Abstract

Background: Key population HIV programmes in sub-Saharan Africa (SSA) require epidemiologic information to ensure equitable and equal access to services. We consolidated survey data among female sex workers (FSW), men-who-have-sex-with-men (MSM), people who inject drugs (PWID), and transgender people to estimate national-level key population size, HIV prevalence, and antiretroviral therapy (ART) coverage for mainland SSA.

Methods: Key population size estimates (KPSE), HIV prevalence, and ART coverage data from 39 SSA countries between 2010-2022 were collated from existing databases and verified against source documents. We used Bayesian mixed-effects spatial regression to model urban KPSE as a proportion of the gender-matched 15-49 years adult population. We modelled subnational key population HIV prevalence and ART coverage with age/gender/year/province-matched total population estimates as predictors.

Findings: We extracted 2062 unique KPSE, 1243 HIV prevalence, and 201 ART coverage data points. Across national urban populations, a median of 1.71% of women were FSW (interquartile range [IQR]=1.21-1.97%); 0.92% of men were MSM (IQR=0.73-1.01%); 0.32% of men injected drugs (IQR=0.28-0.39%), and 0.14% of women were transgender (IQR=0.12-0.17%). Key population HIV prevalence was 4 to 6 times higher than gender-matched total population prevalence. ART coverage was correlated with, but lower than, total population ART coverage. Across SSA, key

populations were estimated as 1.3% (95%CI: 0.9-1.7%) of the total population aged 15-49 years but 6.3% (4.6-8.6%) of people living with HIV.

Interpretation: Key populations in SSA experience disproportionately higher HIV burden and lower ART coverage, underscoring a need for focused prevention and treatment services. However, data availability and heterogeneity limit precise estimates for programming and monitoring trends. Strengthening key population surveys and routine data within national HIV strategic information systems would support more precise estimates.

Research in Context

Evidence before this study

Key populations, including female sex workers (FSW), men who have sex with men (MSM), people who inject drugs (PWID), and transgender populations, are at high risk of HIV globally, including in sub-Saharan Africa (SSA). Delivering appropriate HIV prevention and treatment programming to these populations, and monitoring attainment of an equitable HIV response, requires robust information on key population size, HIV prevalence, the treatment cascade, and new HIV infections. For this reason, key population surveys, including population size estimation and bio-behavioural surveys, are a standard component of a comprehensive national HIV surveillance portfolio.

Several complementary ongoing initiatives consolidate HIV data on key populations to support programme planning and implementation, global advocacy, and research.

These include the Key Population Atlas and Global AIDS Monitoring (Joint United Nations Programme on HIV/AIDS [UNAIDS]), databases maintained by the US Centers for Disease Control and Prevention (CDC) and the Global Fund Against TB, AIDS, and Malaria (The Global Fund), and the Global.HIV initiative (Johns Hopkins University).

These include similar data sources, but vary in scope, inclusion criteria, data elements recorded, and linkage to and validation against primary source data sets and reports.

Incomplete recording of key methodological details limits appraisal and formal evidence synthesis, and therefore utility of data for strategic planning.

Many other research studies have systematically reviewed, analysed, and extrapolated key population survey data in sub-Saharan Africa in single countries or across multiple

countries. These studies have tended to focus on specific outcomes or population groups of interest, and primarily comprise an appraisal of peer-reviewed literature.

Added value of this study

We consolidated and deduplicated data collected between 2010-2022 from existing key population surveillance databases maintained by the UNAIDS Key Population Atlas, UNAIDS Global AIDS Monitoring, US CDC, and the Global Fund. We used the Johns Hopkins University Global.HIV repository of surveillance reports, additional web-based searches, and engagement with country HIV strategic information teams to obtain survey reports in the peer-reviewed and grey literature, and validated each observation of key population size, HIV prevalence, or ART coverage against primary surveillance reports. We used regression analyses to characterise the relationship between key population and total population HIV indicators and extrapolated key population size estimates (KPSE), HIV prevalence, and ART coverage data to national-level estimates for all countries in mainland SSA.

This exercise was the most comprehensive effort to date to consolidate key population HIV data in SSA. We analysed 114 KPSE, 198 HIV prevalence, and 56 ART coverage studies. We estimated that across urban populations in SSA countries aged 15-49, a median of 1.71% of women were FSW; 0.92% of men have sex with men; 0.32% of men injected drugs; and 0.14% of women were transgender. This translated to 3.4 million FSW, 2 million MSM, 870,000 PWID, and 380,000 transgender women (TGW) in SSA who require comprehensive HIV prevention or treatment services. FSW, MSM, PWID, and TGW combined were estimated as 1.3% of the population aged 15-49, but

comprised 6.3% of people living with HIV. ART coverage among members of key populations living with HIV increased with total population ART coverage, but was lower for all key populations. We identified large gaps in data availability. Of the four key populations and three indicators studied, only Mozambique had data for all twelve indicators. Data were particularly sparse for transgender populations and PWID.

Implications of all the available evidence

Key populations experience HIV prevalence and lower ART coverage across all settings in sub-Saharan Africa than the total population. Extrapolated national estimates provide a foundation for planning appropriate key population-focused services for HIV prevention and treatment in all settings, including those with no or limited data.

However, large data availability gaps, inconsistency of existing data, and consequent wide uncertainty ranges around estimates limit the ability of existing data to guide granular programmatic planning and target setting for key population services and to monitor trends. More consistent surveillance implementation and improved routine surveillance through HIV prevention and treatment programmes for key populations would support monitoring equitable and equal programme access, as outlined in the Global AIDS Strategy 2021-2026 to end HIV/AIDS as a public health threat by 2030.

Introduction

Key populations, including female sex workers (FSW), men who have sex with men (MSM), people who inject drugs (PWID), and transgender women (TGW), experience high risk of acquiring and transmitting HIV due to a combination of biological and sociostructural factors, including stigma and criminalisation.^{1–3} The Global AIDS Strategy 2021-2026 calls for “equitable and equal access” to HIV prevention and treatment to reduce HIV incidence and end HIV/AIDS as a public health threat by 2030.⁴ Delivering appropriate HIV services for these populations, and monitoring attainment of an equitable HIV response, requires robust epidemiologic and service engagement indicators, including key population size, HIV prevalence and incidence, treatment and prevention cascades.

Key population surveys often rely on respondent-driven and venue-based sampling methods^{5,6} whose interpretation as population-representative relies upon strong assumptions that can be difficult to meet in practice. Household survey sampling frames are inappropriate for surveying migratory populations that are unlikely to disclose risk behaviour due to societal marginalisation and discrimination.^{7–9} Surveys are often infrequent and commonly restricted to, or disproportionately conducted in, urban areas. Consequently, data are sparse and less representative of a target population than standard general population sampling approaches such as national household surveys or sentinel surveillance.

