This work is submitted for peer-review to Brain Pathology.

1 Magnetic resonance imaging (MRI) of focal or diffuse myelin damage or remyelination may provide important insights into disease pro-2 3 gression and potential treatment efficacy in multiple sclerosis (MS). We performed post-mortem MRI and histopathological myelin mea-4 surements in seven progressive MS cases to evaluate the ability of 5 three myelin-sensitive MRI scans to distinguish different stages of 6 MS pathology, particularly chronic demyelinated and remyelinated lesions. 8 At 3 Tesla, we acquired two different myelin water imaging (MWI) scans and magnetization transfer ratio (MTR) data. Histopathology 10 included histochemical stainings for myelin phospholipids (LFB) and 11 iron as well as immunohistochemistry for myelin proteolipid protein 12 (PLP), CD68 (phagocytosing microglia/macrophages) and BCAS1 (re-13 14 myelinating oligodendrocytes). Mixed-effects modelling determined which histopathological metric best predicted MWF and MTR in nor-15

mal appearing and diffusely abnormal white matter, slowly expand ing, inactive, remyelinated and ischemic lesions.

Both MWI measures correlated well with each other and histology 18 across regions, reflecting the different stages of MS pathology, MTR 19 data showed a considerable influence of components other than 20 myelin and a strong dependency on tissue storage duration. Both 21 MRI and histology revealed increased myelin densities in inactive 22 compared with slowly expanding lesions. Chronic inactive lesions 23 harboured single scattered myelin fibres indicative of low-level re-24 myelination. Mixed-effects modelling showed that smaller differ-25 ences between white matter areas were linked to PLP densities and 26 only to a smaller extent confounded by iron. 27

MWI reflects differences in myelin lipids and proteins across all lev els of myelin densities encountered in MS, including low-level re-

 els of myelin densities encountered in MS, including la myelination in chronic inactive lesions.

Keywords: remyelination | histopathology | myelin protein | MRI | iron

M ultiple sclerosis (MS) is a chronic inflammatory dis-ease of the central nervous system (CNS), leading to 2 the formation of focal areas of destruction, phagocytosis and 3 digestion of CNS myelin sheaths. Remyelination may follow de-4 5 myelination (1), but the proportion of remyelinated MS lesions varies greatly between individuals at autopsy (2). Fostering 6 remyelination reduces axonal loss and may thus curtail MS 7 progression (3), rendering it an important target of new ther-8 apeutic trials. Non-invasive myelin quantification by means of q magnetic resonance imaging (MRI) will be a key component of 10 such trials (4). Among the many MRI techniques for assessing 11 myelin in vivo, multi-echo spin-echo T_2 MWI (5–9) is consid-12 ered one of the most myelin-specific (10-13) as it separately 13

quantifies the MRI signal from water protons in the myelin phospholipid bilayers. The mobility of these protons is highly restricted, resulting in a faster T_2 decay than water protons within axons, cell bodies and the extracellular space. The ratio of the short T_2 signal component over the total water signal, termed myelin water fraction (MWF), is considered a surrogate measure of myelin content (5, 14).

Here, we compared three MRI-based myelin scans for the quantitation of myelin in seven progressive MS cases. MS lesions in various stages of de- and remyelination, normal appearing and diffusely abnormal white matter were included and characterized with histopathology and MRI-based myelin measures: 3D multi-echo T_2 gradient- and spin-echo (GraSE) MWI (15), 3D multi-echo spin-echo MWI (16, 17) and 3D MTR (18). Histopathology included Luxol Fast Blue (LFB) staining for phospholipids and diaminobenzidine-enhanced Turnbull blue (TBB) staining for iron. In addition, immuno-histochemical stainings for proteolipid protein (PLP), one of the major myelin proteins, CD68 for phagocytosing microglia/macrophages and BCAS1 staining for remyelinating oligodendrocytes were obtained (19).

Materials and Methods

Post-mortem samples. Seven *post-mortem* brains of progres-36 sive MS patients (six with secondary-progressive MS, one with 37 primary-progressive MS) were included. Whole brains had 38 been fixed in 4% neutral-buffered formalin for three to four 39 weeks at room temperature. Four cases from the archive at 40 the Neuroimmunology department of the Center for Brain 41 Research, Medical University of Vienna (MUV), Austria, had 42 been fixed in formalin and stored for 9 to 14 years in 1%43 formalin diluted in phosphate-buffered saline (PBS) at 4° C. 44 Three cases derived from the Division of Neuropathology and 45 Neurochemistry, MUV, Austria, were fixed and stored in for-46 malin for up to 1 year. Basic epidemiological and clinical data 47 are provided in Table 1. 48

MRI data acquisition. For Cases 6 and 7, whole brains were available for MRI. Of all other cases, smaller tissue slabs were scanned. Their diameters ranged from 21.1 to 110.2 mm and their thickness from 4.2 to 23.8 mm. Scanning was performed on two identical 3T MRI systems (Philips Achieva, Best, The

