1 ABSTRACT

2 The human semitendinosus muscle is characterized by a tendinous inscription separating
3 proximal (ST_{prox}) and distal (ST_{dist}) neuromuscular compartments. As each compartment is
4 innervated by separate nerve branches, potential exists for the compartments to operate and be
5 controlled independently. However, the morphology and function of each compartment have not
6 been thoroughly examined in a human adult population. Further, the distal semitendinosus
7 tendon is typically harvested for use in anterior cruciate ligament reconstruction (ACLR)
8 surgery, which induces long-term morphological changes to the semitendinosus muscle-tendon
9 unit. It remains unknown if muscle morphological alterations following ACLR are uniform
10 between ST_{prox} and ST_{dist} . Here, we performed magnetic resonance imaging on ten individuals
11 who had undergone ACLR involving an ipsilateral distal semitendinosus tendon graft 14 ± 6
12 months prior, extracting morphological parameters of the whole ST muscle and each individual
13 muscle compartment from both the (non-injured) contralateral and surgical legs. In the
14 contralateral non-surgical leg, volume and length of ST_{prox} were lower than ST_{dist} . No between-
15 compartment differences in volume or length were found for ACLR legs, likely due to greater
16 shortening of ST_{dist} compared to ST_{prox} after ACLR. The maximal anatomical cross-sectional
17 area of both compartments was substantially smaller on the ACLR leg, but did not differ between
18 ST_{prox} and ST_{dist} on either leg. The absolute and relative differences in ST_{prox} morphology on the
19 ACLR leg were strongly correlated with the corresponding between-leg differences in ST_{dist}
20 morphological parameters. Specifically, greater morphological differences in one compartment
21 were highly correlated with large differences in the other compartment, and vice versa for
22 smaller differences. These relationships indicate that despite the heterogeneity in compartment
23 length and volume, compartment atrophy is not independent or random. Further, the tendinous

24 inscription endpoints were generally positioned at the same proximodistal level as the
25 compartment maximal anatomical cross-sectional areas, providing a wide area over which the
26 tendinous inscription could mechanically interact with compartments. Overall, results suggest the
27 two human semitendinosus compartments are not mechanically independent.

29 **Key words:** graft, hamstrings, tendinous inscription, magnetic resonance imaging, tenotomy

30 INTRODUCTION

31 The musculus semitendinosus (ST) is a posterior thigh muscle and one of four human
32 hamstring muscles. The ST muscle's culinary importance has made it an oft-studied muscle in
33 food science (Satorius & Child, 1938; Machlik & Draudt, 1963; Purslow, 1985; Wang *et al.*,
34 2022), but ST has also been widely used as a model to study muscle structure, composition,
35 function, and mechanics across several non-human species (Délèze, 1961; Sivachelvan &
36 Davies, 1981; Street, 1983; Roy *et al.*, 1984; Edgerton *et al.*, 1987; Gans *et al.*, 1989; Kawakami
37 & Lieber, 2000; Shimada *et al.*, 2004). The ST of many, but not all (Appleton, 1928), species is
38 characterized by the presence of a tendinous inscription (TI) that separates the ST into proximal
39 (ST_{prox}) and distal (ST_{dist}) neuromuscular compartments, each containing separate nerve
40 innervations (Hopwood & Butterfield, 1976; Roy *et al.*, 1984; Edgerton *et al.*, 1987; Gans *et al.*,
41 1989; Paul, 2001; Woodley & Mercer, 2005). Despite potential for their asynchronous
42 activations, ST_{prox} and ST_{dist} in cats are mechanically linked and generally functioning in-series,
43 i.e., as a single muscle (Bodine *et al.*, 1982; Edgerton *et al.*, 1987; English & Weeks, 1987;
44 Hutchison *et al.*, 1989; Chanaud *et al.*, 1991). A recent study found no differences in passive
45 mechanical properties between ST compartments in humans, suggesting human ST_{prox} and ST_{dist}
46 also function mechanically in-series (Kositsky *et al.*, 2022). However, the morphology of ST
47 compartments has not been well documented in humans *in vivo*. As a muscle's structure defines
48 its function (Bamman *et al.*, 2000; Fukunaga *et al.*, 2001), evaluating compartment morphology
49 would provide further insight into the interaction between ST compartments.

50 Studies examining ST compartment morphology and structure in humans have generally
51 been restricted to cadaveric investigations, which have reported conflicting results regarding
52 differences, or lack thereof, in fascicle or fiber length (Markee *et al.*, 1955; Barrett, 1962;

53 Wickiewicz *et al.*, 1983; Woodley & Mercer, 2005; Kellis *et al.*, 2012; Haberfehlner *et al.*,
54 2016b) and physiological cross-sectional area (Woodley & Mercer, 2005; Haberfehlner *et al.*,
55 2016b) between human ST_{prox} and ST_{dist}. Regarding volume, Haberfehlner *et al.* (2016b) found
56 no difference between ST compartments. Although allowing for more direct measurements,
57 cadaveric studies are typically not well standardized across investigations and generally consist
58 of older specimens that have a high chance of being affected by neuromuscular disease or
59 impairment. Hence, the translation of information obtained from cadavers to living healthy adults
60 may be limited. *In vivo* studies (Haberfehlner *et al.*, 2016a; Hanssen *et al.*, 2021) have used
61 three-dimensional freehand ultrasound to assess ST compartmental fascicle length, volume, and
62 echo intensity (related to muscle quality) in typically developing children and those with
63 spasticity. However, ST compartment morphology of healthy human adults has not been studied
64 in detail. Further, quantitative examinations of the TI in human cadavers have been limited to
65 detailing the dimensions, angle, and location along whole ST muscle length (Markee *et al.*, 1955;
66 Lee *et al.*, 1988; Garrett *et al.*, 1989; Woodley & Mercer, 2005; Kellis *et al.*, 2012; van der Made
67 *et al.*, 2015), while *in vivo* ultrasound-based studies additionally quantified TI location only with
68 respect to the ischial tuberosity (Kellis *et al.*, 2012; Kellis & Balidou, 2014). As forces may be
69 transferred across ST compartments (Bodine *et al.*, 1982; Edgerton *et al.*, 1987), the location of
70 the TI within and between compartments may play an important role in any potential force
71 transmission function. However, to our best knowledge, the positioning of the TI in relation to
72 ST compartment morphology has yet to be documented.

73 In orthopaedics, the distal ST tendon is routinely harvested as autologous graft tissue,
74 particularly for anterior cruciate ligament reconstruction (ACLR) (Thaunat *et al.*, 2019; Vertullo
75 *et al.*, 2019). Although this surgical procedure effectively sacrifices ST, the ST tendon

76 demonstrates remarkable potential to regenerate and reattach below the knee joint line (Nakamae
77 *et al.*, 2005; Papalia *et al.*, 2015), regaining some level of function. However, after ACLR, the
78 ST muscle belly is substantially shorter, with decreased anatomical cross-sectional area (ACSA)
79 and volume (Williams *et al.*, 2004; Makihara *et al.*, 2006; Snow *et al.*, 2012; Nomura *et al.*,
80 2015; Konrath *et al.*, 2016; Messer *et al.*, 2020; Morris *et al.*, 2021). Recently, de Moulin *et al.*
81 (2022) observed non-uniform morphological adaptations along the ST muscle belly after ACLR,
82 but only defined muscle regions as thirds along muscle belly length and not as anatomical
83 compartments. The shape of ST, particularly distally, has also been qualitatively (Snow *et al.*,
84 2012) and quantitatively (du Moulin *et al.*, 2022) observed to be different after tendon harvesting
85 for ACLR. However, it remains unknown if ST_{prox} and ST_{dist} are altered heterogeneously post-
86 ACLR.