Systematic reviews and meta-analyses of population size, HIV prevalence, or antiretroviral treatment (ART) coverage encompassing sub-Saharan Africa (SSA) have

been conducted for FSW,^{10,11} MSM,^{12,13} PWID,^{14,15} and TGW.^{16,17} Several independent initiatives have been undertaken to consolidate key population surveillance data.^{18–21} These efforts aim to monitor the state of the epidemic, evaluate programmes, and make recommendations on key population data reporting and quality thresholds.

We consolidated and harmonised key population size estimates (KPSE), HIV prevalence, and ART coverage data from existing databases and described data availability across countries and over time for each key population. We characterised the relationship between key population and total population HIV indicators and extrapolated KPSE, HIV prevalence, and ART coverage data to national-level estimates for mainland countries in SSA.

Methods

Data sources and extraction

We consolidated data on KPSE, HIV prevalence, and ART coverage from four existing databases: Joint United Nations Programme on HIV/AIDS (UNAIDS) Global AIDS Monitoring submissions,²² UNAIDS Key Population Atlas,²³ the Global Fund to Fight AIDS, TB, and Malaria (the Global Fund) surveillance database, and a Microsoft Excel database maintained by the US Centers for Disease Control and Prevention (CDC) Division of Global HIV & TB Key Population Surveillance Team, and two systematic review databases^{20,24} (Supplementary Table S1). For each observation, we extracted information about the study methodology, study location (country, subnational location), study population gender and age group, central estimate, sample size, standard error, and primary source or reference (e.g., survey report) (Supplementary Table S2).

Source documents were compiled from archives accompanying each database, the Johns Hopkins University Global.HIV document repository,²⁵ Medline, and Google Scholar, following which we contacted UNAIDS Strategic Information advisors and other HIV programme contacts in each country to seek missing reports. Four authors (OS, RA, EG, AS-B) reviewed source documents to deduplicate observations recorded in multiple databases, validate against sources, and extract missing data elements. During source review, we added observations when additional relevant data were reported or additional sources were ascertained that were not in the initial databases.

Observations were excluded if: key population definition, year, or study area were missing; the study area was non-specific (e.g., ‘urban areas’ or ‘5 provinces’); estimates were modelled or extrapolated; or data could not be confirmed by primary source review. Studies were not excluded or differentiated in our analysis according to study-specific population group definitions based on engaging in risk behaviours or time periods (e.g. sold sex in the last 6 months versus last 12 months; Supplementary Text S1). Transgender men (TGM) were not analysed due to insufficient population size, HIV prevalence, or ART coverage data.

Data processing

To facilitate comparison of population sizes across settings, KPSE reported as counts were converted to population proportions for subnational locations in which key population surveys were conducted. Each KPSE was matched to the total population denominator by age, gender, year, and area. String matching was used to assign each

survey area to geographic boundaries from the Global Rural/Urban Mapping Project (GRUMP) or UNAIDS Naomi subnational district populations.^{26–28}

Age information was missing from nearly all key population reports; missing data was assigned age 15-49 years. Unless gender was specified, sex workers were assumed to be women, PWID assumed to be men. Surveys among transgender people which did not report gender were assumed to be among transgender women because respondents often reported high prevalence of male partners and receptive anal sex, and surveys among TGM in SSA remain rare.¹⁷

KPSE methods were classified into five categories: two-source capture-recapture (2S-CRC), three-source capture-recapture (3S-CRC); [PLACE] and programmatic/hotspot mapping;²⁹ network scale-up (NSUM); and successive sampling population size estimates (SS-PSE). Two additional categories were defined for “Multiple methods – empirical” or “Multiple methods – mixture”. KPSEs derived by solely non-empirical methods were excluded from analyses. Further details are in Supplementary Text S2.

Key population HIV prevalence and ART coverage observations were compared to total population HIV prevalence or ART coverage, respectively, matched by age, gender, year, and first administrative level (henceforth ‘province’). Province-level age/gender-specific HIV prevalence and ART coverage were extracted from UNAIDS Naomi subnational estimates for 2022^{26,27} and projected backwards 2000-2021 parallel to national HIV prevalence and ART coverage trajectories among adults 15-49 years.³⁰

Key population ART coverage observations among only persons who self-reported being aware of HIV positive status or used clinic-based recruitment were excluded. ART usage was determined through either self-report or laboratory methods via antiretroviral metabolite biomarker or viral load testing. Viral load suppression (VLS) observations were converted to estimates of ART coverage assuming 90% VLS among those on ART.

Analysis

We used Bayesian mixed-effects linear regression to model logit-transformed KPSE proportions among the urban total population aged 15-49 at the first administrative (e.g., province) level. Separate regressions were estimated for each key population. The model included effects for study method, spatially correlated national random province-level effects between neighbouring countries and provinces, and a study-level random effect allowing correlation among KPSE proportions at multiple subnational locations from the same study. The study method fixed effect was collapsed to two levels: (1) a pooled reference category of methods that estimated total key population size (2S-CRC, 3S-CRC, SS-PSE, and NSUM); and (2) PLACE/mapped estimates which counted venue- or hotspot-attending population size. Nested method random effects permitted method-specific deviation from the fixed effect. National KPSE counts were extrapolated using urban KPSE proportions, the proportion of the population living in urban areas,³¹ and the rural-to-urban ratio of key population size in urban and rural areas. Qualitative data indicate that KPSE proportions are higher in urban areas than rural areas, but no empirical data were available to quantify the rural-to-urban ratio.^{32–34} To allow wide

uncertainty in the rural-to-urban ratio, we assumed a $Beta(5,3)$ distribution which had mean ratio of 0.6 and 80% of the mass between 0.4 and 0.8.

For HIV prevalence, we modelled the relationship between logit-transformed key population HIV prevalence and logit total population HIV prevalence (age 15-49 years). FSW and PWID were modelled separately. Due to limited data, MSM and TGW were modelled together.¹⁷ Survey HIV prevalence observations were modelled with a beta-binomial distribution to allow overdispersion. Missing testing denominators for HIV prevalence observations were conservatively imputed using the 25th-percentile of observed denominators (imputed denominators: FSW n=127; MSM n=69; PWID n=74; TGW n=32). The model included fixed effects for logit population prevalence interacted with region (eastern and southern Africa [ESA] or western and central Africa [WCA]), a fixed effect for whether HIV status was self-reported or via HIV diagnostic tests, and province-, country-, and study-level random effects. The MSM-TGW model included a fixed effect for population type (TGW vs. MSM). Country- and province-level random effects were spatially correlated. Studies that omitted whether HIV prevalence was self-reported or diagnostically confirmed were assumed to be self-reported.