Table 1. Demographic information of the *post-mortem* brain samples, including approximate time since fixation in years. To preserve anonymity, only age ranges are provided. Causes of death were unrelated to MS and included myocardial infarction, cardiovascular death and pancreatic cancer. Storage time refers to storage time in 1% paraformaldehyde / phosphate-buffered saline (SPMS: secondary progressive MS; PPMS: primary progressive MS; M: male; F: female)

	Age	Sex	Clinical	Disease	Storage
	w/1 [yrs]		course	aur. [yrs]	[yrs]
Case 1	31 - 35	Μ	SPMS	10.0	10.0
Case 2	41-45	Μ	SPMS	11.4	14.0
Case 3	46-50	\mathbf{F}	SPMS	37.0	9.0
Case 4	66-70	Μ	PPMS	7.3	12.0
Case 5	61 - 65	\mathbf{F}	SPMS	33	< 1
Case 6	51 - 55	Μ	SPMS	24	< 1
Case 7	56-60	\mathbf{F}	SPMS	34	< 1

Netherlands) in 2015-2016; four cases at the University of 54 British Columbia (UBC) and three cases at MUV. For all 55 samples, we acquired 32-echo 3D-GraSE T_2 data for MWI 56 $(TE/\Delta TE/TR = 10/10/719 \text{ ms}, \text{ reconstructed } 0.9 \times 0$ 57 1.5 mm^3 (15). 3D-MTR images were acquired for all cases, 58 except Case 6 (TE/TR = 3.7/84.6 ms, reconstructed $0.9 \times$ 59 $0.9 \times 2 \text{ mm}^3$, flip angle(exc/mtc) = $18^{\circ}/520^{\circ}$, $\Delta f = 1.1 \text{ kHz}$ 60 below Larmor frequency). Data acquisition at UBC (Cases 61 1-4) also included 3D multi-echo spin-echo imaging (CPMG 62 – Carr-Purcell Meiboom-Gill, $TE/\Delta TE/TR = 10/10/1200$ 63 ms, reconstructed $0.9 \times 0.9 \times 3 \text{ mm}^3$ (16, 17). T₂-weighted 64 images were acquired for registration purposes at TE/TR =65 $100 \text{ ms}/2500 \text{ ms}, 0.66 \times 0.66 \times 0.7 \text{ mm}^3$. Acquisition parameters 66 were minimally adapted to adjust for the different sample sizes. 67 Only for Case 5, the 3D-GraSE sequence was substantially 68 changed necessitated by the much larger field-of-view. The 69 study and tissue scanning protocol were approved by the 70 71 clinical research ethics boards of both sites (UBC: H15-011, MUV: EK Nr. 1491-2017). 72

MRI data processing. Data processing and analysis was imple-73 mented in MATLAB 2017b. MWF was computed as previously 74 described (5, 20). Briefly, T₂ distributions were obtained us-75 ing the extended phase graph algorithm (21) and regularized, 76 non-negative least squares fitting. T₂ distributions of all tissue 77 samples in multiple white matter (WM) regions were con-78 79 sulted. Subsequently, the MWF was determined as the T_2 signal fraction between 12 - 25 ms relative to all water (intra-80 /extracellular water T_2 range: 25 - 100 ms). MTR maps were 81 calculated as the ratio of the signal difference between the on-82 resonance and off-resonance scan relative to the off-resonance 83 scan (18). 84

Tissue Preparation. After scanning, whole-brain cases were 85 86 cut into 1 cm thick coronal double-hemispheric slices. All other tissue slabs were directly processed for histology. Sam-87 ples were dehydrated (Miles ScientificTM autotechnicon device) 88 and embedded in paraffin. Paraffin blocks were cut into 10 μ m 89 thick serial sections with a tetrander microtome (R. Jung AG. 90 Heidelberg). Sections were stained for hematoxylin and eosin 91 (H&E) to assess general pathology, Luxol fast blue – periodic-92 acid Schiff (LFB-PAS) to visualize myelin and classify MS 93 lesions, and diaminobenzidine (DAB)-enhanced TBB to detect 94

iron (22). Iron is stored in myelin-forming oligodendrocytes, 95 but also in myelin itself and is a known confounder to MWI and 96 MTR (23–25). Immunohistochemistry for mouse monoclonal 97 PLP (Serotec, MCA839G, dilution 1:1000) was performed 98 by heat-steaming sections in ethylenediaminetetraacetic acid 99 (EDTA, pH 9.0, 1h) for antigen retrieval. Unspecific anti-100 body binding was blocked by incubation in 10% fetal calf 101 serum (FCS) diluted in Dako wash buffer (DAKO, 20 min, 102 room temperature). After overnight-incubation at 4° C, a 103 biotinylated donkey anti-mouse secondary antibody was ap-104 plied. Sections were then incubated with avidin-conjugated 105 horseradish peroxidase (Sigma Aldrich, dilution 1:500 in 10%) 106 FCS/DAKO, 1h, room temperature) and developed with the 107 chromogen DAB, producing a brown PLP signal. For CD68 108 (Dako, M0814, Clone KP1, dilution 1:2000) and BCAS1 (Santa 109 Cruz, sc-136342, dilution 1:4000), sections were steamed in 110 TRIS buffer (pH 6.0, 1h). Primary antibodies were applied 111 overnight at 4° C. After application of an appropriate biotiny-112 lated secondary anti-mouse antibody, the Envision system was 113 used according to the manufacturer's protocol. Stainings were 114 visualized by DAB development for 2×5 minutes, producing a 115 brown reaction product. Stainings were scanned using an Agfa 116 Duoscan[®] device under standardized brightness conditions, at 117 800 pixels/inch, and saved as RGB TIFF. 118

