ABSTRACT

Introduction: Although *APOE* $\epsilon 4$ allele carriage confers a risk of coronary disease, its persistence in human populations might be explained by certain survival advantages (antagonistic pleiotropy).

Hypothesis: Combining data from three British cohorts—1946 National Survey of Health and Development (NSHD), Southall and Brent Revised (SABRE) and UK Biobank—we explored whether *APOE* $\epsilon 4$ carriage associates with beneficial or unfavorable left ventricular (LV) structural and functional parameters by echocardiography and cardiovascular magnetic resonance (CMR) in older age.

Methods: Based on the presence of *APOE* $\epsilon 4$, genotypes were divided into: *APOE* $\epsilon 4$ ($\epsilon 2\epsilon 4$, $\epsilon 3\epsilon 4$, $\epsilon 4\epsilon 4$) and non-*APOE* $\epsilon 4$ carriers. Echocardiographic data included: LV ejection fraction, E/e' , systolic and diastolic posterior wall and interventricular septal thickness ($LVPWT_{s/d}$, $IVS_{s/d}$), LV mass and the ratio of the LV stroke volume to the LV myocardial volume called myocardial contraction fraction (MCF). CMR data additionally included longitudinal and radial peak diastolic strain rates (PDSR). Generalized linear models explored associations between *APOE* $\epsilon 4$ genotypes as exposures and echocardiographic/CMR biomarkers as outcomes. As *APOE* genotype is a genetic instrumental variable (unconfounded), Model 1 was unadjusted; Model 2 was adjusted for factors associated with the outcome (age, sex, and socio-economic position) to yield more precise estimates; and subsequent models were individually adjusted for mediators (body mass index, cardiovascular disease [CVD], high cholesterol and hypertension) to explore mechanistic pathways.

Results: 35,568 participants were included. Compared to the non-*APOE* $\epsilon 4$ group, *APOE* $\epsilon 4$ carriers had similar cardiac echocardiographic phenotypes in terms of LV EF, E/e', LVPWT_{s/d}, IVS_{s/d} and LV mass but had a 4% higher MCF (95% confidence interval [CI]: 1–7%, $p=0.016$) which persisted in Model 2 (95% CI 1–7%, $p=0.008$) but was attenuated to 3% after adjustment for CVD, diabetes and hypertension (all 95% CI 0–6%; all $p<0.070$). This was replicated in UK Biobank using CMR data, where *APOE* $\epsilon 4$ carriers had a 1% higher MCF (95% CI 0-1%, $p=0.020$) which was attenuated only after adjusting for BMI or diabetes.

Conclusions: *APOE* $\epsilon 4$ carriage associates with improved myocardial performance in older age resulting in greater LV stroke volume generation per 1 mL of myocardium and better longitudinal strain rates compared to non *APOE* $\epsilon 4$ carriers. This potentially favorable cardiac phenotype adds to the growing number of reported survival advantages attributed to *APOE* $\epsilon 4$ carriage that might collectively explain its persistence in humans.

Keywords: apolipoprotein $\epsilon 4$, cardiovascular disease, myocardial contraction fraction.

INTRODUCTION

Apolipoprotein ε (*APOE ε*) mediates the binding of low-density lipoprotein (LDL) to peripheral receptors. Given the existence of two single-nucleotide polymorphisms, namely rs429358 and rs7412, there are three *APOE ε* isoforms coded by the alleles $\epsilon 2$, $\epsilon 3$ and $\epsilon 4$ giving rise to six genotypes namely $\epsilon 2\epsilon 2$, $\epsilon 2\epsilon 3$, $\epsilon 2\epsilon 4$, $\epsilon 3\epsilon 3$, $\epsilon 3\epsilon 4$ and $\epsilon 4\epsilon 4$ with the commonest being $\epsilon 3\epsilon 3$ ¹.