Primary analysis for key population ART coverage, was restricted to diagnostically confirmed ART usage (either via ARV biomarker or VL testing). Logit-transformed key population ART coverage was modelled as a function of logit total population ART coverage in the same year, age group, and province. All key populations were modelled together with random slopes for each key population to enable sharing of information about the overall relationship for groups with very limited data. The observed number on

ART was modelled with a beta-binomial distribution with fixed effect terms for logit population ART coverage, spatially correlated country- and province-level random effects, and study-level random effects. Missing testing denominators were imputed using the 25th-centile of known denominators (imputed denominators: FSW n=40; MSM n=16; PWID n=13; TGW=12).

We conducted sensitivity analyses which included self-reported ART coverage data with a fixed effect for self-reported versus diagnostically confirmed ART coverage. For all three models (KPSE, prevalence, ART coverage), in sensitivity analysis we used ages 15-29 years as the matched total population denominator for MSM and TGW regression analyses, reflecting the young median age of MSM and TGW survey respondents.^{35,36}

We combined national KPSE, HIV prevalence, and ART coverage estimates to calculate the number of KPLHIV and on ART. 95% uncertainty ranges were generated by combining 1000 posterior samples for each outcome. KPLHIV estimates were compared with 2022 national UNAIDS estimates³⁷ for age 15-49 years to calculate the proportion of PLHIV who were members of each key population.

Data were extracted, deduplicated, and validated in Microsoft Excel. Statistical analyses were conducted in R version 4.2.0 using the R-INLA package (v23.4.24). Further statistical methods details are in Supplementary Text S3. The GATHER reporting checklist³⁸ is in Supplementary Table S14.

Ethics statement

This study received ethical approval from the Imperial College Research Integrity and Governance Team (ICREC #6412027). Regulatory bodies providing ethical approvals or other ethics considerations for included studies are reported in Supplementary File S3.

Role of the funding source

Authors KS, SA-G, MB, and MM are employees of UNAIDS and contributed to the conceptualisation of the study, interpretation of results, and editing the manuscript. OS, RA, and JWI-E had access to all data included in the study. OS and JWI-E accept responsibility to submit for publication.

Results

Key population survey data availability

4215 KPSE conducted between 2010 to 2022 were compiled (Table 1). Following data cleaning, source document review, and area matching, 2062 observations were extracted from 114 studies (Figure 1). Data were most available for FSW (n=959, data from 33/39 countries), followed by MSM (n=664, 30/39 countries), PWID (n=380, 19/39 countries), and TGW (n=110, 11/39 countries). No size estimates were available for transgender men.

KPSE studies have become more common since 2010 (Figure 2). Between 2019-2021, 22 FSW, 17 MSM, 10 PWID, and 8 TGW PSE studies were conducted, increasing from 11, 11, 3, and 0, respectively, in 2010-12 (Figure 2). Seventy-two percent (470/654) of urban MSM population proportion observations were below 1% of the male adult (15-

49y) population (the UNAIDS/WHO guidance for minimum MSM PSE proportions; 78% [280/360] in ESA and 65% [190/294] in WCA; Supplementary Figure S1).

We identified 2416 key population HIV prevalence estimates (Table 1; Supplementary File 2), from which 1243 were extracted from 198 studies after processing.

Denominators were reported for 87% (1082/1243) of observations. Most data were available for FSW (n=665, 36/39 countries), followed by MSM (n=362, 32/39 countries), PWID (n=145, 19/39 countries), TGW (n=74, 20/39 countries), and TGM (n=5, 5/39 countries). 92% (1137/1243) of HIV prevalence observations were diagnostically confirmed.

For ART coverage, 561 observations were identified (Table 1). After processing, 201 observations were extracted from 56 studies. Denominators were available for 99% (199/201). Data were most available for FSW (n=121, 26/39 countries), followed by MSM (n=71, 23/39), TGW (n=16, 9/39 countries) and PWID (n=11, 7/39 countries). No data were available for TGM. The percentage that were diagnostically-confirmed varied by methodology (57% VLS [125/201]; 8% ART metabolite testing [17/201]; 35% self-reported ART usage [77/201]).

Extrapolated urban key population size estimates

Across national urban populations, a median of 1.71% women aged 15-49 years were FSW (interquartile range [IQR] 1.21-1.97%), 0.92% of men had sex with men (IQR 0.73-1.01%), 0.32% of men injected drugs (IQR 0.28-0.39%) and 0.14% of women were transgender (IQR 0.12-0.17%; Figure 3). Incorporating the rural-to-urban ratio, median proportions of national total populations were 1.34% FSW, 0.71% MSM, 0.27% PWID,

and 0.12% TGW. In sensitivity analysis, using age 15-29 years as a denominator for MSM PSEs, the urban proportion was 1.45% (IQR 1.10-1.58%; Supplementary Figure S2).

Urban KPSE proportions were higher in ESA than WCA among FSW (ESA: 1.77%, IQR 1.51-2.08%; WCA 1.45%, IQR 1.07-1.83%) and MSM (ESA: 0.99%, IQR 0.93-1.23%; WCA: 0.73%, IQR 0.69-0.94%). Proportions were similar between regions among PWID and TGW, but KPSE data were sparse overall. PSE proportions derived from PLACE and mapping studies were significantly lower than those derived from other methods among FSW (log odds ratio -0.54; 95%CI: -0.93, -0.16), MSM (-1.38; 95%CI: -1.82, -0.95), and PWID (-1.13; 95%CI: -1.69, -0.55), and lower among TGW (-1.17; 95%CI: -2.43, 0.14) (Supplementary Table S4; Supplementary Figure S3). Supplementary Tables S9-S12 report country-specific KPSE proportions.

HIV prevalence among key populations

Most key population HIV prevalence observations were higher than area-matched total population HIV prevalence (FSW 91% [of observations 607/665]; MSM 85% [305/362]; PWID 85% [123/145]; TGW 85% [63/74]). Logit key population HIV prevalence in ESA was more strongly correlated with matched logit total population HIV prevalence than in WCA (ESA: FSW R=0.43, MSM R=0.51, PWID R=0.39, TGW R=0.42; WCA: FSW R=0.30, MSM R=0.29, PWID R=0.18, TGW R=0.14).