Fig. 1. Overview of processing pipeline. Differently stained histology sections were aligned with 2D FSL FLIRT. To register all quantitative images, first a pipeline was established based on the 3D T_2 scans, which were reoriented and resliced to match the histology. Registration between histology and MRI was performed using NiftyReg. Quantitative maps were then registered to the 3D T_2 and the already established pipeline and registration matrices were applied.

MRI-histology registration. Figure 1 provides an overview of 119 the MRI-histology registration procedure. Histology images 120 were downsampled by a factor of two along both dimensions. 121 LFB-PAS and PLP sections were colour-deconvolved using 122 ImageJ version 1.43r (A.C. Ruifrok, NIH, Bethesda, MD, USA) 123 to extract the blue channel, i.e. the LFB dye, of the LFB-PAS 124 double-stained sections and the red channel, i.e. the DAB 125 dve, of the hematoxylin-counterstained PLP sections. Because 126 mounting of the sections on glass slides can introduce small 2D 127 distortions, TBB and PLP were registered to the LFB section 128 using 2D FSL FLIRT (26) (default parameters, five degrees of 129 freedom). Initial registrations utilized sections prior to colour 130

deconvolution. Registration matrices were then applied to the
 lower-contrast, colour-deconvolved sections.

Within-MRI and histology-MRI registrations were per-133 formed using NiftyReg's aladin and f3d (default parameters) 134 (27). T₂-weighted MRIs were reoriented and sliced to match 135 the histology section plane. To approximate the resolutions, 136 reformatted images were up-sampled and histology images 137 further down-sampled. Manual corrections, such as removal of 138 tissue from unrelated sections, were performed for all cases in-139 dividually. Lastly, registered images were up-sampled to match 140 the histology resolution. MRI data were sent to the histology 141 space to avoid altering the regions-of-interest (ROIs), which 142 were manually defined on the histology sections in FSLview. 143 For the quantitative analysis, all 3D MRIs were registered to 144 the T_2 -weighted images. Linear registrations were performed 145 using individual echoes of the quantitative data (default pa-146 rameters). Subsequently, quantitative maps were transformed 147 using NiftyReg's resample and were then subjected to the same 148 pipeline as the T_2 -weighted images, i.e. volume re-orientation, 149

¹⁵⁰ slice selection and mapping to histology.

Manual ROI definition. ROIs were identified by microscopical 151 inspection of H&E, LFB-PAS and PLP-stained slices using 152 an Olympus BX50[®] microscope by two readers (VE, SH). 153 Non-lesional normal appearing white matter (NAWM) was 154 identified by well-preserved myelin in both LFB-PAS and 155 PLP stainings. Diffusely abnormal white matter (DAWM) 156 had ill-defined areas of LFB-PAS but no PLP reduction (28). 157 Lesional WM included slowly expanding lesions (SEL), in-158 active lesions (InaL), shadow plaques (SdP) and ischemic 159 lesions (IsL). Slowly expanding lesions had few LFB- and PLP-160 positive myelin degradation products within phagocytes at 161 the lesion borders, while their centers were almost completely 162 devoid of myelin in the PLP and LFB stainings. Macrophages 163 in the slowly expanding lesion cores were LFB-negative and 164 frequently harbored PAS-positive material. Inactive lesions 165 occasionally showed PAS-positive macrophages, but no LFB-166 or PLP-positive myelin remnants within phagocytes anywhere. 167 Shadow plaques displayed sharp borders of LFB-myelin reduc-168 tion, resulting from thinner remyelinating sheaths, and evenly 169 distributed intact myelin throughout the plaque. We further 170 encountered circumscribed lesions of myelin reduction but not 171 depletion, similar to shadow plaques. However, these lesions 172 had ill-defined borders and increased LFB-intensity around 173 174 blood vessels traversing the lesions, i.e. a non-homogenous 175 LFB-intensity reduction within the lesion. Their coarse texture indicated pronounced widening of the extracellular spaces. 176 These were labeled ischemic lesions. ROIs were manually out-177 lined on the LFB-PAS images. Anatomical and pathological 178 boundaries were generously spared. To account for small differ-179 ences in slice matching and imperfect registration, the masks 180 were adapted to optimally match the TBB and PLP scans and 181 182 the registered T_2 -weighted MRI. CD68 stainings were qualitatively evaluated for the distinction between slowly expanding 183 (CD68 rim of microglia/macrophages present) and inactive (no 184 CD68 rim present) lesions. BCAS1 stainings were evaluated 185 with a counting grid in NAWM, DAWM and centers of slowly 186 expanding, inactive and remyelinated lesions. The evaluated 187 area covered 1 mm^2 , i.e. four neighboring visual fields at 20x188 magnification. Only clearly and strongly BCAS1-positive glial 189 cells were counted. 190

Data and statistical analysis. ROIs were automatically matched using their voxel location and the classification assigned to each ROI. We applied bwconncomp, a regiondetection algorithm in MATLAB, to correlate histological and MRI values in all ROIs. Gray-scale medians for each ROI were calculated in all MRI and histological images, representative of each ROI's myelin state.