87 Differences in morphological adaptations between ST muscle compartments after ACLR
88 might be expected as the proximal tendon and muscle portion, which remain mechanically
89 connected to surrounding tissues, could still contribute to hip and knee joint torques (Maas &
90 Sandercock, 2008; de Bruin *et al.*, 2011). If so, ST_{prox} would experience greater loading
91 compared to distal areas, at least until the distal tendon may reattach. Lower loading in ST_{dist}
92 could lead to a greater reduction in compartment size and length (Wisdom *et al.*, 2015; Franchi *et*
93 *al.*, 2022) compared to ST_{prox} . Potential non-uniform morphological changes between ST_{prox} and
94 ST_{dist} , as shown in musculoskeletal conditions other than ACLR (e.g., children with cerebral
95 palsy; Haberfehlner *et al.* [2016a]), may disrupt the mechanical interplay between ST
96 compartments seen in healthy legs (Kositsky *et al.*, 2022). Moreover, as ST_{prox} may function
97 primarily at the hip, and ST_{dist} predominantly at the knee (Markee *et al.*, 1955), compartment
98 specific mechanical impairment may be relevant for the common and persistent knee flexion

99 weakness following ACLR with an ST graft, even in the presence of ST tendon regeneration
100 (Nakamae *et al.*, 2005; Makihara *et al.*, 2006; Nomura *et al.*, 2015; Papalia *et al.*, 2015; Konrath
101 *et al.*, 2016).

102 In this study, we used magnetic resonance imaging (MRI) to bilaterally evaluate the
103 morphology of ST, including ST_{prox} and ST_{dist}, in adults with a unilateral ACLR involving a
104 distal ST tendon autograft. Specifically, we aimed to assess whole muscle and compartment
105 morphology on the contralateral (non-surgical) leg, the effects distal ST tendon harvesting has on
106 ST gross morphology, and how compartments may atrophy with respect to each other, the whole
107 muscle, and the TI. We also aimed to describe the positioning of the TI in relation to
108 compartment and whole muscle morphology and if the positioning may be affected by the
109 morphological changes induced by ACLR.

110 **METHODS**

111 **Participants**

112 Ten participants (six females; age: 27.2 ± 4.9 years; height: 171.6 ± 10.0 cm; mass: 72.6
113 ± 13.4 kg; 424 ± 109 days post-surgery) were recruited for the study. All participants, of which
114 five had accompanying meniscal lesions, underwent ACLR with a quadrupled ipsilateral
115 semitendinosus autograft (see *Surgical procedures* section). Exclusion criteria consisted of:
116 ACLR >6 months post initial injury, concomitant harvesting of gracilis tendon for ACLR,
117 previous major knee injuries, neurological disorders, and/or contraindications for MRI scans.
118 Participants were requested to refrain from strenuous exercise commencing 24 hours prior to the
119 investigation and provided written informed consent prior to any involvement in the study. The
120 Griffith University Human Research Ethics Committee (2018/839) approved the study, which
121 was carried out in accordance with the Declaration of Helsinki.

122 **Surgical procedures**

123 A fellowship trained orthopaedic surgeon (C.J.V.) performed all ACLRs. After
124 application of a tourniquet to the thigh, an anteromedial vertical incision was made over the pes
125 anserinus. The sartorius fascia was then incised to visualise the ST tendon. The tendon was left
126 secured to the distal attachment point and an open-ended tendon harvester (Linvatec, Florida,
127 USA) was used to release the entire distal tendon length from its muscular attachment. Then, the
128 ST tendon was removed from its distal bony attachment with a scalpel. A quadrupled ST graft
129 was formed using a wrapping technique over two Tightrope fixation devices (Arthrex, Florida,
130 USA), proximally and distally, and then sutured using Fibrewire (Arthrex, Florida, USA)
131 (Vertullo *et al.*, 2019). The femoral tunnel was created via a transportal drilling technique and
132 the tibial tunnel drilled outside-in. Femoral and tibial fixation with the adjustable fixation devices
133 were undertaken in full extension.

134 **Magnetic resonance imaging acquisition and data analyses**

135 With the participant lying supine, T₁ Dixon three-dimensional fast field echo and two-
136 dimensional proton density magnetic resonance images were acquired with a 3T MRI unit
137 (Ingenia, Phillips, Eindhoven, Netherlands). Scan acquisition parameters are summarized in
138 Table 1. For T₁ Dixon scans, a B1 field map (dual repetition time) was used to minimize signal
139 contrast variation across the field-of-view. Coronal T₁ Dixon images were reconstructed into 691
140 axial slices (1 mm slice thickness) with in-plane pixel resolution of 0.446 mm using Mimics
141 software (Version 20.0, Materialise, Leuven, Belgium). Each compartment was separately traced
142 in every ~5 axial slices in the water in-phase images, with software interpolation used for slices
143 in between. Caution was taken to include as little of the muscle border as possible, and images
144 were manually inspected to ensure interpolation did not cause substantial errors. The ST_{prox} and

145 ST_{dist} masks were also combined and gaps between them filled (i.e., to include the TI, as this is
146 how ST is typically segmented) to create a whole ST mask. Compartment and muscle belly
147 length were calculated in the proximodistal axis by multiplying slice thickness (1 mm) by the
148 number of slices in which the respective compartment/muscle was visible (Fukunaga *et al.*,
149 2001; Messer *et al.*, 2020). The slice containing each compartment's and the entire muscle's
150 largest cross-sectional value was deemed the compartment/muscle maximal ACSA ($ACSA_{\text{max}}$)
151 (Fukunaga *et al.*, 2001; Kositsky *et al.*, 2020). The location of compartment and muscle
152 $ACSA_{\text{max}}$ relative to the respective compartment and entire muscle belly length was also
153 determined, with the proximal end of the muscle corresponding to 0% and the distal end to
154 100%. Compartment and muscle volumes were calculated by multiplying slice thickness (1 mm)
155 by the sum of contiguous ACSAs (Fukunaga *et al.*, 2001; Messer *et al.*, 2020). The position of
156 the proximal (TI_{prox}) and distal (TI_{dist}) endpoints of the TI was determined relative to the length
157 of each compartment and the entire muscle belly, and the proximodistal length (in the axial
158 imaging plane) of the TI was determined from the number of slices in which ST_{prox} and ST_{dist}
159 overlapped. Examples of all morphological analyses are depicted in Figure 1. The distal ST
160 tendon was considered as regenerated if a tendinous structure was visible on proton density and
161 T_1 Dixon scans below the knee joint.