Relative HIV prevalence differentials between key population and total population were larger when population prevalence was lower (Figure 4). For example, in ESA, 1% total population prevalence corresponded to 14% prevalence among FSW (95% prediction

range 10-20%), 5% among MSM (3-8%), 16% among PWID (9-27%), and 7% among TGW (3-16%). Fifteen percent population HIV prevalence corresponded to 49% HIV prevalence among FSW (39-59%), 20% among MSM (13-31%), 28% among PWID (15-45%), and 23% among TGW (15-33%). In WCA, relative patterns were similar, but key population HIV prevalence varied less with total population HIV prevalence than in ESA. Supplementary Table S5-S7 report regression results and Supplementary Table S11 reports country-specific estimates.

ART coverage among key populations

ART coverage among FSW, MSM, PWID, and TGW was correlated with gender-matched population ART coverage (logit-scale $R=0.46$, 0.35 , 0.56 , and 0.42 respectively; Figure 5). At 40% population ART coverage, predicted ART coverage among FSW was 5% lower (95% prediction range 13% lower to 4% higher), among MSM was 1% higher (8% lower to 10% higher), among PWID was 4% lower (17% lower to 12% higher), and among TGW was 6% lower (19% lower to 8% higher). At 80% population coverage, predicted ART coverage among FSW was 11% lower (20–1% lower), among MSM 11% lower (20–1% lower), among PWID 13% lower (41% lower to 9% higher), and among TGW 30% lower (44–16% lower). Supplementary Table S8 reports regression results and S11 reports country-specific estimates.

In sensitivity analysis including a fixed effect for ART measurement method, self-reported ART was lower than lab-confirmed ART (odds ratio 0.77 , 95% CI 0.52 - 1.12 ; Supplementary Figure S4 and Table S8). Assuming MSM surveys represented MSM

aged 15-29 years had minimal impact on HIV prevalence or ART coverage estimates among MSM (Supplementary Table S13).

Disproportionate HIV burden among key populations in SSA

Across SSA, FSW, MSM, PWID, and TGW combined were 1.3% (95%CI: 0.9-1.7%) of the population aged 15-49 years (3.4m FSW, 2.0m MSM, 870,000 PWID, and 380,000 TGW), but 6.3% (4.6-8.6%) of PLHIV aged 15-49 years. In ESA this was 5.0% (3.6-7.0%) of PLHIV compared to 1.3% (0.9-1.9%) of the population and, in WCA, 12.0% (8.4-17.4%) of PLHIV compared to 1.2% (0.9-1.7%) of the population. FSW were 3.8% (2.5-5.4%) of PLHIV in SSA (710,000 PLHIV; 470,000-1,000,000), MSM were 1.5% (1.0-2.4%) or 290,000 PLHIV (190,000-450,000), PWID were 0.5% (0.3-1.0%) or 99,000 PLHIV (55,000-190,000), and TGW were 0.4% (0.2-1.0%) or 79,000 PLHIV (34,000-200,000) (Figure 6).

Discussion

Data from 247 key population surveys provided consistent evidence of key populations at disproportionately high risk of HIV acquisition and transmission in all countries in sub-Saharan Africa. We estimated there are 3.4m FSW, 2.0m MSM, 870,000 PWID, and 380,000 TGW in SSA who require comprehensive HIV prevention or treatment services. HIV prevalence among FSW was estimated to be 21%, 14% among MSM, 11% among PWID, and 20% among TGW. These were 4.6, 5.9, 4.6, and 4.4 times higher than population prevalence, respectively, with larger relative differences when population prevalence was lower. Together, these populations constituted 1.3% of the adult population in SSA but 6.3% of PLHIV. ART coverage among key populations increased

consistently with total population coverage, but lagged behind at high levels. However, there was wide uncertainty about estimates aggregated within countries and across SSA.

This exercise highlighted major data gaps and challenges interpreting existing data. Across the twelve combinations of four key populations and three indicators analysed here, countries had data for six combinations on average and three countries lacked any data (Supplementary Table S3). Data availability gaps widen further when selecting the highest quality and most recent data. These gaps impede delivery of equitable and equal access to HIV services and will remain without firm commitments to regularly collect key population survey data, likely including significant change to entrenched discriminatory practices and punitive laws and policies against key populations.^{3,39–41} In settings lacking or with limited data, our extrapolated estimates should be a foundation with which to guide future surveillance priorities, stimulate in-country data review and use, and estimate HIV epidemic indicators. Future efforts should especially focus on strengthening surveillance for MSM, PWID, and transgender populations, and strengthening use of HIV service delivery data for all key populations, while ensuring the safety and protection of marginalised individuals and their communities.³

Previous key population reviews and meta-analyses^{11,42–44} relied on systematic searches of peer-reviewed literature. Our initial sources were existing databases, primarily populated by surveillance teams in each country or implementing organisations. This resulted in including a larger grey literature body, such as survey reports, which are infrequently indexed by peer-reviewed databases.⁴⁵ However, many

observations from initial databases (3% of PSE data, 31% of HIV prevalence data, 36% of ART coverage data) could not be validated from source documents and were excluded from this analysis, which in some countries excluded the only reported data. Demand for total population HIV estimates in SSA has promoted high-quality comparable surveillance methods, documentation, and dissemination. Review of key population data by national HIV surveillance teams was introduced into the UNAIDS sub-Saharan African estimates process in 2023, providing context for existing surveys, identifying missing sources and adding new data. This, alongside ongoing key population data initiatives and concerted advocacy efforts that ensure public dissemination, will improve the foundation for HIV surveillance among key populations and promote parity for key populations within national HIV data and strategic information.

Systematically collated data on key population size, HIV prevalence, and ART coverage are critical inputs for mathematical modelling analyses that guide optimisation of HIV interventions. Such studies consistently demonstrate that fully meeting the HIV prevention and treatment needs of key populations has a disproportionately large impact on reducing overall population incidence due to network effects of averting further onward transmission over time and to non-key population partners.^{46,47} Model-based counterfactual indicators that capture these impacts, such as the transmission preventable attributable fraction, are a better basis for intervention prioritisation than simple population proportions reported in survey data.^{46,48,49 46,4748,4950–5354–57}

We estimated that 0.27% of men in SSA injected drugs, lower than estimates from Degenhardt *et al.* of 0.38%.⁵⁸ This may reflect incorporating the urban-to-rural ratio in national PSE extrapolation in this analysis. We estimated that 1.4% of women aged 15-49 years sold sex, slightly higher than 1.1% estimated by Laga *et al.*⁵⁹ Our finding of heterogeneous HIV prevalence ratios between MSM and the total population was consistent with Hessou *et al.*⁶⁰, particularly in WCA where HIV burden in neighbouring countries can vary considerably. Our estimate of 62% ART coverage among MSM in 2022 was lower than 73% from a meta-analysis by Stannah *et al.*⁶¹ of studies conducted up to 2022. This may be due to exclusion of self-reported ART usage in this analysis.

