 808 Student's *t*-tests with the multiple hypothesis adjustment by the Holm–Bonferroni method (Fig. 5e). 809 For identifying the module changed by any of the interventions, the intervention effect on RCI (i.e., 810 the mean of RMSs under the rank consensus of own sample group) was assessed using Analysis of 811 Variance (ANOVA; RMS ~ intervention) for each module (Fig. 2b, 2c, 3g, Supplementary Fig. 3a, 812 3b) or each module and each omics (Fig. 5b), while adjusting multiple hypotheses with the 813 Benjamini–Hochberg method. Note that GOBP modules are partly dependent on each other because 814 the same gene/protein can be shared between GOBP terms; hence, this simple adjustment approach 815 could inflate false negatives, and is regarded as a conservative approach. Additionally note that sex was not included in the ANOVA models since RMS and RCI themselves were calculated from the 816 rank consensus of pooled groups, as described above. For subsequently clarifying which intervention 817 818 changed (tightened or loosened) the module, the post hoc comparisons for RCI between control and 819 each intervention were assessed using two-sided Dunnett's test (Fig. 2b-d, 3g, 3h, 5h, Supplementary Fig. 1a, 1c, 1e, 3a-c, 3g, 3j) or repeated two-sided Student's t-tests with the multiple hypothesis 820 adjustment by the Holm-Bonferroni method (Fig. 5b-d). For examining the similarity of module 821 822 regulation among interventions (Fig. 2c, 2e, 3i, Supplementary Fig. 1b, 1d, 1f, 3b, 3d), differences in 823 the mean of RMSs between control and each intervention were assessed for each rank consensus using 824 two-sided Dunnett's test. Note that the sample group corresponding to the rank consensus group was excluded from these tests, because its mean of RMSs (i.e., RCI) is expected to follow different 825 826 distribution from the other sample groups' one. For identifying the module whose regulation similarity to the LC-M004 sample groups (Control-2, 4EGI-1) was different among the LC-M001 sample groups 827 828 (Control-1, ACA, 17aE2, Rapa), the intervention effect on the RMS mean was assessed using 829 ANOVA (RMS ~ intervention) for each module and each rank consensus, while adjusting multiple 830 hypotheses with the Benjamini–Hochberg method (i.e., a conservative approach, as described above). For subsequently clarifying which intervention (similarly or dissimilarly) changed the module (Fig. 5f, 831 832 5g, Supplementary Fig. 3e, 3f, 3h, 3i), the post hoc comparisons for the RMS mean between Control-1 833 and each intervention (ACA, 17aE2, Rapa) were assessed using repeated two-sided Student's t-tests 834 with the multiple hypothesis adjustment by the Holm-Bonferroni method. For examining whether the RCI median was dependent on the characteristics of each group (Supplementary Fig. 4b), two-sided 835 statistical significance of the RCI median was assessed using a permutation test where an empirical 836 837 null-hypothesis distribution of the RCI median was estimated from 20,000 DIRAC re-calculations with the shuffles of sample-group correspondence, while adjusting multiple hypotheses with the 838 Holm-Bonferroni method. For examining overall relationship between the similarity of module 839 840 regulation and stratified group, Spearman's correlation between the mean of RMSs and the quantile 841 order of stratified groups was assessed for each sex and each rank consensus (Fig. 6b, Supplementary 842 Fig. 5d) or each sex, each chronological age tertile (CA3) group, and each rank consensus (Fig. 6f, 843 Supplementary Fig. 6c), while adjusting multiple hypotheses with the Holm–Bonferroni method. For 844 identifying the module whose regulation similarity was associated with chronological age (Fig. 6c, 6d, 845 Supplementary Fig. 5e, 5f), RMS was regressed to chronological age with BMI and ancestry PC1-5 as 846 covariates (RMS  $\sim$  chronological age + log(BMI) + PC1 + PC2 + PC3 + PC4 + PC5) for each module, 847 each sex, and each rank consensus, while adjusting multiple hypotheses with the Benjamini-Hochberg 848 method (i.e., a conservative approach for GOBP modules, as described above). For identifying the 849 module whose regulation similarity was associated with  $\Delta$  age (Fig. 6g, Supplementary Fig. 4d, 6d, 6e), RMS was regressed to  $\Delta$  age with chronological age, BMI, and ancestry PC1–5 as covariates 850 851  $(RMS \sim \Delta age + chronological age + log(BMI) + PC1 + PC2 + PC3 + PC4 + PC5)$  for each module, 852 each sex, each CA3 group, and each rank consensus, while adjusting multiple hypotheses with the Benjamini–Hochberg method (i.e., a conservative approach for GOBP modules, as described above). 853 854 For identifying the WGCNA module changed by any of the interventions, the intervention effect on the module eigengene was assessed using ANOVA ( $E^{(q)} \sim$  intervention + sex + intervention 855