162 **Statistical analyses**

163 Paired samples t-tests were used to assess the between-leg differences in whole ST
164 muscle morphology (volume, $ACSA_{\text{max}}$, length), TI length, and the location of whole ST muscle
165 $ACSA_{\text{max}}$ relative to whole muscle and TI lengths. The effects of compartment (ST_{prox} , ST_{dist})
166 and leg (contralateral, ACLR) on volume, $ACSA_{\text{max}}$, and length were assessed using full-
167 factorial, two-way repeated measured ANOVAs. To confirm grouping all participants in a single

168 cohort regardless of tendon regeneration status did not affect our results, the paired samples t -
169 tests and two-way repeated measured ANOVAs for volume, $ACSA_{max}$, and length were repeated
170 with only tendon regenerated participants included. A two-way repeated measures ANOVA was
171 performed to assess if the location of ST_{prox} $ACSA_{max}$ relative to muscle length changed after
172 ACLR or differed from TI_{prox} across legs. A separate ANOVA was performed comparing the
173 locations of ST_{dist} $ACSA_{max}$ and TI_{dist} . For all repeated measures ANOVAs, Bonferroni
174 corrections were applied when significant interactions were found. The between-leg differences
175 for each compartment morphological parameter (e.g., volume of ST_{prox} on the ACLR leg minus
176 volume of ST_{prox} on the contralateral leg) were determined and Pearson's r correlation
177 coefficients used to assess the relationships in between-leg differences for (i) ST_{prox} and ST_{dist}
178 morphology, (ii) compartment and whole muscle morphology, and (iii) compartment and TI
179 length. All statistical analyses were performed with SPSS (v27, SPSS Inc., Chicago, IL, USA).
180 All data are presented as mean \pm one standard deviation.

181 **RESULTS**

182 Distal ST tendon regeneration was observed in seven of the ten participants. Whole ST
183 muscle volume ($p < 0.001$), $ACSA_{max}$ ($p = 0.02$), and length ($p = 0.001$) were all smaller on the
184 ACLR compared to contralateral leg (Table 2). The location of whole muscle $ACSA_{max}$ relative
185 to whole muscle length was more distal on the ACLR leg (contralateral: $40.8 \pm 3.3\%$; ACLR:
186 $49.0 \pm 8.4\%$; $p = 0.025$), but the location of $ACSA_{max}$ along the TI length did not differ across
187 legs (contralateral: $36.5 \pm 12.0\%$; ACLR: $39.5 \pm 15.8\%$; $p = 0.623$).

188 Compartment morphology results are presented in Table 3. A significant interaction ($p <$
189 0.001) revealed that although volume was smaller for both compartments on the ACLR
190 compared to the contralateral leg, ST_{dist} was larger than ST_{prox} on the contralateral ($p = 0.007$),

191 but not the ACLR ($p = 0.369$), leg. There were no differences in $ACSA_{max}$ between
192 compartments on either leg (main effect: $p = 0.774$; interaction: $p = 0.951$). However, a
193 significant main effect ($p = 0.002$) revealed $ACSA_{max}$ to be smaller in both ST compartments on
194 the ACLR compared to the contralateral leg. As with volumetric results, a significant interaction
195 ($p = 0.002$) revealed length to be shorter for both compartments on the ACLR compared to the
196 contralateral leg, but ST_{dist} was longer than ST_{prox} on the contralateral ($p < 0.001$), but not the
197 ACLR ($p = 0.726$), leg.

198 The proximodistal length of the TI was shorter after ACLR (contralateral: 10.6 ± 2.0 cm;
199 ACLR: 9.3 ± 2.0 cm; $p = 0.005$) but traversed a greater percent of muscle belly length
200 (contralateral: $31.8 \pm 5.7\%$; ACLR: $34.7 \pm 4.7\%$; $p = 0.015$). The TI spanned from $28.8 \pm 2.5\%$
201 (TI_{prox}) to $60.5 \pm 4.7\%$ (TI_{dist}) of muscle belly length on the contralateral leg, and from $34.5 \pm$
202 7.2% (TI_{prox}) to $69.2 \pm 8.0\%$ (TI_{dist}) of muscle length on the ACLR leg. This corresponded to
203 $47.6 \pm 5.9\%$ of ST_{prox} length to $44.3 \pm 7.1\%$ of ST_{dist} length on the contralateral leg and $49.4 \pm$
204 6.4% of ST_{prox} length to $53.2 \pm 8.7\%$ of ST_{dist} length on the ACLR leg. The location of ST_{prox}
205 $ACSA_{max}$ (contralateral: $29.6 \pm 2.0\%$; ACLR: $35.7 \pm 6.8\%$) did not differ from TI_{prox} on either
206 leg (main effect: $p = 0.126$; interaction $p = 0.615$), although ST_{prox} $ACSA_{max}$ and TI_{prox} were both
207 more distal on the ACLR leg (main effect: $p = 0.005$) (Figure 2). While the location of ST_{dist}
208 $ACSA_{max}$ with respect to muscle length did not differ between legs (contralateral: $58.6 \pm 3.9\%$;
209 ACLR: $62.5 \pm 9.7\%$; $p = 0.139$), a significant interaction ($p = 0.021$) revealed the location of
210 ST_{dist} $ACSA_{max}$ and TI_{dist} differed only on the ACLR leg ($p = 0.025$), and not the contralateral leg
211 ($p = 0.211$), due to a slightly more distal position (relative to muscle length) of TI_{dist} after ACLR
212 ($p = 0.007$).

213 The between-leg differences in each morphological parameter (volume, $ACSA_{max}$,
214 length) were highly correlated between compartments ($r \geq 0.66$; $p \leq 0.037$; Figure 3). Between-
215 leg differences in compartment volume and $ACSA_{max}$ were strongly correlated with
216 corresponding whole ST muscle differences ($r \geq 0.93$; $p < 0.001$; Figure 4), although length
217 differences in ST_{dist} were much more strongly correlated with whole ST length differences ($r =$
218 0.99 ; $p < 0.001$) than was ST_{prox} ($r = 0.75$; $p = 0.013$). Conversely, the difference in ST_{prox} length
219 was more strongly correlated ($r = 0.99$; $p < 0.001$) with the difference in TI length than was the
220 length difference of ST_{dist} ($r = 0.71$; $p = 0.021$; Figure 5).

221 In the tendon regenerated subgroup, ST whole muscle volume ($p = 0.007$) and length ($p =$
222 0.002) differed between legs, although no statistical difference was detected for $ACSA_{max}$ ($p =$
223 0.185). Compartment morphology results from the tendon regenerated subgroup demonstrated
224 the same main effects and interactions as with the overall sample (Table 3). For volume, a
225 significant interaction ($p = 0.002$) revealed ST_{dist} was larger than ST_{prox} only on the contralateral
226 leg (contralateral: $p = 0.004$; ACLR: $p = 0.185$). For $ACSA_{max}$, there was a main effect of leg (p
227 $= 0.031$), but not compartment ($p = 0.724$), and no significant interaction ($p = 0.551$). For length,
228 a significant interaction ($p = 0.030$) revealed ST_{dist} was longer than ST_{prox} only on the
229 contralateral leg (contralateral: $p = 0.002$; ACLR: $p = 0.261$).

