Abstract 23

24 Introduction: With the economic recession and pandemic fatigue, milder viral variants and higher vaccine coverage along the time lay the basis for lifting anti-COVID policies to restore 25 COVID-19 normalcy. However, when and how to adjust the anti-COVID policies remain under 26

27 debate in many countries.

Methods: In this study, four countries (Singapore, South Korea, Australia, and New Zealand) 28 29 and one region (Hong Kong SAR), that have shifted from the zero-COVID (ZC) policy to or 30 close to the living-with-COVID (LWC) during or after the Omicron outbreak, were selected as research objects. All-cause mortality data were collected for these objects from 2009-2019. 31 32 The expected mortality was estimated by a simple linear regression method. Excess mortality 33 over time was calculated as the difference between the expected mortality and the observed 34 mortality. Finally, percent excess mortality (PEM) was calculated as the excess mortality 35 divided by the expected mortality.

Results: In the examined four countries, PEM fluctuated around 0% and was lower than 10% 36 37 most of the time under the ZC policy before 2022. After shifting to the LWC policy, all the examined countries increased the PEM. Briefly, countries with high population density 38 39 (Singapore and South Korea) experienced an average PEM of 20-40% during the first half of 40 2022, and followed by a lower average PEM of 15-18% during the second half of 2022. For countries with low population density under the LWC policy, Australia experienced an average 41 PEM of 39.85% during the first half of 2022, while New Zealand was the only country in our 42 analysis that achieved no more than 10% in average PEM all the time. On the contrary, Hong 43 Kong SAR under their ZC policy attained an average PEM of 71.14% during the first half of 44 2022, while its average PEM decreased to 9.19% in the second half of 2022 with LWC-like 45 policy. 46

Conclusion: PEM under different policies within each country/region overtime demonstrated 47 that the mortality burden caused by COVID-19 had been reduced overtime. Moreover, anti-48 49 COVID policies are suggested to control the excess mortality to achieve as low as 10% in PEM.

56

Contribution to the field 57

- This study compared excess mortality within the same country/region, instead of among 58 • countries, thus, PEM during the outbreaks of different SARS-cov-2 variants overtime 59 could reflect the effectiveness of regional specific anti-pandemic policies in protecting 60 the lives of citizens locally. 61
- Our analysis demonstrated that Singapore, South Korea and Australia might implement 62 • the LWC policy without sufficient preparation, which resulted in a very high mortality 63 burden during the first half of 2022. 64
- The reduced PEM in late 2022 in the examined countries/regions suggested that the 65 • 66 mortality burden caused by COVID-19 was reduced overtime, laying a great foundation to call for a further relief of LWC policy in the world in the near future. 67

Introduction 71

On November 24, 2021, a new variant of SARS-CoV-2 (B.1.1.529) was reported to the World 72 Health Organization (WHO) by South Africa which was later named Omicron (1). Since the 73 74 emergence of the Omicron variant, the world has entered a post-COVID-19 era. Compared 75 with other variants, Delta in particular, Omicron is characterized by its relatively low pathogenicity and high transmissibility (2). The low pathogenicity considerably reduces the 76 77 risks of hospitalization and fatality; however, the high transmissibility significantly increases the number of confirmed cases, which in turn, may overwhelm hospitals and cause high 78 mortality in the end. Taken together, whether the mortality burden caused by the Omicron surge 79 80 is tolerable to the society is unclear. Subsequently, when and how to adjust the anti-COVID policies has been under debate in the world. 81

82 Besides the evolution of the SARS-Cov-2 variants, with the accelerated vaccination coverage and the emergence of effective antiviral drugs (3), the case fatality rate of SARS-CoV-2 virus 83 decreased from 80 times higher than that of influenza in April 2020 to less than 2 times higher 84 85 than that of influenza in early 2022 (4). Accordingly, some countries, such as Singapore and New Zealand, transitioned step by step from a zero-COVID (ZC) policy to a living-with-86 COVID (LWC) policy prior to or during the Omicron outbreak (5). By contrast, some other 87 88 countries, such as China, (4) continue to stick to the dynamic ZC policy, with the considerations of the limited medication resources, the high transmissibility of Omicron and its tendency to 89 90 escape from vaccine-induced immunity (6). The ZC policy aims at zero uncontrolled 91 transmission of COVID-19 viruses in a specific geographic region (5) by means of control 92 measures such as COVID mass testing, case quarantine, contact tracing, and border closure (7) to varying degrees depending on their epidemiological situations. Existing evidence showed 93 that the ZC policy could effectively prevent the spread of the virus and significantly reduce the 94 95 fatality rate by up to 96% (8). In addition, China kept positive economic growth in 2020 and 2021 under the ZC policy, which was not easy considering the worldwide economic hardship 96 (9). However, the continuation of the ZC policy has its own challenges. Taking China as an 97 98 example, its current "dynamic ZC" policy is encountering enormous pressure and high costs of 99 disease prevention, especially during the epidemic outbreak in Shenzhen, Jilin Province, and Shanghai in the first half of 2022 (10, 11). In addition, more stringent prevention and control 100 101 measures during the pandemic affect the quality of life, which is owing to the decreased social connections caused by mandated lockdowns and socially restrictive physical distancing (12). 102 However, when and how to implement the LWC policy appropriately need to consider the 103 104 balance between the public health and economics.