Population size estimates measured in the same population at different times or with multiple methods were highly heterogeneous, limiting data use for establishing meaningful programmatic targets or monitoring temporal trends. Very large uncertainty ranges around population size and PLHIV modelled estimates were consistent with findings of other statistically summarised and extrapolated PSE from multiple sources.⁵⁰⁻⁵³ Non-existence of rural KPSE studies to empirically inform rural-urban population proportions contributed to five-fold or greater relative uncertainty in extrapolated national estimates. Quality assessments of individual KPSE studies were not conducted as part of this analysis. Both systematically improving and evaluating study-specific implementation quality and methodological assumptions may reduce heterogeneity and increase the utility of KPSE data.^{54-57,62}

Seventy-two percent of MSM KPSE observations and 34/39 modelled urban MSM estimates were below 1% of the male adult (15-49) population which UNAIDS and WHO

recommended in 2020 as a minimum MSM population proportion.⁶³ The minimum threshold was specified to ensure that MSM were not overlooked due to lack of data. Variation in MSM proportions measured in PSE studies may reflect ability to engage in sexual behaviours, affected by legal and social environment and other factors, rather than differences in distribution of sexual preference. It is also uncertain whether MSM recruited in surveys, who are disproportionately young^{12,13}, are representative of the total MSM population (Supplementary Figure S2). Nonetheless, specifying a minimum 1% threshold for MSM population could result in unrealistic MSM-focused service targets. The threshold should be reconsidered with the wider range of data now available, aligned with risk-based approaches to quantifying sex work and injecting drug use. Study-specific quality assessments will be key to producing accurate KPSE given stigma experienced by MSM in many settings.

Integrating key population programme data within key population estimates should be a priority to improve utility of surveillance data to guide programmatic response and monitor trends and subnational variation.⁶⁴ Triangulating routine HIV testing and treatment data with biobehavioural survey data may help disentangle programmatic double counting, coverage of key population-specific services, and accounting for linkage to care in the estimation of ART coverage and viral load suppression.^{65–67} Future surveillance should consider moving beyond strictly defined key population definitions accurately to reflect heterogenous risks among individuals in overlapping risk environments including cisgender MSM and transgender women who sell sex, and FSW and MSM who inject drugs.^{68–70}

Several limitations should be considered when interpreting these data and estimates.

Firstly, surveys used a range of key population definitions and inclusion criteria which limited comparability, though there was sufficient overlap (Supplementary Text S2).

Second, lack of explicit geographic survey sampling frames made it challenging to define appropriate subnational population denominators for KPSE proportions; the urban extents derived from the Global Rural/Urban Mapping Project may not accurately reflect the catchment population for a given survey, particularly given the mobility of key populations.⁷¹ This likely exacerbates the observed heterogeneity in KPSE proportions

(Figure 3B), and is a major limitation for extrapolating KPSE proportions for programmatic planning. Going forward, careful data quality assessments to determine study inclusion and interpretation, and specification of population catchments with key population surveillance reports will improve future data use. Third, sample size or standard errors and age ranges were omitted from most population size data entries.

This limited ability to statistically weight or age-standardise data in model extrapolations.

Finally, data were insufficient and too heterogeneous to estimate time trends in population proportions, HIV prevalence, or ART coverage. Application of standardised recruitment methods, population definitions, and indicator reporting in consistent locations will improve monitoring of trends.

In conclusion, key populations across SSA experience disproportionate HIV burden and have lower antiretroviral treatment coverage. Consolidated key population data and synthesised estimates provide a basis for key population programming in all countries, including those with limited locally available data. Despite increasing focus on key populations in HIV/AIDS strategies in SSA, new surveillance strategies, improved use of

509 routine data, and more consistent surveillance implementation are required to furnish
510 more precise estimates and trends for programme planning and support the monitoring
511 of equitable and equal access to HIV prevention and treatment programmes outlined in
512 the Global AIDS Strategy 2021-2026.

Authors' contributions

OS, KS, MM and JWI-E conceptualised the study. KS, SAG, JZ, AMcl, KW, LD curated key population survey databases. OS, RA, EG, AS-B reviewed primary source documents, deduplicated data, and extracted data. OS analysed the data and wrote the first draft of the manuscript. All authors contributed to interpretation of results and edited the manuscript for intellectual content. All authors read and approved the final version of the manuscript for submission.

Figures and Tables

Population size estimates

HIV prevalence

ART coverage

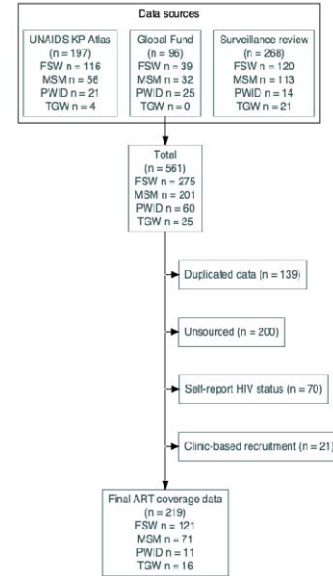

Figure 1: Flow diagrammes describing identified data for key population size estimates, HIV prevalence data, and key population ART coverage. Each *n* represents number of population/method/location observations, with potentially observations for multiple subnational locations from the same study in same country. ART: Antiretroviral coverage; FSW: Female sex worker; MSM: Men who have sex with men; PWID: People who inject drugs; TGW: Transgender women; KP: Key Population; GAM: Global AIDS Monitoring; CDC: US Centers for Disease Control and Prevention; PSE: Population size estimate.

Table 1: Availability of population size, HIV prevalence, and ART coverage data by key population and region during period 2010-2022.

Region	Key population	Key Population Size Estimates (KPSE)		HIV prevalence		ART coverage	
		Observations	Countries with data (n; %)	Observations	Countries with data (n; %)	Observations	Countries with data (n; %)
SSA (39 countries)	FSW	959	33 (85)	665	36 (92)	121	26 (67)
	MSM	664	30 (77)	362	32 (82)	71	23 (59)
	PWID	380	19 (49)	145	19 (49)	11	7 (18)
	TGW	110	11 (28)	74	20 (51)	16	9 (23)
	TGM	0	0 (0)	5	4 (10)	0	0 (0)
ESA (18 countries)	FSW	552	17 (94)	336	18 (100)	77	14 (78)
	MSM	365	14 (78)	140	15 (83)	38	12 (67)
	PWID	238	7 (39)	62	9 (50)	6	4 (22)
	TGW	68	6 (33)	32	11 (61)	13	7 (39)
	TGM	0	0 (0)	2	2 (5)	0	0 (0)
WCA (21 countries)	FSW	407	16 (76)	329	18 (86)	44	12 (57)
	MSM	299	16 (76)	222	17 (81)	33	11 (52)
	PWID	142	12 (57)	83	10 (48)	5	3 (14)
	TGW	42	5 (24)	42	9 (43)	3	2 (10)
	TGM	0	0 (0)	3	3 (8)	0	0 (0)

SSA: Sub-Saharan Africa; ESA: East and Southern Africa; WCA: Western and Central Africa; FSW: female sex workers; MSM: men who have sex with men; PWID: people who inject drugs; TGW: transgender women; TGM: transgender men; KPSE: key population size estimate; ART: antiretroviral therapy

Figure 2: Distribution of size estimation methods implemented over time by key population. The number of size estimation studies is shown above the bars. Bars are colour coded by method empiricism from highest (3S-CRC) to lowest (non-empirical).