230 DISCUSSION

231 This study is the first to characterize in detail the *in vivo* gross morphology of proximal
232 and distal ST compartments in human adults, using ACLR patients as a model to study the
233 morphological interactions between ST compartments. In the healthy contralateral leg, we found
234 volume and length were both larger in ST_{dist} compared to ST_{prox} , although $ACSA_{max}$ did not
235 differ between compartments. In the ACLR leg, no between-compartment differences in

236 morphological parameters were seen, indicating larger volume and length changes in ST_{dist}
237 compared to ST_{prox} following ACLR. We also found the TI endpoints to generally be positioned
238 around the $ACSA_{\text{max}}$ of each compartment. These results provide novel insight into the structure
239 and function of the human ST muscle and how ST compartments contain the potential to be
240 heterogeneously altered, particularly via their overall lengths.

241 **Gross morphology of semitendinosus**

242 The ST compartment volumes from healthy contralateral legs were higher than previous
243 reports due to the demographics studied previously (e.g., cadavers, children with or without
244 diseased ST; Haberfehlner *et al.*, [2016b, 2016a]; Hanssen *et al.*, [2021]). We found the volume
245 of ST_{dist} to be greater than ST_{prox} on the contralateral leg (Table 3). Previous studies
246 (Haberfehlner *et al.*, 2016b, 2016a; Hanssen *et al.*, 2021) reported contradictory evidence to one
247 another regarding any between-compartment volumetric differences, likely due to age and
248 demographics. We also found ST_{dist} to be longer than ST_{prox} , although it should be noted this
249 refers to the proximodistal length of the respective compartment. Inferences regarding potential
250 differences in fascicle length from our results are limited as the MRI sequences used only allow
251 for gross morphology to be quantified. Nonetheless, a longer ST_{dist} compared to ST_{prox} is in
252 agreement with studies of cats (Bodine *et al.*, 1982; Edgerton *et al.*, 1987; Loeb *et al.*, 1987) and
253 goats (Gans *et al.*, 1989). The fiber and fascicle length of human ST_{dist} was originally reported to
254 be longer than ST_{prox} (Markee *et al.*, 1955; Barrett, 1962), although more recent dissections
255 suggest average fascicle lengths may be equal between compartments (Wickiewicz *et al.*, 1983;
256 Woodley & Mercer, 2005; Kellis *et al.*, 2012; Haberfehlner *et al.*, 2016b). However, due to the
257 oblique nature of the TI and muscle-tendon junctions, fascicle length can vary substantially
258 proximodistally (Haberfehlner *et al.*, 2016b) and depth-wise (Kellis *et al.*, 2012) within a given

259 compartment. In addition to three-dimensional freehand ultrasound, more complex MRI
260 methods, such as diffusion tensor imaging (Bolsterlee *et al.*, 2019), are needed to quantify
261 compartment fascicle lengths *in vivo*.

262 Despite being unable to document at the level of fascicles, the between-compartment
263 differences in length seem to explain the greater volume in ST_{dist} compared to ST_{prox} , as
264 $ACSA_{\text{max}}$ did not differ between compartments. $ACSA_{\text{max}}$, a strong determinant of muscle force,
265 and by extension joint torque (Bamman *et al.*, 2000; Fukunaga *et al.*, 2001), is a good proxy of
266 physiological cross-sectional area in muscles with little-to-no pennation, such as ST (Makihara *et*
267 *al.*, 2006; Haberfehlner *et al.*, 2016b). Therefore, despite larger volume in ST_{dist} , the lack of a
268 between-compartment difference in $ACSA_{\text{max}}$ suggests the maximal force producing capacity of
269 each compartment does not differ in healthy legs. A lack of between-compartment differences in
270 maximal force producing capacity (present study) and passive forces throughout the range of
271 motion (Kositsky *et al.*, 2022) support the paradigm of human ST_{prox} and ST_{dist} functioning
272 mechanically as a single unit.

273 In accordance with previous reports (Lee *et al.*, 1988; Woodley & Mercer, 2005; van der
274 Made *et al.*, 2015), we found the TI originated at approximately one-third of muscle length and
275 continued obliquely into the lower half of the ST, although Garrett *et al.* (1989) found the TI to
276 terminate slightly more proximally. We also found the TI endpoints (TI_{prox} , TI_{dist}) are centered
277 approximately in the middle of each compartment, connecting regions where compartments are
278 of their maximal size. Thus, the TI is well placed to interact between the two compartments, and
279 the possible functional implications of this placement (e.g., force transmission) are discussed
280 below (see *Role and function of the tendinous inscription*). Practically, TI endpoints coinciding
281 spatially with compartment $ACSA_{\text{max}}$ enables TI endpoints to be used as reference to standardize

282 measures of maximal compartment size, which could also be performed using other, more
283 accessible imaging modalities, such as ultrasonography (Haberfehlner *et al.*, 2016b; Kositsky *et*
284 *al.*, 2020; Hanssen *et al.*, 2021). However, given the slightly more proximal position of ST_{dist}
285 ACSA_{max} compared to TI_{dist} in the ACLR leg, assessments of ACSA of ST_{dist} after ACLR should
286 include images proximal to the end of the TI, to ensure ACSA_{max} is obtained. Additionally, as
287 the location of whole ST muscle ACSA_{max} along the TI was highly variable, standardized
288 locations for measures of ST ACSA_{max} (e.g., at 50% of TI length; Haberfehlner *et al.*, [2016b])
289 should be taken with caution as potential inter-limb and/or inter-individual differences at that
290 single location may just be normal variation.

291 **Effects of anterior cruciate ligament reconstruction on semitendinosus morphology**

292 The differences in whole ST muscle morphology after ACLR were comparable with
293 those seen in previous studies (Williams *et al.*, 2004; Makihara *et al.*, 2006; Snow *et al.*, 2012;
294 Nomura *et al.*, 2015; Konrath *et al.*, 2016; Messer *et al.*, 2020). Although both compartments
295 were smaller in volume and shorter after ACLR, the presence of statistically significant between-
296 compartment differences in volume and length only for the contralateral, but not ACLR, leg
297 indicates greater volume and length differences in ST_{dist} compared to ST_{prox} on the ACLR leg.
298 Likewise, previous studies have also observed greater ST whole muscle volume loss in
299 individuals with more muscle shortening (Williams *et al.*, 2004; Nomura *et al.*, 2015). Although
300 de Moulin *et al.* (2022) found greater ACSA_{max} and volume differences in proximal and middle
301 ST regions post-ACLR, regions were scaled based on whole muscle length. Thus, given the
302 greater shortening in ST_{dist}, it is highly likely that the results of de Moulin *et al.* (2022) were
303 influenced by a different contribution of ST_{prox} and ST_{dist} to each muscle region between legs. A
304 shorter and smaller ST_{dist} compared to ST_{prox} is consistent with findings in children with

305 spasticity (Haberfehlner *et al.*, 2016a). Greater differences in ST_{dist} compared to ST_{prox} post-
306 ACLR is likely explained by the surgical procedure and the effects of epimuscular myofascial
307 connections (Maas & Sandercock, 2010). To harvest the ST tendon, the sartorius fascia is incised
308 and the most distal portion of the ST muscle belly is stripped off the ST tendon with a tendon
309 harvester device. This surgical procedure not only damages the distal muscle end of ST_{dist} , but
310 further reduces the myofascial linkages that could maintain some loading through ST_{dist} and
311 physically prevent muscle retraction in the absence of a distal insertion point. It is thus no
312 surprise that attenuated strength deficit and less ST muscle shortening were found when only a
313 partial width of the ST tendon was harvested (Sasahara *et al.*, 2014), although future work is
314 needed to determine if less severe morphological alterations in ST_{dist} would also have occurred
315 with this partial ST tendon harvesting technique.