Apolipoprotein ε4 is regarded to be a major risk factor for developing Alzheimer's disease² even from young age, especially in females³. In addition, it may associate with decreased physical performance in older age⁴ and decrease cognitive performance (e.g., verbal episodic memory) in healthy young adults⁵. Yet despite its adverse associations, this ancestral allele has persisted in human populations instead of being replaced by the more recently evolved alleles, $\epsilon 3$ and $\epsilon 2$ ⁶ suggesting its carriage might be conferring some survival advantages. Indeed, *APOE ε4* carriers have been shown to have increased fertility^{7,8}, resistance to infections⁷, decreased perinatal and infant mortality⁷, decreased chronic airway obstruction⁹, fewer arterial aneurysms⁹ and peptic ulcers⁹, less liver disease and slight cognitive advantages^{7 10}.

In terms of the cardiovascular system, carriage of $\epsilon 4$ (rs429358-cytosine and rs7412-cytosine) has been associated with adverse clinical sequelae including ischaemic heart disease (IHD)¹¹, hypertension¹², diabetes¹³ and high LDL¹⁴. Moreover, heart function was also suggested to be a mediator in the association between *ApoE ε4* and gray matter decline¹⁵. However, to date it remains unclear whether *APOE ε4* carriage independently associates with a better or worse long-term cardiac phenotype in terms of heart size and function. Using cohort data from the Medical Research Council (MRC) 1946 National Survey of Health and Development (NSHD), Southall And Brent Revised (SABRE) and United Kingdom (UK) Biobank, we explored this association.

METHODS

Study population

The MRC NSHD is the world's longest-running birth cohort with continuous follow-up. In 1946 in Britain, 5,362 individuals (2547 males and 2815 females) born in the same week in March were enrolled. Participants were invited for periodic follow-ups in which health and socio-economic assessments were performed which have been described elsewhere¹⁶.

The SABRE study is a tri-ethnic cohort of European, South Asian, and African Caribbean participants living in North and West London. Between 1988-1981, participants aged 40-69 years were randomly selected from 5-year age and sex stratified primary care lists (n=4063) and workplaces (n=795). Full details have been described elsewhere¹⁷.

The UK Biobank is a large prospective cohort study with more than half a million individuals recruited between 2006 and 2010 when study participants were aged 40-69 years old, and features demographic, genetic, health outcome and imaging data for participants.¹⁸ Details of subjects' comorbidities were obtained through self-reported diagnoses and International Classification of Disease (ICD-9 and ICD-10) codes from linked medical records This project was conducted using the UK Biobank (UKBB) resource under application numbers 40616 and 46696.

Data availability

NSHD data is available from: <https://www.nshd.mrc.ac.uk/data> , SABRE data is available from <https://www.sabrestudy.org/> , and UK Biobank data is available from <https://www.ukbiobank.ac.uk/> .

Ethical approval

The 2006-2010 NSHD data collection sweep included an in-depth cardiovascular assessment and was granted ethical approval from the Greater Manchester Local Research Ethics Committee and the Scotland Research Ethics Committee¹⁶ and written informed consent was given by all study participants. Similarly, the SABRE study was granted ethics approval from Ealing, Hounslow and Spelthorne, Parkside, and University College London Research Ethics Committees with all participants giving written consent. Our project was approved by both the SABRE and NSHD committees. UK Biobank's ethical approval was from the Northwest Multi-centre Research Committee (MRCEC) in 2011, which was renewed in 2016 and then in 2021. All procedures performed were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

Outcomes: Echocardiographic data

In NSHD, when study members were 60-64 years (2006-2010), British-based NSHD participants who had not been lost to follow-up or withdrawn, were invited to attend a clinic-based assessment that included resting transthoracic echocardiography using General Electric (GE) Vivid I machines. The echocardiographic protocol included long and short axis (LAX and SAX), apical 5-, 4-, 3- and 2- chamber, aortic SAX views¹⁹. In SABRE, study members were invited between 2008 and 2012 to a clinic visit in which echocardiographic data was acquired using a Phillips iE33 ultrasound machine S5-1 phased array and a X3-1 matrix transducer and analyzed using Philips QLAB software 7,0¹⁷ in line with the with the American Society of Echocardiography (ASE) guidelines²⁰. In both cohorts, echocardiographic data provided left ventricular (LV) ejection

fraction (EF), E/e', systolic and diastolic LV posterior wall and interventricular septal thickness (LVPWTs/d, IVSs/d), LV mass (LVmass). Myocardial contraction fraction (MCF) was calculated as the ratio between stroke volume and myocardial volume. Although indexation to body surface area (BSA), is commonly done in clinical practice, BSA is a poor indexation metric as it creates a bias for overweight individuals²¹. Although indexation to allometric height is a better alternative²¹, indexation might lead to spurious associations, as the exposure might be associated with height/weight rather than with the outcome itself. Therefore, we used unindexed echocardiographic outcomes in all subsequent analyses.