effect on the module eigengene was assessed using ANOVA ( $E^{(q)} \sim$  intervention + sex + intervention 856 × sex) for each module, while adjusting multiple hypotheses with the Bonferroni method. For 857 subsequently clarifying which intervention changed the module eigengene (Fig. 3b), the post hoc 858 comparisons for the  $E^{(q)}$  mean between control and each intervention were assessed using two-sided

859Dunnett's test. For examining the relationship between the intervention effect on each protein in the860module and their respective intramodular connectivity (Fig. 3d), the main effect of intervention on861each protein k was calculated using ANOVA (Protein $_k^{(q)} \sim$  intervention + sex + intervention × sex),862and then Spearman's correlation between the calculated main effect of intervention and intramodular863connectivity was assessed.

864 For identifying the reaction whose flux was changed by any of the interventions (Fig. 4a), the intervention effect on the flux value was assessed using Kruskal–Wallis H-test (flux value ~ 865 866 intervention) for each reaction, while adjusting multiple hypotheses with the Benjamini-Hochberg method. Note that reactions in GEM are partly dependent on each other because the same 867 gene/protein/metabolite can be shared between the reactions; hence, this simple adjustment approach 868 869 could inflate false negatives, and is regarded as a conservative approach. Additionally note that samples were pooled per intervention to increase the statistical power from small sample size, while 870 871 recognizing the false negative risks for potential sex or age-dependent changes. For subsequently 872 clarifying which intervention changed the reaction flux (Fig. 4b-d), the post hoc comparisons for the flux value median between control and each intervention were assessed using two-sided Dunn's test 873 874 with the multiple hypothesis adjustment by the Holm–Bonferroni method. For examining the difference between CR and MR (Supplementary Fig. 2c-f), the additional post hoc comparisons were 875 assessed between CR and its control, between MR and its control, and between CR and MR. For 876 examining which subsystems in GEM were shifted by ACA, MR, GHRKO, and SnellDW (Fig. 4e, 877 878 Supplementary Fig. 2a, 2b) or differently shifted between CR and MR (Supplementary Fig. 2g), enrichment in the significantly changed reactions was assessed using overrepresentation test for each 879 of the subsystems that were annotated to any of the significantly changed reactions, while adjusting 880 881 multiple hypotheses with the Benjamini-Hochberg method.

#### Data visualization

882

883

901

884 Almost all results were visualized using Python (version 3.7.6 or 3.9.7) with Python matplotlib 885 (version 3.1.3 or 3.4.3), seaborn (version 0.10.1 or 0.11.2), venn (version 0.1.3) libraries, while the results of enrichment analyses were visualized using R (version 4.1.1) with R ggplot2 (version 3.3.6) 886 and enrichplot (version 1.14.2) packages. The results were summarized as the mean with 95% 887 confidence interval (CI) or the boxplot, as indicated in each figure legend. Note that this 95% CI of 888 889 mean or median was simultaneously calculated during visualization using the seaborn barplot or boxplot API, respectively; hence, this CI is not exactly same with that used in statistical analysis but 890 891 for presentation purpose only. Hierarchical clustering was simultaneously performed during 892 visualization using seaborn clustermap API with the Ward's linkage method for Euclidean distance. 893 For the values used in Fig. 4a, the group mean of flux values for each reaction was centered by 894 subtracting the group mean of the corresponding control, and then scaled by the maximum absolute 895 value across intervention groups using MaxAbsScaler of Python scikit-learn library (version 1.0.1). In 896 the scatterplots with regression lines, the adjusted sample RMS with the covariates was calculated as the mean  $\pm$  residual using the OLS linear regression for each plot that was the same used in statistical 897 898 analysis except for dropping the independent variable (i.e., chronological age in Fig. 6d, 899 Supplementary Fig. 5f;  $\Delta$  age in Supplementary Fig. 4d, 6e), and the regression line with 95% CI was 900 simultaneously computed during visualization using the seaborn regplot API.