3S-CRC: Three-source capture-recapture; 2S-CRC: Two-source capture-recapture; SS-PSE: Successive sampling population size estimate; NSUM: network scale-up method; PLACE: Priorities for Local AIDS Control Efforts

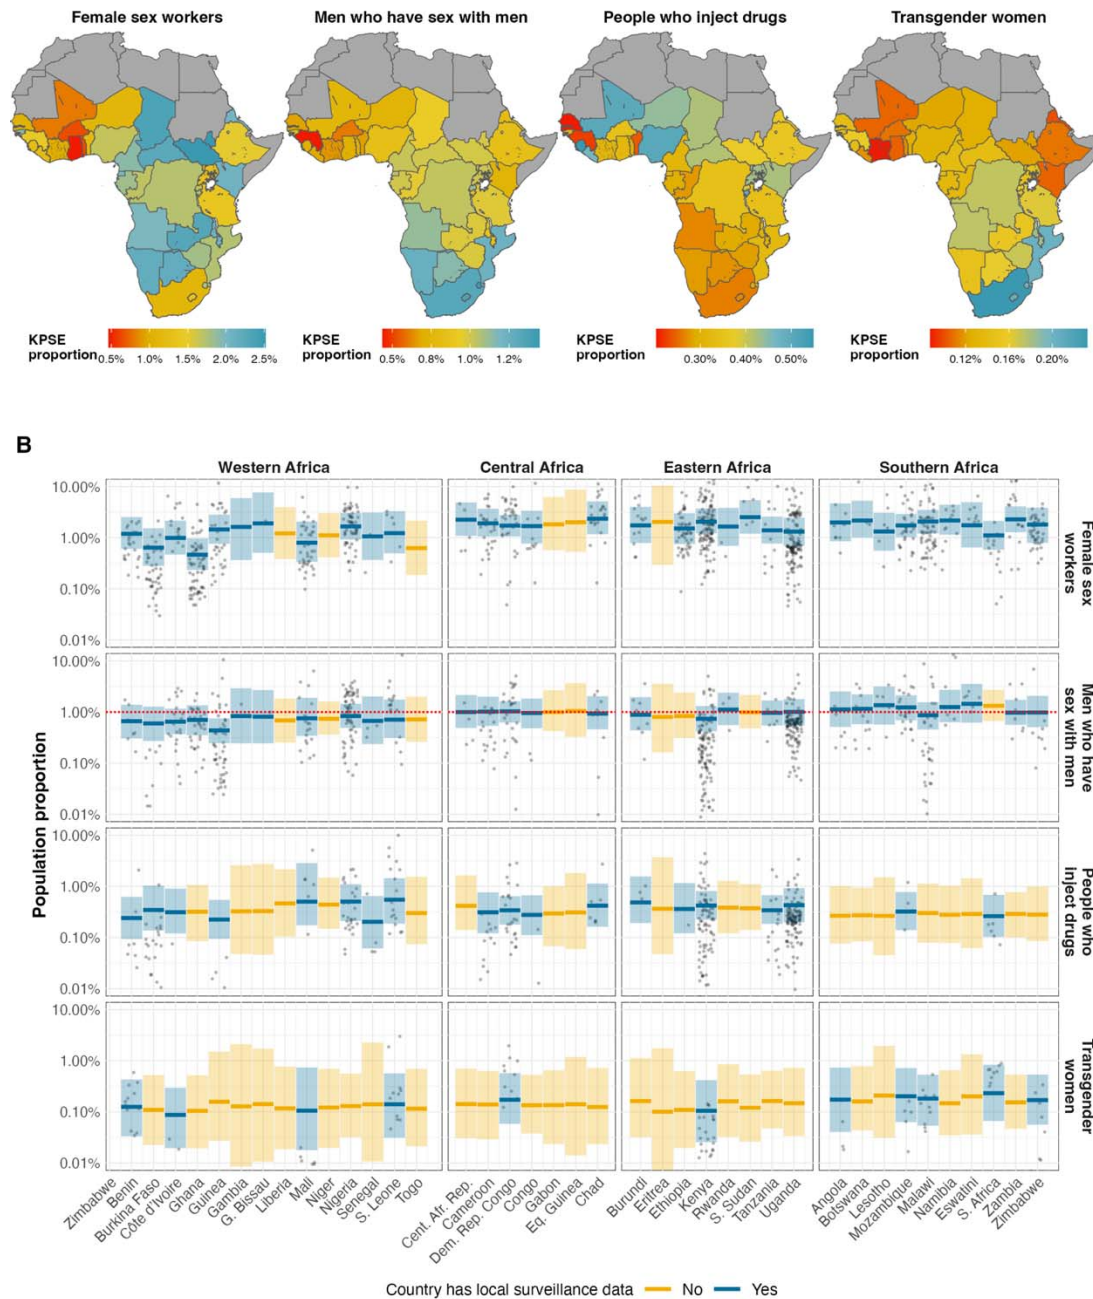

Figure 3: Model estimated urban key population size estimate (KPSE) proportions for female sex workers, men who have sex with men, people who inject drugs, and transgender women as a proportion of gender-matched 15-49 years adult total population. (A) Posterior median estimate for each country. Note: colour range is different for each key population choropleth. (B) Posterior median estimate and 95% credible intervals for each country. Points represent observations of subnational KPSE proportions that used empirical methods. Countries that had local surveillance data are shown in blue, and countries informed only by spatial smoothing from neighbouring countries in yellow. Vertical axis shown on log-scale.