Outcomes: Cardiovascular magnetic resonance data

Participants in the UK Biobank were randomly invited for a CMR scan on a 1.5 T Siemens Aera scanner from 2014. Briefly, the CMR imaging protocol consisted of three long-axis views and a complete short axis stack of balanced steady state free precession cines²². Grey-scale short axis cine stacks were automatically segmented using a deep learning neural network that has optimised for UKBB scan images, with human expert level performance²³. The short-axis segmentations underwent post-processing to compute end-systolic, end-diastolic and stroke volumes in both ventricles²⁴. Left ventricular mass (LVM) was computed from left ventricular volume (assuming a density of 1.05 g/ml). Left ventricular wall thickness was computed as the perpendicular radial-line distance between endocardial and epicardial surfaces at end-diastole for each of the 17 myocardial segments as defined by the American Heart Association (AHA)²⁵. MCF was derived as above. Thickness of the IVS was calculated as the mean wall thickness of segments 2, 3, 8, 9 and 14, while PWT was taken as the mean of segments 5,6, 11, 12, and 16. To compute longitudinal and radial peak diastolic strain rates, non-rigid image co-registration was performed

between successive frames to enable dynamic motion tracking of the heart during the cardiac cycle

²⁶. Unindexed CMR metrics were used in all subsequent analyses as discussed above.

Exposures: *APOE* ϵ genotype

In NSHD, blood samples were collected at age 53 by a trained research nurse, and DNA was extracted.²⁷ Genetic analysis of stored samples took place in 1999 and 2006-2010. In SABRE, blood samples were collected during baseline studies in 1988-1991 and during follow-up from 2007-2012¹⁷. Genotyping of rs439358 and rs7412 was conducted at the Exeter University for SABRE and by LGC, Huddleston, UK for NSHD²⁸. . Genotyping of UK Biobank participants is detailed elsewhere ²⁹, however in brief, genotyping for 488,252 subjects was performed using the UK BiLEVE or UK Biobank Axiom arrays and imputation based on the HaplotypeReference Consortium and UK10K+1000 Genomes panels. Imputation V3 (in GRCh37 coordinates) was used for the current study. Genotypes in their released PLINK-format files were used on the DNANexus platform (<https://www.dnanexus.com/>). Based on the presence or absence of *APOE* $\epsilon 4$, genotypes were categorically defined as: non-*APOE* $\epsilon 4$ carriers ($\epsilon 2\epsilon 2$, $\epsilon 2\epsilon 3$, $\epsilon 3\epsilon 3$), heterozygous-*APOE* $\epsilon 4$ ($\epsilon 2\epsilon 4$ and $\epsilon 3\epsilon 4$) or homozygous-*APOE* $\epsilon 4$ ($\epsilon 4\epsilon 4$). Heterozygous-*APOE* $\epsilon 4$ and homozygous-*APOE* $\epsilon 4$ were further grouped into *APOE* $\epsilon 4$ carriers.

Covariates

Sex was recorded as male or female. The age, weight, and height at the time of the imaging were used to compute the body mass index (BMI) in all 3 cohorts. In NSHD, participants' socioeconomic position (SEP) was evaluated at the time of echocardiography according to UK Surveys Registrar General's social class, dichotomized as manual or non-manual. In UK Biobank,

we used the Townsend deprivation index scores derived from national data about ownership and unemployment aggregated by postcodes³⁰. The presence of cardiovascular disease (CVD), diabetes or high cholesterol was recorded as 1=present or 0=absent.

Statistics

All analyses were performed in R 4.0³¹. For all analyses, a two-tailed p -value <0.05 was considered statistically significant.