316 As fascicles of ST_{prox} terminate on the TI and a new set of fascicles (ST_{dist}) originate on
317 the TI (Markee *et al.*, 1955; Barrett, 1962; Garrett *et al.*, 1989; Woodley & Mercer, 2005;
318 Haberfehlner *et al.*, 2016b), the relationships between compartment shortening and whole muscle
319 (Figure 4) and TI shortening (Figure 5) demonstrate the distoproximal manner of shortening
320 consequent to distal tendon harvest (Street, 1983). The greater reduction in ST_{dist} compared to
321 ST_{prox} length is likely due to initial retraction and the distal muscle stump being left free from
322 distal attachment after tendon harvesting, and thus shortening of ST_{dist} is the immediate driver of
323 whole ST length change. Shortening of ST_{dist} distoproximally would not independently have
324 great influence on TI dimensions, as the TI is proximal to the main site of shortening. On the
325 other hand, distoproximal shortening of ST_{prox} , whose fascicles are distally attached to the TI, is
326 thus the main regulator of TI shortening. Although we only measured its proximodistal length,
327 the overall length of the TI would also have decreased due to the concomitant radial muscle

328 atrophy. The shortening of the TI after ACLR may simply be slackening or crimping as a
329 consequence of geometric constraints. On the other hand, as the mechanical behaviour of
330 aponeuroses can change due to unloading (Lee *et al.*, 2006) and aponeurosis width may increase
331 in response to resistance training (Wakahara *et al.*, 2015), TI shortening may also demonstrate
332 the TI is a plastic structure that can adapt to its environment. The intrinsic modulation of the TI
333 and whether these alterations occur concomitantly with, or delayed in response to, compartment
334 changes should be examined in future investigations.

335 In contrast to different adaptations between compartments in volume and length and as
336 was the case in the contralateral leg, $ACSA_{max}$ did not differ between compartments in the ACLR
337 leg, indicating the maximal force producing capacity was likely reduced by a comparable amount
338 in both ST_{prox} and ST_{dist} after ACLR. The between-compartment relationships in the differences
339 in morphological parameters (Figure 3) further demonstrate compartment morphology is linked,
340 even after such drastic radial and longitudinal morphological adaptations. Large differences in
341 $ACSA_{max}$ between compartments would be severely detrimental to any mechanical interaction as
342 transmission of high levels of force from a larger compartment to a smaller compartment would
343 expose the latter to excessive stresses and a high risk of damage. The slightly different location
344 of TI_{dist} compared to ST_{dist} $ACSA_{max}$ post-ACLR may result from a change in the oblique angle
345 of the TI, possibly leading to less efficient force transmission between compartments via altering
346 the orientation between muscle fibers and the collagen within TI. Further, should greater
347 proximodistal shortening of ST_{dist} be reflective of fascicle and sarcomere adaptations, the force-
348 velocity characteristics of the two compartments may become incongruous. Additionally, the
349 more drastic shortening of ST_{dist} may reflect a greater change in the length and/or number of
350 sarcomeres in-series (Crawford, 1977; Abrams *et al.*, 2000; Van Dyke *et al.*, 2012), resulting in

351 fibers in ST_{dist} being too short to produce high levels of force, particularly at highly flexed knee
352 joint angles corresponding to short ST muscle belly lengths (Wickiewicz *et al.*, 1984). A reduced
353 operating range of ST is consistent with experimental results demonstrating greatly decreased
354 knee joint moment in deep knee flexion post-ACLR with an ST graft (Makihara *et al.*, 2006;
355 Nomura *et al.*, 2015; Morris *et al.*, 2021). Future studies employing microendoscopy (Pincheira
356 *et al.*, 2022) may be valuable in elucidating compartment-specific changes at the level of the
357 sarcomere across various joint angles in healthy and ACLR legs.

358 In the regenerated tendon subgroup, whole ST muscle $ACSA_{max}$ did not statistically
359 differ between legs. The failure to detect a significant difference in whole ST muscle $ACSA_{max}$
360 in the regenerated tendon subgroup may stem from the large within-sample variation (between-
361 leg mean difference $-7.3 \pm 14.9\%$), but may be a real finding given previous studies assessing ST
362 $ACSA_{max}$ post-ACLR did not statistically test this parameter for regenerated participants against
363 a control or contralateral leg (Williams *et al.*, 2004; Snow *et al.*, 2012; Konrath *et al.*, 2016; du
364 Moulin *et al.*, 2022) or used an average of five 3.6 mm slices when determining $ACSA_{max}$
365 (Messer *et al.*, 2020). Given $ACSA_{max}$ of both ST compartments were significantly smaller on
366 the ACLR leg in this subgroup, at minimum these results suggest measuring at the whole muscle
367 level may not fully reflect adaptations at compartment level. Further, the longer and larger ST_{dist}
368 compared to ST_{prox} in the contralateral leg only for both the whole sample and the regenerated
369 tendon subgroup (Table 3) signifies having grouped all participants together did not influence the
370 main results. Although we were unable to statistically compare between regeneration status due
371 to the low sample size for this subgroup ($n = 3$), greater morphological differences seemed to
372 occur in non-regenerated tendon individuals (Figures 3-5, Tables 2 and 3), which is consistent
373 with previous reports of greater shortening and muscle atrophy after a lack of tendon

374 regeneration (Davenport & Ranson, 1930; Crawford, 1977; Nomura *et al.*, 2015; Konrath *et al.*,
375 2016; du Moulin *et al.*, 2022). Failure of the harvested distal tendon to regenerate would result in
376 chronic underloading of ST_{dist} , as seen by more extensive shortening of ST_{dist} in the non-
377 regenerated cohort. Although the material and compositional properties of the regenerated
378 tendon possibly differ from the native tendon (Papalia *et al.*, 2015), the more substantial
379 morphological changes when the ST tendon does not regenerate highlights the clinical and
380 functional importance of facilitating tendon regrowth (when the whole tendon is harvested), as
381 re-establishing a distal insertion point provides a functional mechanical linkage between the
382 muscle, its surroundings, and bone, allowing greater loading and attenuation of ST atrophy.
383 Future studies targeting improved ST tendon healing are thus welcome.