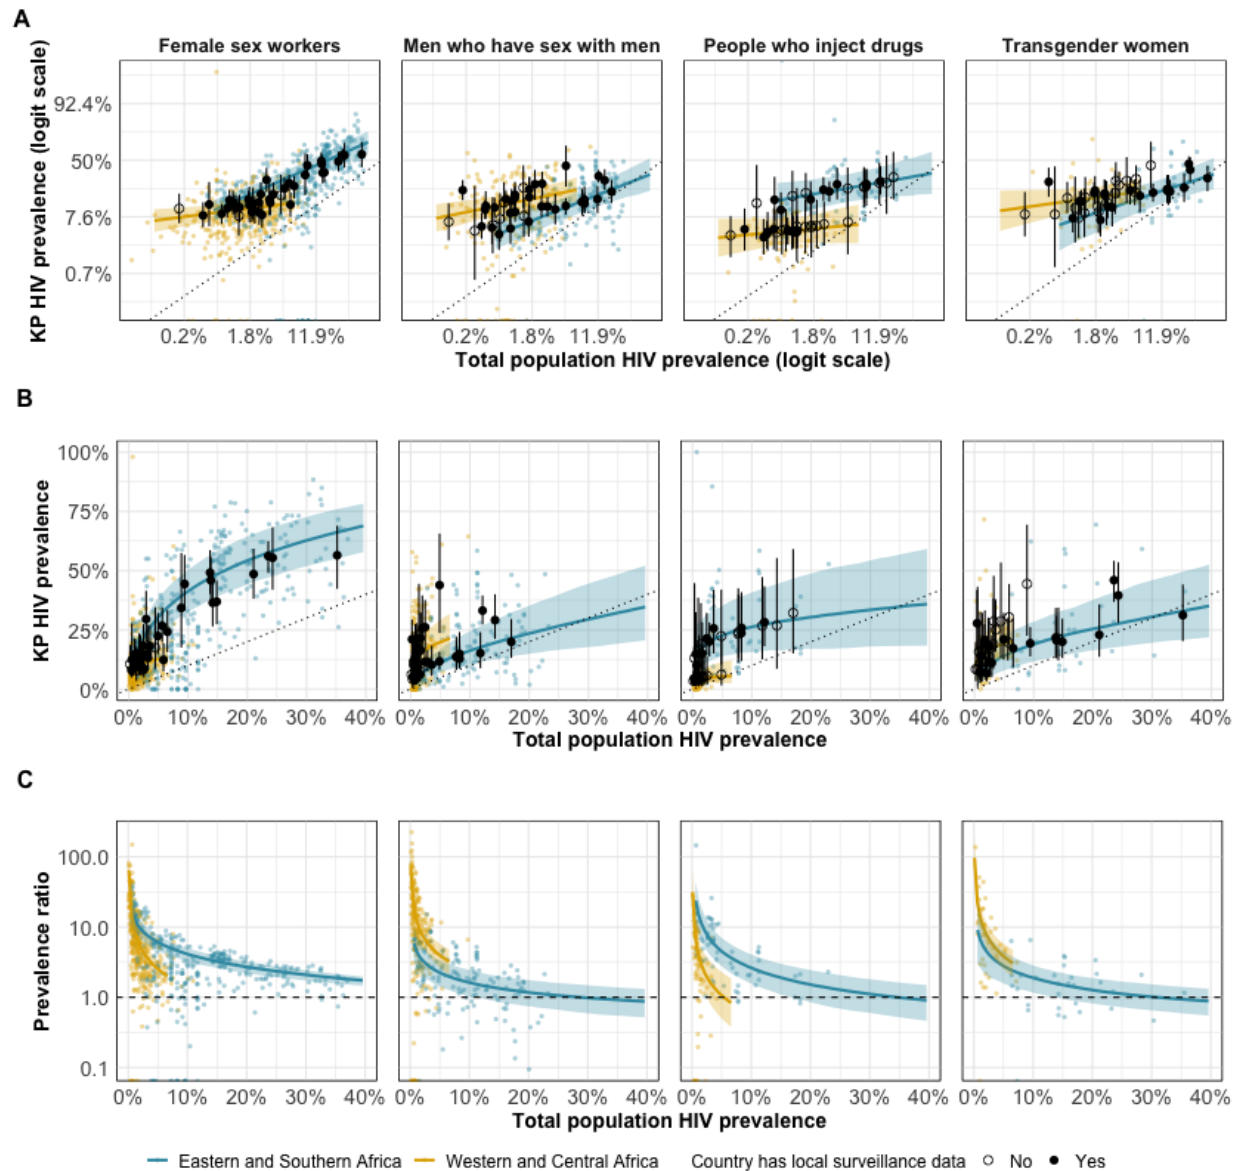

Figure 4: Key population and total population HIV prevalence on the logit scale (A), natural scale (B), and expressed as a ratio of key population and total population prevalence (C) for female sex workers, men who have sex with men, people who inject drugs, and transgender women. Coloured points indicate observed key population prevalence plotted against gender/year/province-matched total population prevalence. Coloured lines and shading represent regional estimate and 95% uncertainty results. Points represent country estimates [filled for countries with HIV prevalence data and empty for countries without HIV prevalence data] and 95% uncertainty ranges. Dotted line represents line of equality.