Distribution of data were assessed on histograms and using Shapiro-Wilk test. Continuous variables are expressed as mean \pm 1 standard deviation (SD) or median (interquartile range) as appropriate; categorical variables, as counts and percent.

In the main analysis, we compared non-*APOE* $\epsilon 4$ carriers with *APOE* $\epsilon 4$ carriers. Given the skewed distributions of echocardiographic and CMR data, generalized linear models with gamma distribution and log link were used to investigate the association of *APOE* $\epsilon 4$ genotypes as the exposures to predict the continuous echocardiographic and CMR variables as the outcomes. As the longitudinal and radial PDSR also spanned negative values, generalized linear models with Gaussian distribution and identity link were used instead. Being a combination of gene variants, *APOE* ϵ genotype is expected to be an instrumental variable and therefore unconfounded. Thus, Model 1 was unadjusted. To obtain more precise regression estimates, Model 2 was adjusted for factors associated with the outcome, namely age, sex, and SEP. To explore the mechanistic pathway downstream of *APOE* ϵ genotype but upstream of the echocardiographic outcomes, subsequent models were adjusted for mediators as follows: Model 3 for BMI; Model 4 for the presence of CVD; Model 5 for diabetes; Model 6 for high cholesterol; and Model 7 for

hypertension (**Figure 1**). Model assumptions were verified with regression diagnostics and found to be satisfied.

For all the models, regression estimates were obtained separately for NSHD, SABRE and UK Biobank (i.e., cohort specific analyses). Since both NSHD and SABRE participants had echocardiography, random-effects meta-analyses were performed across these 2 cohorts. Heterogeneity was evaluated using the Cochran Q test and Higgins I² statistic. Since UK Biobank had CMR data, it was not included in the meta-analysis.

To explore dose responses, *APOE* $\epsilon 4$ genotypes were recoded as an ordered category based on the number of $\epsilon 4$ possessed. Thus, class 0 = $\epsilon 2\epsilon 2$, $\epsilon 2\epsilon 3$, $\epsilon 3\epsilon 3$; class 1 = $\epsilon 2\epsilon 4$ and $\epsilon 3\epsilon 4$; and class 2 = $\epsilon 4\epsilon 4$. Given the existence of 3 classes, generalized linear models with gamma distribution (or Gaussian distribution for longitudinal and radial PDSR) and orthogonal polynomial contrasts with 2 equally spaced levels (i.e., linear and quadratic) were employed to look for a dose response by $\epsilon 4$ variants.

As a sensitivity analyses, *APOE* $\epsilon 4$ carriers were split into heterozygous-*APOE* $\epsilon 4$ ($\epsilon 2\epsilon 4$ and $\epsilon 3\epsilon 4$) and homozygous-*APOE* $\epsilon 4$ ($\epsilon 4\epsilon 4$), and all the analyses were replicated as above.

RESULTS

Participant characteristics

Participants with available *APOE* $\epsilon 4$ genotype and at least one cardiac imaging metric were included yielding a total of 35568 participants (n=1467 from NSHD, n=1187 from SABRE and n=32972 from UK Biobank). Their characteristics are shown in **Table 1**. In total, there were 816 (2.29%) homozygous-*APOE* $\epsilon 4$, and 9103 (25.59%) heterozygous-*APOE* $\epsilon 4$ individuals with a good agreement between NSHD, SABRE and UK Biobank. SABRE participants were more likely

to be males (76.75%), have a higher BMI (median 27 years) or suffer from hypertension (58.98%) compared to NSHD and UK Biobank. On the other hand, UK Biobank participants were least likely to suffer from CVD (6.53%), diabetes (18.64%) or hypertension (27.62%).