## 902 Data availability

903The MS data of the LC-M001 and LC-M004 proteomics have been deposited to the ProteomeXchange904Consortium via the PRIDE partner repository (PXD035255)<sup>82</sup>. Note that this data will be available905after journal publication; until then, requests should be directed to the corresponding authors. The906processed data of M001-related transcriptomics was kindly provided by Vadim N. Gladyshev907(Harvard Medical School), and raw data is available on the NCBI's Gene Expression Omnibus (GEO)908repository (GSE131901). The Arivale datasets can be accessed by qualified researchers for research

- 909purposes. Requests should be sent to data-access@isbscience.org. The de-identified data will be910available to the qualified researchers on submission and approval of a research plan.
- 912 Code availability

911

914

913 Code used in this study is freely available in GitHub (https://github.com/longevity-consortium).

#### 1084 Acknowledgements

1085 We thank Vadim N. Gladyshev (Harvard Medical School) for kindly providing the processed dataset of mouse liver transcriptomics; Eric S. Orwoll (Oregon Health and Science University) and Gilbert S. 1086 Omenn (University of Michigan) for providing comments to the manuscript; Jennifer Dougherty and 1087 1088 Mary Brunkow (Institute for Systems Biology) for their coordination efforts in the National Institute 1089 on Aging (NIA) Longevity Consortium; all Arivale participants who consented to using their deidentified data for research purposes. This work was funded by the National Institutes of Health 1090 1091 (NIH) grant U19AG023122 awarded by NIA (to S.R.C., N.J.S., R.A.M., R.L.M., and N.R.), the M.J. Murdock Charitable Trust (Reference No. 2014096:MNL:11/20/2014, awarded to N.D.P. and L.H.), 1092 and a generous gift from Carole Ellison (to K.W. and T.W.). K.W. was supported by The Uehara 1093 1094 Memorial Foundation (Overseas Postdoctoral Fellowships). 1095

#### 1096 Author Contribution

1097 K.W., T.W., P.B., M.R., R.A.M., R.L.M., and N.R. conceptualized the study. K.W., T.W., P.B., M.R., 1098 and N.R. participated in the study design. G.G.G. and R.A.M. performed mouse experiments. M.R.H., 1099 M.K.M., D.H.B., M.M., S.R.M., K.M.C., C.K., U.K., and R.L.M. contributed to the generation of the 1100 mouse proteomics. J.C.L. and A.T.M. managed the logistics of data collection and integration for the 1101 human datasets. K.W., T.W., and P.B. performed data analysis and figure generation. J.W., J.L., C.L., J.C.R., G.G., S.R.C., N.J.S., N.D.P., and L.H. assisted in result interpretation. K.W., T.W., P.B., M.R., 1102 and N.R. were the primary authors of the paper, with contributions from all other authors. All authors 1103 1104 read and approved the final manuscript. 1105

1169

Figure 4. Prolongevity interventions shifted the flux regulation in fatty acid metabolism.

1170 $\mathbf{a}-\mathbf{e}$  An integrated analysis of the M001-related liver transcriptomics45 with mouse genome-scale1171metabolic model (GEM; see Supplementary Data 3 and 4 for complete results). CR: calorie restriction;1172MR: methionine restriction; GHR: growth hormone receptor; WT: wild-type; KO: knockout; Control11731: control for Acarbose, 17 $\alpha$ -Estradiol, Protandim, Rapamycin, and CR diet; Control 2: control for1174MR diet. a Change in the group mean of flux values for each reaction. The presented group mean1175value was centered and scaled (see Methods); i.e., its positive value corresponds to an increase in the