Differences between slowly expanding and inactive lesions 198 were assessed by a two-sided rank sum test (5% significance 199 level). Correlations were performed on a per-case basis to 200 suppress the influence of varying post-mortem delays, forma-201 lin fixation and storage times. Weighted average within-case 202 slopes, intercepts and p-values were obtained, with weights 203 represented by the variance of the individual within-section 204 slopes, intercepts and correlation coefficients, respectively. Av-205 erage correlation coefficients were determined by transforming 206 the r-values using Fisher's z-transformation and subsequently 207 computing the hyperbolic tangent of the average of the trans-208 formed r-values. Finally, a linear mixed effects regression 209 model was used in R to determine the standardized correlation 210 coefficients as a measure of relative importance of LFB, PLP, 211 TBB and storage time in predicting MWF and MTR (lm.beta 212 package) (29). The data offset was modelled with two random 213 factors that accounted for inter- and intra-subject variability. 214 Collinearity between predictors was evaluated using the vif 215 function (30). BCAS1 count differences were tested using 216 an ANCOVA. ROI was used as fixed factor and slice ID as 217 random factor to correct for multiple data points derived from 218 the same cases. 219

Results

Matching MRI and histology data, we obtained 27 section 221 planes from the seven MS cases. GraSE MWF data of Case 5 222 were excluded due to unexpectedly low contrast, presumably 223 related to changes in acquisition. One section from Case 6 224 was also excluded due to unreliable GraSE MWF signal. All 225 cases showed pathological alterations typical of progressive MS, 226 including DAWM, slowly expanding and inactive lesions as 227 well as remyelinated shadow plaques. Classical active lesions 228 were not observed. Major confounding pathology was noted 229 in Case 7, which harboured ischemic lesions together with 230 severely atherosclerotic large meningeal arteries. Only lesions 231 of either clear ischemic or MS origin were analyzed. In total, 232 610 ROIs were outlined (median size 5.69 mm^2 , range: 0.14233 mm^2 – 32.09 mm^2). Figure 2 exemplifies matched MRI and 234 histology with corresponding ROIs from four MS cases. 235

Histological stainings of one section of Case 7 are exem-236 plified in Figure 3. NAWM was predominantly found in sub-237 cortical WM areas, since the progressive MS cases displayed 238 typical widespread diffuse myelin injury in deep WM areas 239 (Fig. 3g, black arrows). Inactive, but not slowly expanding le-240 sions, harboured scattered thin myelin sheaths in their centers 241 (compare Fig. 3i & Fig. 3j). BCAS1 staining (Fig. 3h) showed 242 the highest cell densities in peri-plaque WM close to the rim of 243 slowly expanding lesions (Fig. 3k), but on average hardly any 244 positive cells in the lesion cores. A subset of inactive lesions, 245 however, displayed clustered positive cells in the lesion center 246 (Fig. 31). Upon morphological evaluation of BCAS1+ cells, we 247 noted that one portion of positive cells 248

220

Fig. 3. Histological sections of a double-hemispheric coronal slice level of Case 7. (A) CD68 immunohistochemistry revealed accumulated activated microglia and macrophages at the edge of a slowly expanding periventricular lesion (left black square, enlarged in C), but not at the inactive periventricular lesion edge (right black square, enlarged in D). (B) Similarly, TBB staining showed iron accumulation at the slowly expanding (E), but not at the inactive lesions edge (F). Both lesions had iron loss in their centers. In WM, iron staining was highest subcortically, gradually decreased in DAWM and towards lesions, and was lowest within lesion centers. (G) LFB-PAS myelin staining visually distinguished areas of NAWM (mainly subcortically and in the capsula interna), DAWM and MS lesions. Black arrows indicate the ill-defined DAWM, characterized by reduced myelin intensity. Both periventricular MS lesions (enlarged in 1 and J) showed myelin loss. Notably, scattered thin myelin sheaths were present within some inactive lesion centers (J, high magnification inset with arrows), but never in slowly expanding lesions (I). Occasional macrophages with PAS-positive cytoplasmic inclusions, indicative of remote demyelination, were found. (H) BCAS1 immunohistochemistry revealed moderate immunoreactivity in myelin, rendering exquisite histological myelin contrast. Strongly BCAS1-positive glial cells without processes and dystrophic morphology accumulated in areas of WM damage, such as DAWM (see quantitative data) and WM abutting slowly expanding lesions (L) and shadow plaques.