Associations between *APOE* $\epsilon 4$ genotypes and echocardiographic data

In NSHD, when compared to the non-*APOE* $\epsilon 4$ group, *APOE* $\epsilon 4$ carriers had a 6% higher MCF (95% confidence interval [CI] 0-12%, $p=0.050$) which persisted after adjusting for sex and SEP (95% CI 0-12%, $p=0.038$) and diabetes (95% CI 0-12%, $p=0.056$), was attenuated to 5% after adjusting for BMI (95% CI 0-11%, $p=0.064$), CVD (95% CI 0-12%, $p=0.112$) and hypertension (95% CI 1-11%, $p=0.081$), and was increased to 8% after adjusting for high cholesterol (95% CI 1-14%, $p=0.020$, **Supplementary Table S1**). Similarly, *APOE* $\epsilon 4$ carriers had a 5% higher LVmass $p=0.057$ which was increased to 6% after adjusting for CVD ($p=0.040$) and hypertension ($p=0.040$), and to 7% after adjusting for diabetes $p=0.024$. No significant associations were found in SABRE (**Supplementary Table S2**).

In the meta-analyses, compared to the non-*APOE* $\epsilon 4$ group, *APOE* $\epsilon 4$ carriers had similar cardiac phenotypes in terms of EF, E/e' , $LVPWT_{s/d}$, $IVS_{s/d}$ and LVmass but had a 4% higher MCF (95% CI 1-7%, $p=0.016$) which persisted after adjustment for sex and SEP (95% CI 1-7%, $p=0.008$) and was attenuated to 3% after adjustment for CVD, diabetes and hypertension (all 95% CI 0-6%, all $p<0.070$, **Table 2, Figure 1**). However, no significant dose response of *APOE* $\epsilon 4$ carriage was found in the association of *APOE* $\epsilon 4$ genotype with MCF (**Table 4, Supplementary Table S3**).

In the sensitivity analysis, only heterozygous-*APOE* $\epsilon 4$ carriers had a 4% higher MCF (95% CI 1-7%, $p=0.016$) which persisted after adjusting for sex and SEP (95% CI 1-7%, $p=0.013$), and BMI (95% CI 1-7%, $p=0.018$) but was attenuated to 3% after adjusting for CVD (95% CI 0-6%,

$p=0.043$, diabetes (95% CI 0-7%, $p=0.060$), and hypertension (95% CI 0-6%, $p=0.028$, **Table 5, Supplementary Table S4**).

Associations between *APOE* $\epsilon 4$ genotypes and CMR data

In UK Biobank, when compared to the non-*APOE* $\epsilon 4$ group, *APOE* $\epsilon 4$ carriers had a 1% higher MCF 95% (CI 0-1%, $p=0.020$) which persisted after adjusting for age, sex and SEP (Model 2, $p=0.080$), CVD (Model 4, $p=0.006$), high cholesterol (Model 5, $p=0.0001$) and hypertension (Model 7, $p=0.034$) but was attenuated to 0% (95% CI 0-1%) after adjusting for BMI (Model 3, $p=0.079$) or diabetes ($p=0.058$, **Table 3, Figure 1**). There was a dose-response relationship especially when adjusting for CVD in Model 4 ($p=0.036$) and high cholesterol in Model 6 ($p=0.006$, **Table 4**). However, although heterozygous-*APOE* $\epsilon 4$ carriers had a higher MCF, the association was not significant for homozygous-*APOE* $\epsilon 4$ carriers (**Table 5**).

In addition, *APOE* $\epsilon 4$ carriers had a 2% higher longitudinal PDSR (95% CI 0-3%, $p=0.045$), which persisted after adjusting for CVD and diabetes, but was attenuated to 0% in Model 2 and to 1% after adjusting for diabetes (Model 5). Conversely, they had a 5% lower radial PDSR (95% CI 0.90-1.00, $p=0.05$) which behaved similar to longitudinal PDSR on adjustment (**Table 3**).

DISCUSSION

Data from >35,000 British older adults show that *APOE* $\epsilon 4$ carriage associates with slightly advantageous myocardial performance manifesting as higher MCF and longitudinal strain rates, but slightly lower radial strain rates. A graphical abstract of this work is presented in **Figure 2**.

APOE $\epsilon 4$ might be another example of antagonistic pleiotropy⁶ as $\epsilon 4$ carriage appears to be both beneficial (e.g., fertility and resistance to infections⁷) and detrimental (e.g., Alzheimer's disease)

to human health. The occurrence of the latter further down the fertility timeline in older age might explain the allele's persistence in spite of natural selection.