1176	mean of flux values compared to corresponding control group, and vice versa. Among 7,930 reactions
1177	whose flux values were successfully predicted across all samples (78 mice), presented are the 2,156
1178	reactions that exhibited nominal or "conservatively" false discovery rate (FDR)-adjusted $P < 0.05$ (see
1179	Methods) for the main effect of intervention on each flux median by Kruskal–Wallis H-test and that
1180	exhibited significantly different flux median in intervention group from control group (i.e., "changed"
1181	reaction; $P < 0.05$ by post hoc two-sided Dunn's test with the Holm–Bonferroni adjustment). These
1182	significantly changed modules are highlighted in the top color columns per intervention group, except
1183	for 17α-Estradiol, Protandim, and CR diet due to no significantly changed reactions by them. <b>b</b> , <b>c</b>
1184	Venn diagrams of the significantly changed reactions by each intervention (conservatively FDR-
1185	adjusted $P < 0.05$ ). <b>d</b> Changed reactions within the central energy metabolism. The 25 reaction IDs
1186	highlighted in the diagram are the reactions that had the predicted flux values across all samples. Flux
1187	value distributions are presented for the 10 reactions that exhibited nominal $P < 0.05$ by the
1188	aforementioned Kruskal–Wallis H-test. Data: the 25 <sup>th</sup> percentile ( $Q_1$ , box bottom), median (center
1189	line), and the 75 <sup>th</sup> percentile ( $Q_3$ , box top); whiskers span [max( $x_{min}$ , $Q_1 - 1.5 \times IQR$ ), min( $x_{max}$ , $Q_3 +$
1190	$1.5 \times IQR$ )], where $x_{\min}$ and $x_{\max}$ are the minimum and maximum, respectively, in the observed values
1191	and IQR = $Q_3 - Q_1$ ; $n = 12$ (Control 1, Acarbose, Rapamycin, CR diet), 6 (17 $\alpha$ -Estradiol, Protandim),
1192	3 (the others) mice. $*P < 0.05$ , $**P < 0.01$ by two-sided Dunn's test with the Holm–Bonferroni
1193	adjustment. e Shifted subsystems by MR diet. Significance of the shifted subsystems was assessed
1194	using enrichment analysis on the significantly changed reactions (conservatively FDR-adjusted $P <$
1195	0.05) while adjusting multiple hypotheses with the Benjamini–Hochberg method. Only the subsystems
1196	that exhibited nominal $P < 0.05$ are presented. AdjPval: FDR-adjusted P-value from the enrichment
1197	analysis.
1198	

1201

Figure 5. Prolongevity interventions likely tightened the module regulation partly through capindependent translation.

1202 a Differential Rank Conservation (DIRAC) analysis of the M001-related liver transcriptomics using 1203 Gene Ontology Biological Process (GOBP)-defined modules (see Supplementary Data 5 for complete 1204 results). Presented is overall distribution of module rank conservation index (RCI). CR: calorie restriction. Data: the  $25^{\text{th}}$  percentile ( $O_1$ , box bottom), median (center line, notch: 95% confidence 1205 interval (CI) for the median), and the 75<sup>th</sup> percentile ( $Q_3$ , box top); whiskers span [max( $x_{min}$ ,  $Q_1 - 1.5$ 1206 1207  $\times$  IQR), min( $x_{max}$ ,  $Q_3 + 1.5 \times$  IQR)], where  $x_{min}$  and  $x_{max}$  are the minimum and maximum, respectively, in the observed values and IQR =  $Q_3 - Q_1$ ; n = 3,747 modules. \*\*\*P < 0.001 by two-sided Dunnett's 1208 1209 test. **b**–**d** Comparison of DIRAC results between the LC-M001 liver proteomics and the M001-related 1210 liver transcriptomics (see Supplementary Data 6 for complete results). **b** Venn diagram of the modules 1211 that exhibited "conservatively" false discovery rate (FDR)-adjusted P < 0.05 (see Methods) for the 1212 main effect of intervention on each module RCI by Analysis of Variance (ANOVA) and that exhibited significantly higher RCI in intervention group than control group (i.e., "tightened" module; P < 0.051213 1214 by post hoc two-sided Student's t-tests with the Holm–Bonferroni adjustment). P: proteomics, T: 1215 transcriptomics. c, d Sample rank matching score (RMS) distributions for an example of the tightened 1216 modules in both proteins and transcripts (c; GO:0006635, fatty acid  $\beta$ -oxidation) or the tightened modules only in proteins (d; GO:0019441, tryptophan catabolic process to kynurenine). Data: the 1217 mean (dot) with 95% CI (bar); n = 12 mice. \*\*P < 0.01, \*\*\*P < 0.001 by two-sided Student's *t*-tests 1218 with the Holm–Bonferroni adjustment. e-g DIRAC analysis of the LC-M001 and LC-M004 liver 1219 1220 proteomics using GOBP-defined modules (see Supplementary Data 7 for complete results). Control 1: control for Acarbose,  $17\alpha$ -Estradiol, and Rapamycin; Control 2: control for 4EGI-1. e Overall 1221 1222 distribution of module RCI. Data: each boxplot metric is the same with  $\mathbf{a}$ ; n = 153 modules. \*\*\*P <1223 0.001 by two-sided Student's t-tests with the Holm–Bonferroni adjustment. f Venn diagram of the 1224 modules that exhibited nominal or "conservatively" FDR-adjusted P < 0.05 (see Methods) for the 1225 main effect of intervention on each module mean of RMSs under 4EGI-1 rank consensus by ANOVA 1226 and that exhibited significantly higher mean of RMSs in intervention group than control group (i.e., "similarly" changed module to the 4EGI-1 group; P < 0.05 by post hoc two-sided Student's *t*-tests 1227 1228 with the Holm–Bonferroni adjustment). The number in square brackets corresponds to the similarly 1229 changed modules (nominal *P*-value < 0.05). g, h Sample RMS distributions for an example of the