384 **Role and function of the tendinous inscription**

385 The placement of an oblique, full-thickness TI within the human (and a variety of
386 mammalian) ST has been puzzling anatomists for over a century (Humphry, 1869; Parsons,
387 1898). Ontogenetically, it is thought the TI marks the fusion between two separately developing
388 anlagen (Macalister, 1868; Bardeen, 1906) and is possibly a neomorph (Appleton, 1928)
389 resulting from the crossing of two muscles (Haines, 1934). However, Parsons (1898) noted a TI
390 is not always present at the union of two muscle heads and thus there may be further
391 morphogenetic explanations. Parsons' sentiments were supported by later works finding a small
392 number of fascicles bridge the TI and course from ST_{prox} to distal tendon insertion (Markee *et al.*,
393 1955; Loeb *et al.*, 1987; Woodley & Mercer, 2005), and that a TI separating compartments can
394 also be present even when ST_{prox} is itself divided into two (dorsal and ventral) heads (Roy *et al.*,
395 1984). As fascicles generally terminate (ST_{prox}) or originate (ST_{dist}) on the TI and to date
396 intrafascicularly terminating muscle fibers within the human ST have not been observed (Barrett,

397 1962; Woodley & Mercer, 2005), the TI potentially serves to simply connect in-series muscle
398 fibers (Humphry, 1872; Trotter *et al.*, 1995). Connecting serial muscle fibers through a TI allows
399 fibers to be of various lengths and experience varying levels of strain (Loeb *et al.*, 1987), which
400 could reduce the risk of fiber damage without severely affecting the function of ST given its
401 wide operating range (Peters & Rick, 1977; Cutts, 1989), and allow for deep-to-superficial
402 subunits within a given compartment (Bodine *et al.*, 1982; Chanaud *et al.*, 1991; Kellis *et al.*,
403 2012). However, intrafascicularly terminating muscle fibers have been found in other human
404 muscles with TIs (e.g., rectus abdominis; Cullen & Brödel, [1937]; Woodley *et al.* [2007]) and
405 within ST compartments in other mammals whose ST contains a TI (Loeb *et al.*, 1987; Gans *et*
406 *al.*, 1989). Therefore, even if human ST fibers do span entire fascicles, the TI seems to have
407 another, main functional role than to just connect serial fibers.

408 Using shear-wave elastography, we recently indirectly demonstrated passive forces do
409 not differ between human ST compartments, although it was unclear if forces were
410 independently but equally developed or transmitted from one compartment to the other, resulting
411 in equilibrium across the whole muscle (Kositsky *et al.*, 2022). Here, we document the TI is
412 advantageously positioned to possibly assist in force transmission by connecting the largest
413 regions of each compartment (Figure 2), and this placement generally remains after the
414 substantial gross morphological changes induced by harvesting the ST tendon for ACLR. As
415 efficient force transmission to from muscle fibers to the connective tissue network occurs
416 through shear at fiber ends (Purslow, 2020), the oblique arrangement of the TI provides a
417 geometrical design facilitating shearing at the junction between fiber and connective tissue that
418 would not be possible if the TI was completely transverse or coursing in the fascicle direction.
419 The consequence of such an anatomical arrangement could allow for re-distribution and

420 transmission of forces across fascicles of each compartment, as suggested by Kellis et al. (2012).
421 Further, the TI endpoints being located around each compartment's $ACSA_{max}$ ensures the two
422 compartments are mechanically linked and provides the TI a wide area over which to distribute
423 forces. In support of a force transmission role of the TI, muscle fiber-TI connections have been
424 reported to be comparable with myotendinous junctions (Hijikata & Ishikawa, 1997), and the TI
425 of other muscles, such as in the cat neck, has been shown to house and/or be surrounded by
426 Golgi tendon organs and muscle spindles (Richmond & Abrahams, 1975a, 1975b). Should the TI
427 of ST also contain these sensory receptors, detection of local forces by Golgi tendon organs
428 (Maas *et al.*, 2022) and muscle spindles (Smilde *et al.*, 2016) combined with the potential for
429 asynchronous activation (English & Weeks, 1987; Hutchison *et al.*, 1989) and unequal strains
430 (Markee *et al.*, 1955; Edgerton *et al.*, 1987) between compartments provides a mechanism by
431 which the central nervous system could use the TI to regulate compartmental force and stiffness
432 to control intercompartmental coordination and enable efficient force transmission between
433 compartments. Future studies combining complex computational models assessing force
434 transmission (Sharafi & Blemker, 2011; Zhang & Gao, 2012) and muscle fiber interaction with
435 internal aponeuroses (Knaus *et al.*, 2022) may be able to confirm the main functional role(s) of
436 the TI.

437 **Limitations**

438 We only used the contralateral, non-surgical leg as the healthy baseline/control. However,
439 unlike the quadriceps, hamstring morphology on the injured leg remains unchanged following
440 anterior cruciate ligament injury alone (Lorentzon *et al.*, 1989; Kariya *et al.*, 1989; Williams *et*
441 *al.*, 2004; Konishi *et al.*, 2012) and after ACLR the morphology of ST on the non-injured leg
442 does not differ compared to pre-surgical (Williams *et al.*, 2004) and control (Morris *et al.*, 2021;

443 du Moulin *et al.*, 2022) groups. Additionally, the substantial between-leg differences in
444 morphology we found compare well with previous literature (Williams *et al.*, 2004; Makihara *et*
445 *al.*, 2006; Nomura *et al.*, 2015; Konrath *et al.*, 2016; Messer *et al.*, 2020) and exceed bilateral
446 asymmetry measures previously reported for ST (Williams *et al.*, 2004; Kulas *et al.*, 2018;
447 Speedtsberg *et al.*, 2022). Therefore, using the contralateral, non-injured leg as the baseline
448 control was unlikely to have influenced the results. Further, compartment length was quantified
449 by the proximodistal length of the respective compartment. As the TI is a complex three-
450 dimensional structure, compartments are comprised of fascicles of various lengths (Kellis *et al.*,
451 2012; Haberfehlner *et al.*, 2016b) and thus compartment length may not accurately represent
452 fiber or fascicle length. Therefore, we do not make any concrete conclusions at length scales
453 below proximodistal compartment length as they were not possible to assess from our MRI
454 scans. Finally, the ACLR surgical intervention induces secondary trauma at the knee joint and is
455 thus more complex than regular tenotomy. However, slightly greater changes in ACSA are seen
456 in the distal compared to proximal gracilis muscle when its distal tendon is harvested for
457 shoulder reconstruction (Flies *et al.*, 2020). Therefore, the results found in the present study are
458 likely due to the ST tendon harvest for the ACLR procedure, rather than post-ACLR
459 immobilization and disuse, but should be confirmed in future studies assessing ST compartment
460 alterations after an ST tendon autograft has been used for reconstructing other lower (Cody *et al.*,
461 2018; Stenroos & Brinck, 2020) and upper (Virtanen *et al.*, 2014; Ranne *et al.*, 2020) limb
462 tendons. The compartment alterations in the ACLR leg may also not be representative of other
463 (un)loading conditions, whose adaptations can also be assessed using the MRI acquisition
464 parameters presented in this study.