In terms of cardiovascular health, *APOE* $\epsilon 4$ carriage was previously associated with CVD (IHD¹⁴ and myocardial infarction³²) and CVD risk factors (such as hypertension¹² and diabetes¹³). Although the exact mechanism is yet to be elucidated, it is postulated that *APOE* $\epsilon 4$ might contribute to the development of metabolic syndrome³³. *APOE* $\epsilon 4$ differs from *APOE* $\epsilon 3$ at amino acid position 112 where arginine (positively charged side chain) is present instead of cysteine (non-polar side chain). Given its ability to bind to peripheral and hepatic lipoprotein receptors, it is plausible for the *APOE* ϵ isoforms to have different binding affinities explaining the link with dyslipidemia¹⁴. However, emerging evidence points to more a complex mechanism as *APOE* ϵ can also alter the levels of *APOB*³⁴ which is itself also associated with CVD³⁵. In addition, *APOE* ϵ is mainly produced by the liver, but can also be synthesized in and regulate the activity of adipocytes³⁶ which might explain the relationship between *APOE* $\epsilon 4$ and insulin resistance^{33,37}.

Here we show that *APOE* $\epsilon 4$ carriage appears to associate with a higher MCF. The MCF is a volumetric index of LV myocardial shortening which captures maladaptive myocardial hypertrophy otherwise missed by conventional biomarkers such as EF, mass, and wall thickness, as it considers the relationship between LVmass and SV³⁸. It has been previously associated with CV morbidity and mortality independent of conventional risk factors³⁹. In addition, it is regarded as a highly-sensitive metric of systolic function, and low values have been linked to negative outcomes even in the presence of apparently normal LV EF⁴⁰ indicating its strength as a subclinical disease marker. A higher MCF in the context of *APOE* $\epsilon 4$ carriage might mean a slightly advantageous cardiac phenotype in terms of heart function. Dissociable effects of *APOE* $\epsilon 4$ carriage have been previously reported in the context of better attention despite the higher risk of

Alzheimer's disease¹⁰. Although the literature is sparse, *APOE* ϵ 4 carriage has been previously linked to higher levels of androgens⁴¹ or dysregulated glucose and ketone metabolism⁷ which could putatively increase myocardial contractility leading to a higher stroke volume per unit of LV mass which is being captured by the MCF⁴². We go on to show that there is likely to be a dose response relationship based on the number of ϵ 4 alleles carried by an individual, as per the polynomial contrasts analyses (in the sensitivity analysis the association of homozygous *APOE* ϵ 4 with MCF likely did not persist as only 2.29% of individuals (816) were homozygous for *APOE* ϵ 4). Another explanation is that healthier *APOE* ϵ 4 carriers may have been more likely to survive and/or to participate in the studies resulting in selection bias. This would fit with the known effects of *APOE* ϵ 4 carriage on IHD, HT, lipids, and cognitive function. Previous studies have described cognitive advantages in heterozygotes that were not replicated in the homozygotes⁴³ mirroring our data. Indeed, *APOE* ϵ 4 carriage was associated with a greater longitudinal but lower radial strain suggesting that different myocardial contraction dynamics might be contributing to the observed association with MCF. The observed trend linking *APOE* ϵ 4 carriage with slightly better echocardiographic LV filling pressures (lower E/e' may suggest less ventricular stiffness in some but not all cases⁴⁴), albeit attenuated in multivariable models, lends plausibility to this theory. The CMR analyses indicated a slight association between *APOE* ϵ 4 carriage and thinner ventricular walls, and similarly the echocardiographic analyses found no association between *APOE* ϵ 4 carriage and LV hypertrophy biomarkers (LVPWT_{s/d}, IVS_{s/d}, LVmass). These data collectively suggest that the observed MCF enhancement is not mediated by pathological ventricular thickening but through improved myocardial energetics and contractility, with calcium potentially implicated^{41,42}.