Fig. 2. Qualitative comparison of the histology and co-registered MRI data for four sections from four cases (A: Case 4, B: Case 7, C: Case 1, D: Case 2). The histological images were contrast-inverted to visually match the MRI contrasts so that lower intensities represent lower myelin or iron concentrations. Co-registration achieved good matching of the MRI to the LFB stains, which were chosen as histology reference. ROIs were centered in representative regions, yielding good local correspondence of ROIs on visual inspection. The ROIs were drawn with a gap to avoid partial volume effects at anatomical or lesion borders. (Acronyms: normal appearing WM (NAWM); diffusely abnormal WM (DAWM); inactive lesions (InaL); shadow plaques (SdP); slowly expanding lesions (SEL); ischemic lesions (IsL))

had strong cytoplasmic immunoreactivity, and either absent 249 or very short and dystrophic-appearing processes. This type 250 of BCAS1+ cell morphology was found in NAWM, DAWM 251 and was most prominent in periplaque WM close to slowly 252 expanding lesion (Fig. 3k). Conversely, BCAS1+ cells in 253 inactive and remyelinated lesion cores had multiple, partly 254 parallel processes (Fig. 31). Ischemic lesions were reminiscent 255 of shadow plaques regarding their myelin densities but differed 256 morphologically. Shadow plaques were characterized by a 257 sharp border and homogeneously thin myelin sheaths in the 258 plaque area. By contrast, ischemic lesions showed a gradient 259 of myelin intensity, including ill-defined borders, as well as a 260 coarse lesion tissue texture with loss of whole myelin fibers, 261 but preservation of normal myelin sheath thickness in the 262 remaining fibers. 263

Comparison of MRI-based myelin estimates. Fig. 4a displays 264 the regression between GraSE and CPMG MWF ($R^2 = 0.862$, 265 slope = 0.858 %/%, intercept = -0.42% MWF), which demon-266 267 strates excellent agreement of these two myelin water scans. However, the regression of CPMG MWF and MTR was in-268 significant (Fig. 4c, $R^2 < 0.01$). Note that CPMG data were 269 only acquired in samples with storage times longer than 9 270 vears. The MTR – GraSE MWF relationship was modelled by 271 two different, storage time dependent regression lines (Fig. 4b). 272 GraSE MWF and MTR correlated significantly in tissue blocks 273 with storage times of < 1 year, ($\mathbb{R}^2 = 0.436$), but not in those 274 with extended storage times ($R^2 < 0.01$). Notably, the re-275

Fig. 4. Correlation of all MRI metrics. Both MWF estimates showed excellent agreement with a minimal intercept (A), whereas correlations between MWF and MTR depended on storage times (B,C). Correlations between MWF and MTR were significant in tissues with storage times of < 1 year (dotted line) and were non-significant for tissues with extended storage time > 9 years (dashed line). Note that CPMG data were only available for samples with extended storage time (C). Symbols indicate different cases; colors distinguish different tissue types. (Acronyms: normal appearing WM (NAWM); diffusely abnormal WM (DAWM); inactive lesions (InsL); shadow plaques (dsP); slowly expanding lesions (SEL); ischemic lesions (IsL))

gression intercepts in all correlations with MTR were different from zero. In cases stored < 1 year, the intercept for GraSE MWF and MTR was 19.3 a.u.. In cases with extended storage, the intercepts were 14.2 a.u. and 14.5 a.u., when comparing GraSE MWF and CPMG MWF with MTR, respectively. 280

Histological and MRI-based myelin measurements in differ-281 ent ROIs. Figure 5 displays the stratification of histological 282 optical densities and MRI data according to ROI. WM LFB 283 (Fig. 5a) and PLP (Fig. 5c) optical densities were highest in 284 NAWM, followed by DAWM, shadow plaques and inactive 285 lesions, and were lowest in slowly expanding lesions. LFB and 286 PLP densities in ischemic lesions resembled those of shadow 287 plaques. In contrast to LFB, PLP hardly differed between 288 NAWM and DAWM. Iron was lower in DAWM compared to 289 NAWM, and markedly depleted in slowly expanding and inac-290 tive lesions. In shadow plaques, iron densities ranged between 291 the densities of DAWM and demyelinated lesions. Few high 292 NAWM iron densities were derived from Case 1. 293

Of all MRI metrics (Figs. 5b and 5d, CPMG data not 294 shown), relative differences in GraSE MWF between ROIs 295 most closely matched the LFB and PLP intensity distribu-296 tions (Figs. 5a and 5c). All myelin MRI metrics were reduced 297 in DAWM compared to NAWM, though less so than LFB. 298 MWF was lower in all WM lesions than in NAWM or DAWM. 299 In shadow plaques and ischemic lesions, MWF was between 300 slowly expanding lesions and DAWM, best reflecting LFB and 301 PLP relations. By contrast, MTR in shadow plagues exceeded 302 NAWM MTR. All three MRI measures yielded higher values 303 in inactive compared to slowly expanding lesions, sensitively 304 reflecting histological myelin data. LFB (p < 0.001), GraSE 305 MWF (p = 0.016) and MTR (p < 0.001) were all significantly 306 higher in inactive compared to slowly expanding lesions, also 307 after Bonferroni correction. BCAS1 counts, indicative of the 308 number of actively remyelinating oligodendrocytes, were gen-309 erally in line with the observations from LFB and MWF. The 310 number of BCAS1+ cells in lesion areas was generally lower 311 than counts in NAWM and DAWM. Slowly expanding lesions 312 were found to have, on average, slightly lower BCAS1+ counts 313 than inactive lesions and shadow plaques, although the differ-314