465 **CONCLUSIONS**

466 The proximal and distal compartments of human ST muscle appear to be modified in a
467 non-uniform manner following harvest for ACLR. However, the heterogenous changes in length
468 do not affect the homogeneity in compartment maximal radial size. The location of the tendinous
469 inscription with respect to compartment morphology provides a wide area over which this
470 connective tissue sheath could mediate the mechanical interaction of ST compartments. Overall,
471 these results suggest the proximal and distal compartments of the human ST muscle are not
472 mechanically independent.

FIGURES

Figure 1. Raw coronal water in-phase magnetic resonance imaging (MRI) sequence (left). Axially reconstructed MRI image with segmentations of proximal (ST_{prox}) and distal (ST_{dist}) semitendinosus (ST) compartments overlaid on the anterior cruciate ligament (ACLR) leg (upper right). Example reconstruction of proximal (contralateral: dark blue; anterior cruciate ligament reconstructed: light blue) and distal (contralateral: pink; anterior cruciate ligament reconstructed: red) semitendinosus compartments (lower right). Note the full length of the ST muscle is not seen in the coronal slice, reconstructed segmentations are not scaled to the coronal image, and all images are from the same participant, who had ST tendon regeneration and 7.2 cm of muscle shortening. The tendinous inscription (TI) is indicated with yellow arrows on MRI images. *A*: ST whole muscle length. *B*: ST_{prox} compartment length. *C*: ST_{dist} compartment length. *D*: ST whole muscle $ACSA_{max}$. *E*: ST_{prox} compartment $ACSA_{max}$. *F*: ST_{dist} compartment $ACSA_{max}$. *G*: proximal endpoint of TI. *H*: distal endpoint of TI. *I*: TI length.

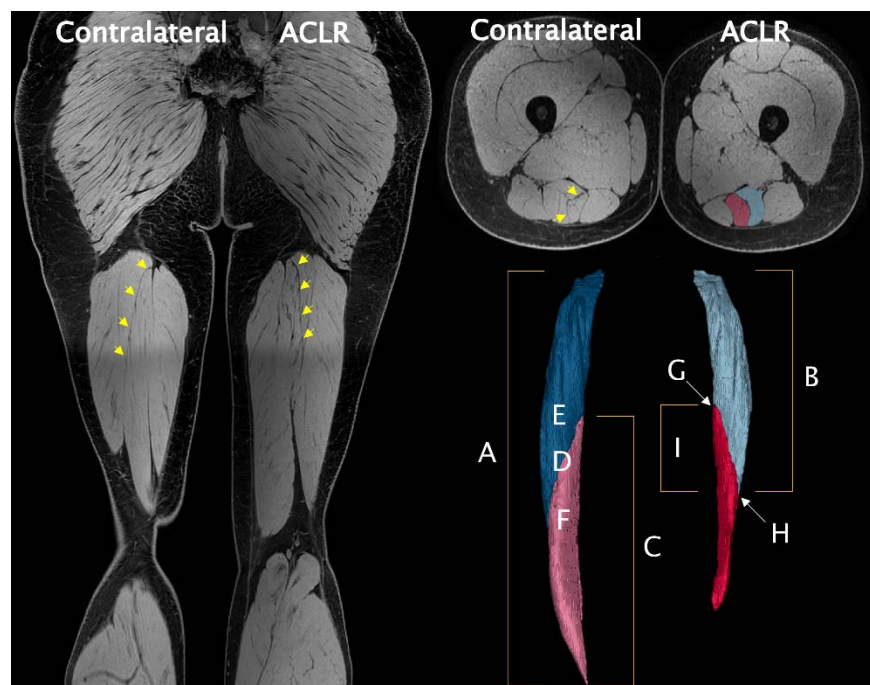

Figure 2. The location of proximal (contralateral: dark blue; anterior cruciate ligament reconstructed: light blue) and distal (contralateral: pink; anterior cruciate ligament reconstructed: red) semitendinosus compartment maximal anatomical cross-sectional area ($ACSA_{max}$; unbroken lines) compared to tendinous inscription (TI) endpoints (broken lines) for anterior cruciate ligament reconstructed (ACLR) and contralateral legs. Data are presented as means and standard deviations, with dots representing individual data points.

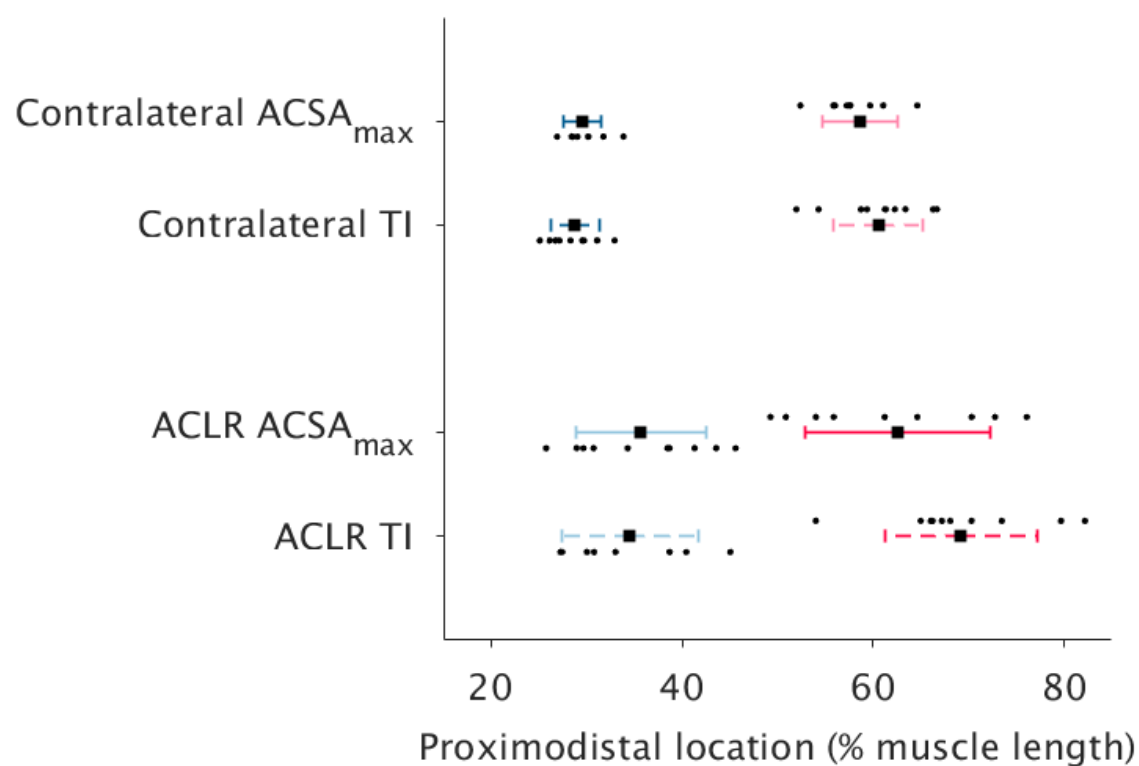

Figure 3. Pearson's correlation coefficients (r) for the between-leg differences in proximal (ST_{prox}) versus distal (ST_{dist}) semitendinosus compartment volume (left), maximal anatomical cross-sectional area ($ACSA_{max}$; middle), and length (right), plotted for absolute (upper) and relative (lower) differences. Dots represent individual data points from participants with (filled) and without (unfilled) tendon regeneration. All comparisons were significantly correlated ($p \leq 0.037$).