The main strength of our study is that we were able to replicate the findings in three independent cohorts encompassing >35000 individuals, across imaging modalities (echocardiography and CMR). In addition, as the MRC NSHD is a birth cohort, the participants were implicitly age-matched across all the analyses, exposed to similar epoch-related risk factors and had access to similar treatment facilities across the decades. Since both SABRE and NSHD were longitudinal cohorts in which timing of genotyping and echocardiography were not necessarily contemporaneous, selective follow-up may have potentially excluded homozygous or heterozygous individuals who already passed away with the worst cardiac phenotypes.

CONCLUSION

APOE ϵ 4 carriage associates with improved myocardial performance in older age resulting in greater LV stroke volume generation per 1 mL of myocardium and better longitudinal strain rates compared to non *APOE* ϵ 4 carriers. This potentially favorable cardiac phenotype adds to the growing number of reported survival advantages attributed to *APOE* ϵ 4 carriage that might collectively explain its persistence in humans.

The *APOE* $\epsilon 4$ genotypes were coded as an ordered category based on the number of $\epsilon 4$ possessed. Thus, level 0 encompassed $\epsilon 2\epsilon 2$, $\epsilon 2\epsilon 3$, $\epsilon 2\epsilon 3$, level 1 $\epsilon 2\epsilon 4$ and $\epsilon 3\epsilon 4$ and level 2 $\epsilon 4\epsilon 4$. Given the existence of two levels, generalized linear models and orthogonal polynomial contrasts with 2 equally spaced levels (i.e., linear and quadratic) were employed to look for a dose response by $\epsilon 4$ variants. Significant *p*-values are highlighted in bold. Abbreviations as in **Table 2**.

Table 5. Associations between *APOE* $\epsilon 4$ genotypes and echocardiographic data in older age by comparing non-*APOE* $\epsilon 4$ ($\epsilon 2\epsilon 2$, $\epsilon 2\epsilon 3$, $\epsilon 2\epsilon 3$) with heterozygous-*APOE* $\epsilon 4$ ($\epsilon 2\epsilon 4$ and $\epsilon 3\epsilon 4$) and homozygous-*APOE* $\epsilon 4$ ($\epsilon 4\epsilon 4$) genotypes.

All reported analyses here consisted of generalized linear models with gamma distribution and log link. Significant *p*-values are highlighted in bold. Abbreviations as in **Table 2**.

Figure 1. Associations between *APOE* $\epsilon 4$ genotypes and echocardiographic and cardiac MRI data in older age.

As *APOE* $\epsilon 4$ carriers had a higher myocardial contraction fraction, the mechanistic pathways were explored by adjusting the models for mediators (body mass index, cardiovascular disease, diabetes, high cholesterol, and hypertension).

EF, ejection fraction; *IVS*, interventricular septal thickness; *Lvmass*, left ventricular mass, *LVPW* left ventricular posterior wall thickness; *MCF* myocardial contraction fraction; *PDSR*, longitudinal/radial peak diastolic strain rate.