Fig. 5. Comparison of quantitative MRI values and optical densities across regions of interest. Panels on the left display the histological density measurements (LFB (A), PLP (C), TBB (E)), panels on the right the MRI myelin measurements (GraSE MWF (B), MTR (D)). Panel F displays the separately obtained BCAS1 counts. LFB and PLP differences between ROIs, including in lesions, were well reflected in both MWF measurements. By contrast, MTR changes appeared more closely linked to the TBB staining intensities, and MTR values overlapped between regions. Note that the data collection for CPMG and MTR were incomplete, thus not all ROIs are present in the MTR plot. (Acronyms: normal appearing WM (NAWM); diffusely abnormal WM (DAWM); inactive lesions (InaL); shadow plaques (SdP); slowly expanding lesions (SEL); ischemic lesions (IsL))

ence was statistically not significant (p = 0.987). Significantly more BCAS1-positive cells were found in damaged DAWM compared to NAWM (p < 0.001).

Per-case correlations and average correlation coefficients 318 (data not shown) between the MRI metrics and stainings reflect 319 the findings of Figs. 4 and 5, i.e. strong correlations between 320 myelin MRI metrics and myelin stainings, albeit with a non-321 zero intercept in correlations with MTR. Exemplarly, Figure 6 322 presents the GraSE MWF vs. LFB correlations. Note that 323 sections containing only NAWM or DAWM, i.e. no lesions, 324 exhibited typically insignificant, flat correlations and that 325 MWF and MTR values varied between cases. 326

Despite moderate to strong correlation coefficients across 327 different tissue classes, within tissue class correlation coeffi-328 cients were substantially smaller. To determine the extent 329 to which LFB, PLP and TBB, in combination, predict the 330 331 MRI metrics within specific tissue classes, we applied a linear mixed effects model. Data from all cases were included, and 332 time since fixation was added as a fixed effect to account for 333 differences in the MRI metrics related to storage time. Table 2 334 summarizes the significant contributors that were determined 335 in the regression model. BCAS1 data were not included in 336 the mixed effects model as they were separately obtained and 337 analyzed. 338

PLP significantly explained variations in NAWM and
 DAWM GraSE MWF, while CPMG MWF and MTR were
 strongly influenced by tissue storage time. TBB significantly

related to DAWM GraSE MWF and MTR. Similar to NAWM, 342 MRI myelin values in shadow plaques were predicted by PLP, 343 storage time and in part LFB. In line with the above-described 344 differences between inactive and slowly expanding lesions, the 345 mixed effects model revealed some association between LFB 346 and MWF in inactive, but not in slowly expanding lesions. 347 The latter only showed a dependency for MTR on LFB. Stan-348 dardized regression coefficients, i.e. the amount of change 349 that a variation in each of the predictor variable yields in the 350 MRI-measured myelin values, are provided together with the 351 p-values in Table 2. 352

353

Discussion

We assessed the ability of three myelin-sensitive MRI tech-354 niques to differentiate various degrees of myelin damage, recov-355 ery and lesional activity in a larger sample of progressive MS 356 cases. Using histochemical and immunohistochemical stain-357 ings for myelin, we showed low levels of myelin in completely 358 inactive lesions. We suggest that this myelin signal may rep-359 resent remyelination occurring in chronic MS lesions without 360 microglia or iron rims. These low myelin levels were conspicu-361 ous in the high-magnification of the histological stainings and 362 captured by all investigated myelin-sensitive MRI techniques 363 and in part corroborated by BCAS1 stainings. Importantly, 364 our data showed that BCAS1-positivity is not exclusively a 365 marker for remyelinating oligodendrocytes, but that it also 366 marks degenerating glial cells in DAWM and in the vicinity of 367 the chronic active lesion edges. Detecting and following subtle 368 remyelination in vivo in chronic lesions provides an additional 369 avenue for assessing repair in MS and may be a relevant con-370 sideration for trials of remyelinating therapies, which typically 371 are believed to be most efficacious in younger MS lesions. 372

Comparison of MWF, MTR and histopathological metrics. The 373 excellent agreement of CPMG and GraSE MWF ($R^2 = 0.862$) 374 corroborates in vivo comparisons (15). We attributed the two 375 different relationships of MWF with MTR to storage time. 376 MTR is known to decrease with formaldehyde fixation (31), but 377 longer-term pH changes may also affect MTR similar to other 378 off-resonance techniques (32). NAWM and DAWM showed the 379 most pronounced storage-related MTR shifts of up to 20 a.u., 380 much more than the difference in intercept. Between cases, 381 acquisition differences and differences in iron content affect 382 MTR. Increased TR is known to result in MTR reductions 383 (33), while strong WM iron depletion significantly increases 384 MTR (22, 24, 25). More work is warranted to understand the 385 dependency of MTR on the storage duration after formalin 386 fixation. 387