1230similarly tightened modules (GO:0070934, coding region instability determinant (CRD)-mediated1231mRNA stabilization) in proteins (g) or transcripts (h). Dashed line in g indicates the mean of RMSs1232for the sample group corresponding to the rank consensus (i.e., RCI). Data: the mean (dot) with 95%1233CI (bar); n = 8 (Control-2, 4EGI-1), 12 (the others) mice. \*\*P < 0.01 by two-sided Student's *t*-tests1234with the Holm–Bonferroni adjustment (g) or Dunnett's test (h).

1235

1237 Figure 6. Module regulation was changed across chronological and biological ages.

1236

1238 $\mathbf{a}$ - $\mathbf{g}$  Differential Rank Conservation (DIRAC) analysis of the Arivale plasma proteomics, with the1239stratified groups by chronological age ( $\mathbf{a}$ - $\mathbf{d}$ ) or  $\Delta$  age ( $\mathbf{e}$ - $\mathbf{g}$ ), using Gene Ontology Biological Process1240(GOBP)-defined modules (see Supplementary Data 8 for complete results).  $\mathbf{a}$  Overall distribution of

1241	module rank conservation index (RCI). Data: the $25^{th}$ percentile ( $Q_1$ , box bottom), median (center line,
1242	notch: 95% confidence interval (CI) for the median), and the 75 <sup>th</sup> percentile ( $Q_3$ , box top); whiskers
1243	span [max( $x_{\min}$ , $Q_1 - 1.5 \times IQR$ ), min( $x_{\max}$ , $Q_3 + 1.5 \times IQR$ )], where $x_{\min}$ and $x_{\max}$ are the minimum
1244	and maximum, respectively, in the observed values and IQR = $Q_3 - Q_1$ ; $n = 19$ modules. <b>b</b> Overall
1245	distributions of module mean of rank matching scores (RMSs) under the rank consensus of the
1246	youngest (Q1) or oldest (Q10) group. Data: each boxplot metric is the same with $\mathbf{a}$ ; $n = 19$ modules.
1247	<i>P</i> -value for Spearman's correlation was adjusted across sexes with the Holm–Bonferroni method. <b>c</b>
1248	Association between module similarity to the Q1 or Q10 group and chronological age. For each
1249	module, each rank consensus, and each sex, significance of the association was assessed using
1250	ordinary least squares (OLS) linear regression with Body Mass Index (BMI) and ancestry principal
1251	components (PCs) as covariates while "conservatively" adjusting multiple hypotheses with the
1252	Benjamini–Hochberg method (see Methods). d An example of the significant association in c
1253	(GO:0030593, neutrophil chemotaxis). In each subplot, the adjusted sample RMS with the covariates
1254	(i.e., mean ± residual) is plotted, and the colored line and background correspond to the OLS linear
1255	regression line with 95% CI and the range of rank consensus group, respectively. e Distribution of $\Delta$
1256	age in the $\Delta$ age-stratified groups (see Supplementary Fig. 4c for the chronological age distribution).
1257	The numbers in the subplots indicate the minimum-median-maximum of each group. f Overall
1258	distributions of module mean of RMSs under the rank consensus of the chronologically and
1259	biologically youngest (Y-subQ1) or oldest (O-subQ5) group. Data: each boxplot metric is the same
1260	with $\mathbf{a}$ ; $n = 19$ modules. Spearman's correlation was assessed for each of chronological age tertile
1261	(CA3) groups, and its P-value was adjusted across CA3 groups and sexes with the Holm-Bonferroni
1262	method. <b>g</b> Association between module similarity to the Y-subQ1 or O-subQ5 group and $\Delta$ age. For
1263	each module, each rank consensus, each sex, and each CA3 group, significance of the association was
1264	assessed using OLS linear regression with chronological age, BMI, and ancestry PCs as covariates
1265	while "conservatively" adjusting multiple hypotheses with the Benjamini-Hochberg method (see
1266	Methods).