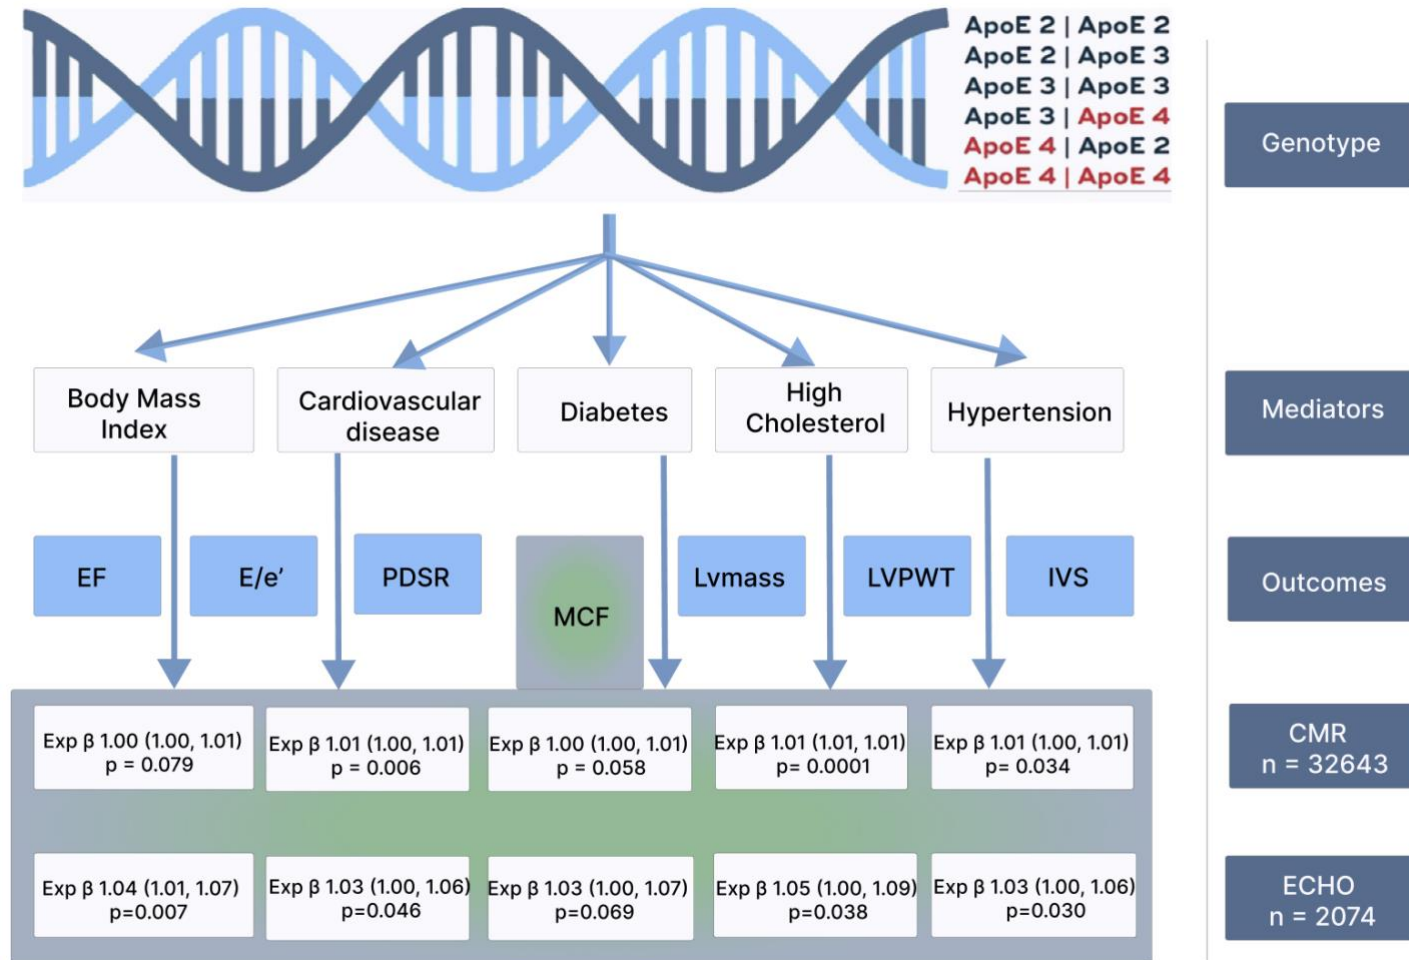

Figure 2. Graphical abstract.

Combining data from three British cohorts—1946 National Survey of Health and Development (NSHD), Southall and Brent Revised (SABRE) and UK Biobank—we explored whether *APOE* $\epsilon 4$ carriage associates with beneficial or unfavorable left ventricular (LV) structural and functional parameters by echocardiography and cardiovascular magnetic resonance (CMR) in older age. Based on the presence of *APOE* $\epsilon 4$, genotypes were divided into: *APOE* $\epsilon 4$ ($\epsilon 2\epsilon 4$, $\epsilon 3\epsilon 4$, $\epsilon 4\epsilon 4$) and non-*APOE* $\epsilon 4$ carriers. Compared to the non-*APOE* $\epsilon 4$ group, *APOE* $\epsilon 4$ carriers had a higher myocardial contraction fraction resulting in greater LV stroke volume generation per 1 mL of myocardium and better longitudinal strain rates compared to non-*APOE* $\epsilon 4$ carriers.