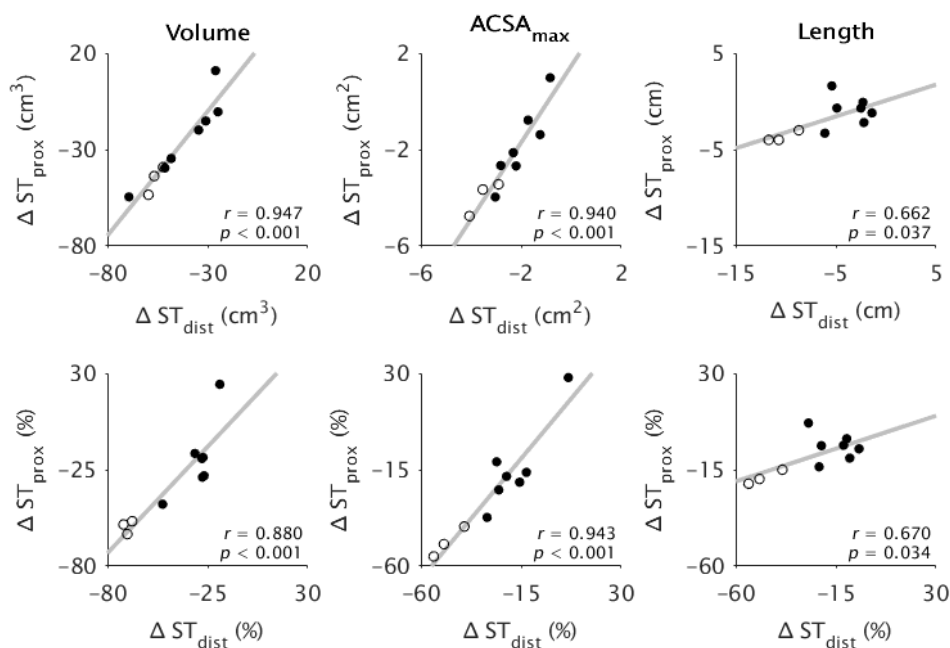

Figure 4. Pearson's correlation coefficients (r) for the between-leg relative differences in whole semitendinosus (ST) muscle versus proximal (ST_{prox} ; upper) and distal (ST_{dist} ; lower) ST compartment volume (left), maximal anatomical cross-sectional area ($ACSA_{max}$; middle), and length (right). Dots represent individual data points from participants with (filled) and without (unfilled) tendon regeneration. All comparisons were significantly correlated ($p \leq 0.013$).

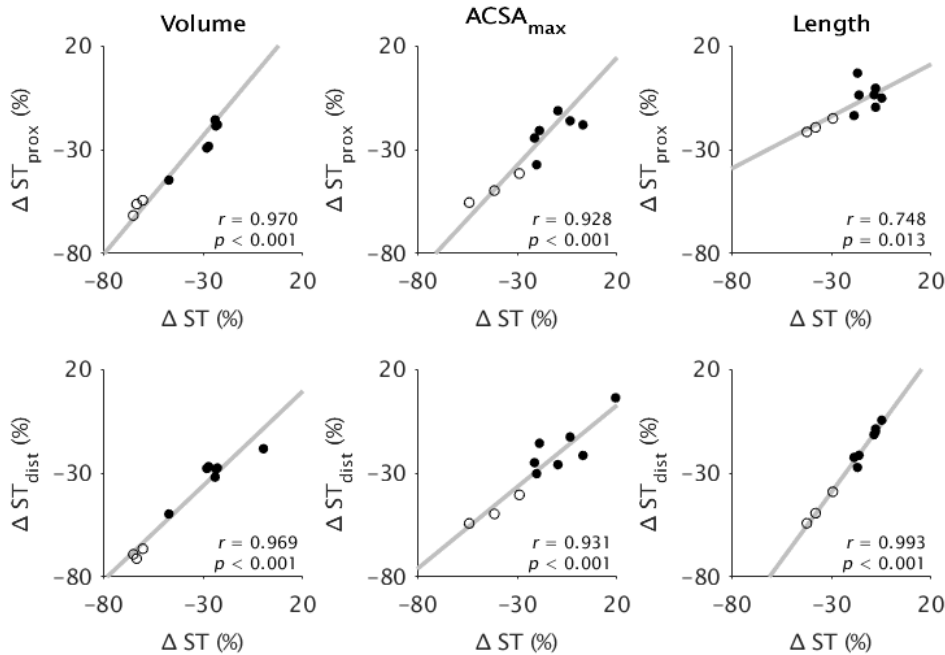

Figure 5. Pearson's correlation coefficients (r) for the between-leg relative differences in tendinous inscription (TI) length versus between-leg relative differences in proximal (ST_{prox} ; left) and distal (ST_{dist} ; right) semitendinosus compartment length. Dots represent individual data points from participants with (filled) and without (unfilled) tendon regeneration. Both correlations were significant ($p \leq 0.021$).

TABLES

Table 1. Acquisition parameters for magnetic resonance imaging scans.

	T₁ Dixon	Proton density
Main purpose	Muscle/compartiment segmentation	Visualize ST tendon
Acquisition plane	Coronal (3D)	Axial (2D)
Number of stations	Two	One
Number of slices	252	80-95
Slice thickness	1 mm	3 mm
Slice gap	0 mm	0.3 mm
Station overlap	30 mm	-
Repetition time	7.45 ms	2853-3804 ms *
Echo time(s)	1.19, 2.37 ms	25 ms
Flip angle	10°	90°
Voxel size	1 x 1 x 1 mm	0.8 x 0.88 mm
Minimum FOV	360 x 450 x 252 mm	200 x 380 mm
Acceleration factor	SENSE 2	SENSE 2.5
Acquisition time	14 min (7 min per station)	5-7 min *

FOV = field of view; ST = semitendinosus; 2D = two-dimensional; 3D = three-dimensional.

*depending on the FOV and the number of slices

Table 2. Means and standard deviations of volume, maximal anatomical cross-sectional area (ACSA_{max}), and length of the whole semitendinosus muscle for contralateral and anterior cruciate ligament reconstructed (ACLR) legs. Paired samples t-tests for between-leg differences were performed for the entire sample and for the tendon regenerated only subgroup, and not for the non-regenerated only subgroup due to sample size.

	Total (<i>n</i> = 10)		Regenerated only (<i>n</i> = 7)		Non-regenerated only (<i>n</i> = 3)	
	Contralateral	ACLR	Contralateral	ACLR	Contralateral	ACLR
Volume	211.9 ± 64.9	138.8 ± 65.7***	234.0 ± 66.2	172.7 ± 44.6##	160.3 ± 11.3	59.6 ± 1.5
ACSA_{max}	10.8 ± 2.6	9.0 ± 3.3*	11.8 ± 2.6	10.8 ± 2.1	8.6 ± 0.6	5.1 ± 1.1