Independently, non-zero regression intercepts between MTR 388 and LFB, PLP and the other two MRI myelin measures in-389 dicate that MTR reflects not only myelin lipids and proteins 390 but also other tissue characteristics, despite being positively 391 correlated with high \mathbb{R}^2 . Although MTR is widely used to 392 detect de- and remyelination (34), other non-aqueous tissue 393 components, such as axonal and glial cell membranes, soluble 394 proteins in the extracellular space, and astrocytic and axonal 395 densities also play a role (35). Inflammation and edema further 396 confound the specificity of MTR for myelin (35, 36), while 397 MWF remains relatively unchanged (37, 38). Note the large 398 overlap in MTR across different tissue types and the relatively 399 high MTR in slowly expanding and inactive lesions, resulting 400

Fig. 6. Within-case correlations between LFB and GraSE MWF across all ROIs. In order to suppress between-section deviations, all correlations shown are weighted averages of the individual within-section correlations. Different symbols distinguish data from different sections of a case. Different colors indicate different ROI types. The slopes of the average correlations ranged from 0.06 to 0.15 % MWF per optical density unit. All correlations, except for Case 6, were significant. Case 5 is not shown as the GraSE data were deemed unreliable for analysis. (Acronyms: normal appearing WM (NAWM); diffusely abnormal WM (DAWM); inactive lesions (InaL); shadow plaques (SdP); slowly expanding lesions (SEL); ischemic lesions (IsL))

 $_{401}$ $\,$ from the non-zero intercept.

Limitations of earlier MWI approaches (5, 16), i.e. small field-of-view and very long acquisition times, have been overcome by introducing the 3D GraSE sequence in MWI (15). However, the now widely used GraSE-MWI approach has never been histopathologically validated. Previous MWF histopathological comparison focused on LFB intensities (8) and recently, electron microscopy validated CPMG-MWI in rat spinal cord samples (9). We assessed myelin more broadly, including lipids as well as myelin proteins and iron to explain variations in MWF (28), with CD68 and BCAS1 for further validation. Gradient echoes in the GraSE sequence may make MWF more susceptible to static field inhomogeneities. However, in agreement with other work (24), we did not observe differences 408

Table 2. Linear mixed effects model ANOVA predictors of MR myelin measurements. Unadjusted p-values are reported together with their relative importance coefficients. Values reported in bold font are p < 0.05, non-bolded values reflect p-values between 0.05 and 0.1. If no significant factor was reported by the ANOVA (ns) or the largest β -coefficient did not correspond to the significant entry, the highest importance factor is listed in gray in the second half of the respective cell. (Acronyms: normal appearing WM (NAWM); diffusely abnormal WM (DAWM); inactive lesions (InaL); shadow plaques (SdP); slowly expanding lesions (SEL); ischemic lesions (IsL))

Tissue Type	GraSE MWF	CPMG MWF	MTR
NAWM	PLP $\mathbf{p} = 0.002 \ (\beta = 0.543)$ TBB $p = 0.052 \ (\beta = -0.198)$	Time p = 0.010 (β = 0.732)	Time p = 0.020 (β = -0.506)

⁴¹⁵ between GraSE and CPMG MWF, although TBB contributed
⁴¹⁶ to the prediction of GraSE MWF in some regions (Table 2).
⁴¹⁷ Note that iron was highly variable between cases in the present
⁴¹⁸ study, possibly due to reduced tissue iron concentrations in
⁴¹⁹ progressive cases with long disease duration (22).

Relative differences in MWF between tissues agreed well 420 with the differences in LFB and PLP stainings, including in 421 lesions. This demonstrates excellent sensitivity of MRI-based 422 423 myelin imaging to the detection of different stages or degrees of de- or remyelination, despite low lesional myelin concentrations. 424 Integrating the different stainings in a multi-linear regression 425 showed that both myelin lipid and protein concentrations are 426 needed to predict variations within tissue classes, such as 427 within DAWM or between different shadow plaques. Notably, 428 LFB and PLP explained much greater variation in MWF than 429 TBB. 430

Slowly Expanding and Inactive Lesions. Differently from 431 slowly expanding lesions (39), inactive lesions do not have 432 a rim of degradation products, but both are typically de-433 scribed as relatively free of myelin containing macrophages, 434 microglial activation, and inflammation in their lesion centers 435 (40). By contrast, we observed non-zero MWF and MTR in 436 inactive lesions and found few, thin myelin sheaths in LFB 437 sections, not seen in slowly expanding lesions (Figure 3). LFB 438 and both MWF and MTR showed consistently higher levels 439 in inactive compared to slowly expanding lesions. Correspond-440 ingly, the statistical model detected, albeit insignificantly, that 441 LFB influenced GraSE and CPMG MWF for inactive, but not 442 for slowly expanding lesions. 443