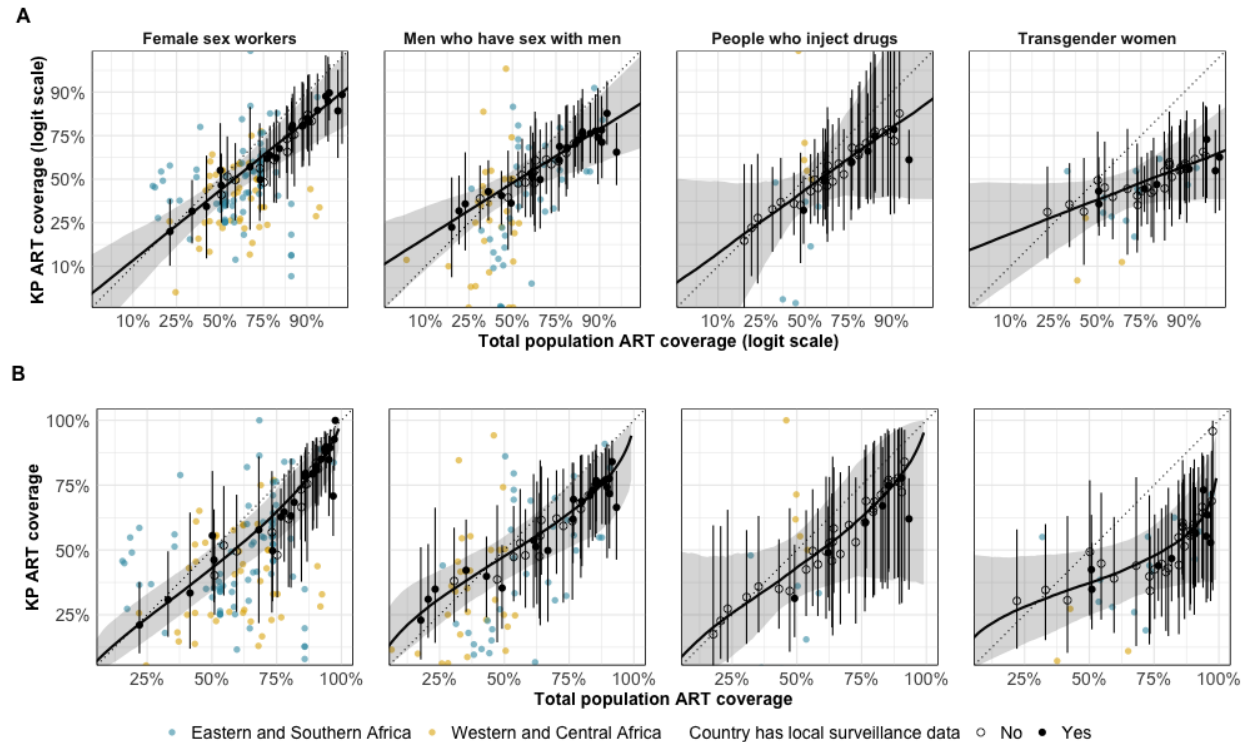

Figure 5: Estimated key population ART coverage as a function of total population ART coverage on the estimated logit scale (upper) and natural scale (lower). Coloured points indicate observed key population prevalence plotted against gender/year/province-matched total population ART coverage. Black line and shading represent estimate for sub-Saharan Africa and 95% uncertainty results. Black points represent country estimates and 95% uncertainty ranges. Dotted line represents line of equality.

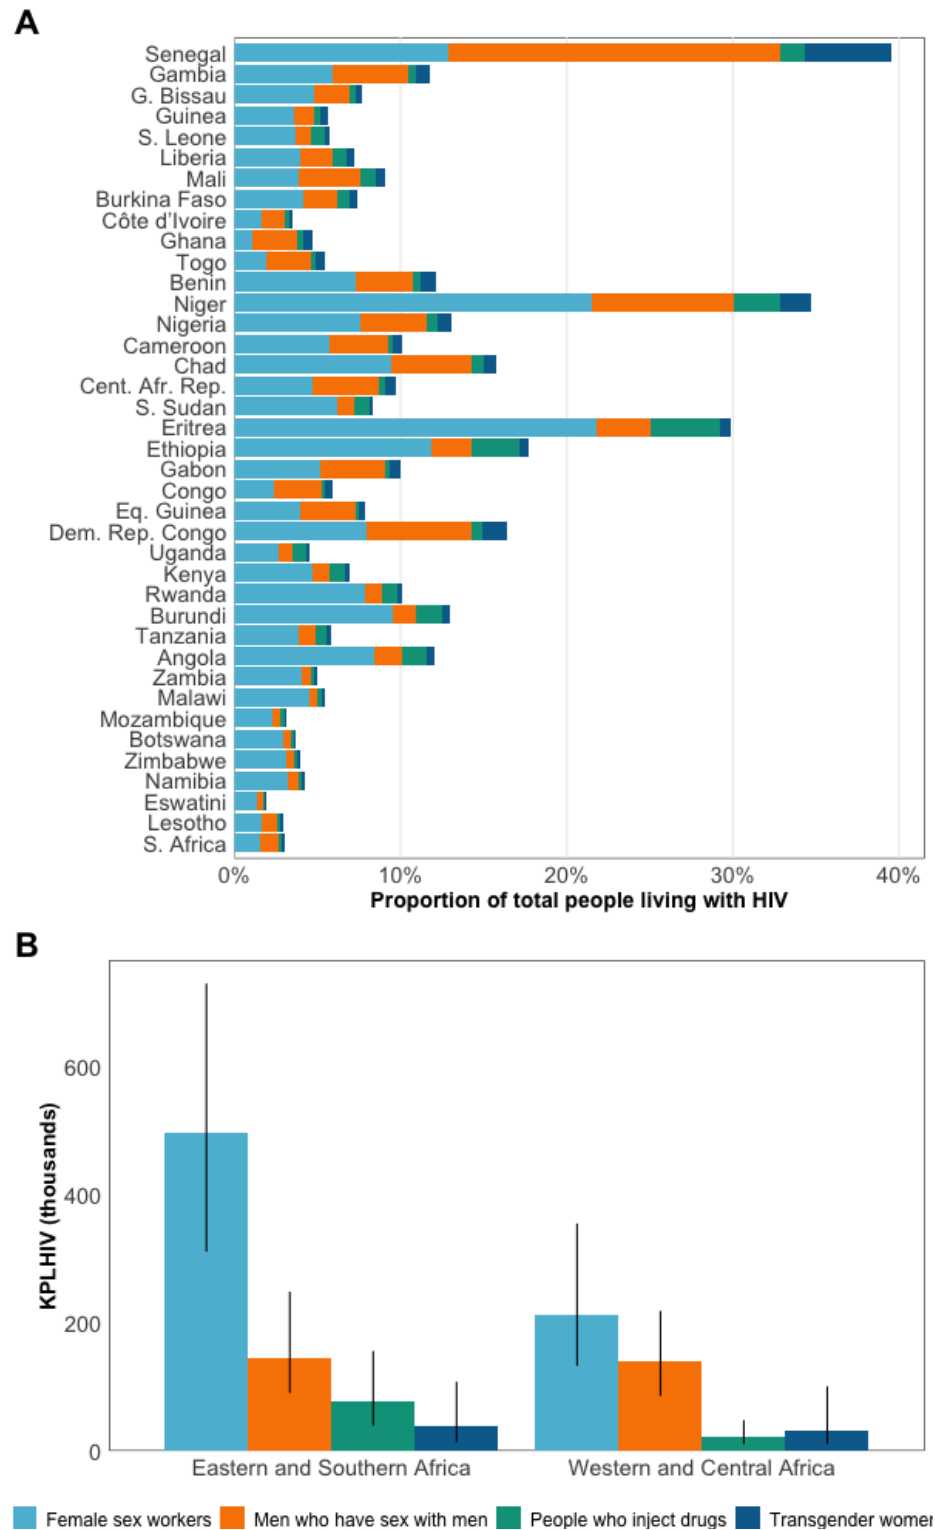

Figure 6: (A) HIV positive key population members as a proportion of all PLHIV aged 15-49 years. Countries are ordered geographically. (B) Estimated number of key populations living with HIV (KPLIV) in Eastern and Southern Africa and Western and Central Africa.