Our findings are in line with post-mortem work showing in-444 significantly higher MTR and macromolecular proton fractions 445 in inactive compared to slowly expanding lesions (35). More-446 over, in vivo susceptibility and myelin imaging demonstrated 447 that rim lesions have lower myelin values than inactive lesions 448 (41). Most of these studies attributed the lower signal to the 449 greater destructiveness of slowly enhancing lesions. Meanwhile, 450 it has been shown that both slowly expanding and inactive 451 lesions may contain BCAS1+ premyelinating oligodendrocytes, 452 indicating the ability of both lesion types to remyelinate (19). 453 It is believed that while the rim of activated microglia and 454 macrophages exists, it may prevent lesional myelin recovery 455 (39, 42). Our data suggest that inactive lesions, for which the 456 rim has resolved, start to recover some thin myelin sheaths to 457 a degree that the lipid signal can be detected on histological 458 stainings and with myelin-sensitive MRI techniques. 459

Thus, it may be possible to capture varying degrees of
late remyelination also in vivo using MRI. All these observations warrant further investigation to better characterize the
difference between slowly expanding and inactive lesions.

Notably, our data showed that BCAS1+ also stains de-464 generating glial cells. This is supported by the BCAS1+ cell 465 466 morphology in areas of DAWM and periplaque WM, where cells had either no or short and twisted dystrophic processes. 467 By contrast, in few areas within inactive or partly remyeli-468 nated lesions many BCAS1+ cells had extensive branches and 469 formed processes to multiple internodes, vielding a morphology 470 reminiscent of that described for PLP-positive myelinating 471 oligodendrocytes (43). However, this was only found in few 472 lesions and might relate to the transient nature of remyelina-473 tion. 474

Normal appearing and diffusely abnormal WM & Shadow 475 Plaques and Ischemic Lesions. The lower LFB but similar 476 PLP signal between DAWM and NAWM (Figure 5) agrees 477 with the lipid abnormality characteristic of DAWM (28). Inter-478 estingly, our mixed effects model suggested that more subtle 479 differences within NAWM and DAWM GraSE MWF relate 480 to differing PLP-concentrations. TBB also played a role in 481 distinguishing subtle differences between NAWM and DAWM 482 regions, in line with the importance of iron for myelin pro-483 duction in oligodendrocytes and previously described iron loss 484 in DAWM (44). Given the widespread diffuse injury, NAWM 485 ROIs were confined to subcortical regions. These tissue block 486 areas are more likely to be affected by misregistration errors, 487 possibly explaining why the MRI-measured NAWM-DAWM 488 difference was smaller than expected from their LFB intensi-489 ties. CPMG and MTR were predominantly related to storage 490 time or a combination of predicting factors. 491

Shadow plaques and ischemic lesions were well reflected in 492 GraSE MWF, but both lesion types had higher MTR than 493 NAWM and DAWM. This may again relate to the inverse 494 relationship between MTR and iron concentrations (23, 25). 495 Note that our shadow plaques yielded non-zero TBB staining, 496 although they have been generally found to remyelinate with-497 out iron recovery (22). Regardless, myelin-related regression 498 coefficients for GraSE MWF in shadow plaques were noticeably 499 larger than the TBB coefficients, indicating that iron plays a 500 minor role in the estimation of MWF in shadow plaques. No 501 specific histopathological factor predicted MWF or MTR of 502 ischemic lesions. 503

Study strengths and limitations. We tested how myelin lipids, 504 proteins and iron contribute to MWF and MTR. Our data 505 provide the first validation of the use of the GraSE sequence 506 for MWI. We demonstrated the sensitivity of these myelin 507 imaging techniques on a case-by-case basis. Across cases, 508 we utilized mixed effects modeling to provide a combined 509 assessment of the role of lipids, proteins, and iron to the MRI 510 measures, rather than assessing them in isolation. We did not 511 consider axonal density, which is relevant for MTR (35), due 512 to its strong collinearity with myelin. Assessing gliosis and 513 inflammation, however, may help to shed further light on the 514 observed lesional differences. BCAS1 staining was performed 515 separately to support our initial findings. Dedicated sample 516 selection to investigate specific tissue classes or class differences 517 would be advantageous but was beyond the scope of the work 518 presented here. 519

Our investigation included MTR (6), rather than quantita-520 tive magnetization transfer (35), as MTR is more frequently 521 used, both in clinical trials and research. Assessing other 522 techniques, e.g. T_2^* -based myelin mapping (7, 45), may be of 523 interest in the future. Although other MRI techniques may 524 have advantages over traditional MWI acquisitions, including 525 potentially faster acquisition times (6), higher spatial reso-526 lution (46), improved signal-to-noise ratio and lower specific 527 absorption rates, they are also known to be influenced by 528 axonal water (12), magnetization transfer effects (11, 36, 47)529 or to suffer phase errors due to field inhomogeneities and phys-530 iological noise (48, 49). Current MWI approaches (14, 21) also 531 have the advantage of being model-free, and new developments 532 in MWI may alleviate limitations in scan time and spatial 533 resolution (50). 534

Conclusions 535

Both MWI strategies, the original CPMG and the faster 536 GraSE acquisition, as well as MTR reflected the histologically 537 assessed myelin concentrations across tissues and allowed to 538 539 detect subtle within-tissue class differences. Notably, the range of MWF and MTR values observed in inactive lesions 540 appeared to reflect variable degrees of late, slowly progressing 541 remvelination. 542