Mortality rate is considered as an objective indicator to assess the burden of the disease on 105 106 society and is also the basis for decision-making in the public health (13). The quantification of COVID-associated deaths varies among countries/regions due to the differences in the 107 definition of "COVID-associated deaths", such as the calculation of the number of cases that 108 "die from COVID-19" and "die with COVID-19" (14). Besides COVID-associated deaths, 109 there might also be non-negligible deaths due to insufficient medical resources during the 110 pandemic, which are not included in the statistics of COVID-19 deaths (14). Thus, COVID-111 112 associated deaths alone underestimate the impact of the pandemic. By contrast, all-cause mortality is more robust and objective. To better evaluate the magnitude of COVID-19 and its 113 effects on society, scientists proposed the use of "excess mortality," which is defined as the net 114 difference between observed mortality and expected mortality (15). The recent mainstream 115 studies (14-16) focused on comparing excess mortality/percent excess mortality (PEM) and 116 COVID-associated deaths/death rate. These comparisons mainly reflected the differences in 117 the measurements of deaths across countries/regions. However, the impact of different virus 118

medRxiv preprint doi: https://doi.org/10.1101/2022.08.31.22279422; this version posted November 28, 2022. It is made available under a CC-BY-NC 4.0 International license .

variants or different anti-pandemic policies on society within the same country/region has not 119 been evaluated. Therefore, there is a lack of evidence to evaluate the effectiveness of the LWC 120

policy in saving lives during the Omicron era overtime. 121

Herein excess mortality was employed to evaluate the effectiveness of different policies in 122 protecting the lives of citizens within the same country/region during the pandemic. Based on 123 excess mortality, this study adopted the concept of PEM for assessing the mortality burden 124 attributed to different variants of the virus and different public health policies. PEM is the 125 percentage of excess mortality divided by the threshold (15), which is the expected mortality 126 in this study. Since the SARS-COV-2 variant and the vaccination rate were the dominant 127 factors in adopting the LWC policy from the ZC policy in many areas, we selected four 128 129 countries (Singapore, South Korea, Australia, New Zealand) and one region (Hong Kong) as the representative research objects. The four countries implemented the LWC policy during the 130 Delta/Omicron era, while Hong Kong experienced Omicron outbreaks under specialized ZC 131 policies. The influence of natural fluctuation in expected mortality each year was considered 132 via simple linear regression. This analysis focused on the changes in PEM within the same 133 134 country/region over the entire pandemic period. Our results delineated a threshold of PEM as a criterion to assess the effectiveness of anti-COVID policies. Furthermore, our study revealed 135 the significant reduction in PEM overtime in the examined countries/regions under LWC 136 137 policy and suggested that the mortality burden caused by COVID-19 was reduced overtime, laying a great foundation to call for a further relief of LWC policy in the world in the near 138 future. 139

140

Materials and Methods 141

1. Data Collection 142

143 Data on all-cause mortality were obtained for four countries (i.e., Singapore, South Korea, Australia, and New Zealand) and one region (i.e., Hong Kong) from governmental sources, 144 including either weekly or monthly mortality data during the pandemic from January 2020 to 145 146 September 2022 for Singapore, September 2022 (week 39) for South Korea, July 2022 (week 30) for Australia, October 2022 (week 43) for New Zealand and September 2022 for Hong 147 Kong. Details were listed in Table 1. In addition, data on confirmed cases and COVID-148 associated deaths of four countries and one region were extracted from Google's COVID map 149 (originally from Johns Hopkins University) (17). 150

151

2. Calculation of expected mortality 152

Expected mortality is defined as deaths that occurred in a period assuming there is no pandemic 153 and is estimated based on the past trends of all-cause mortality. This study adopted the simple 154 155 linear regression method to estimate expected mortality. Data on all-cause mortality were obtained for four countries (i.e. Singapore, South Korea, Australia, and New Zealand) and one 156 157 region (i.e. Hong Kong SAR) from 2009 to 2019. Firstly, we examined different periods of the death data ranging from 2009 to 2019 and employed simple linear regression analysis. Only 158 the data period with R² larger than 0.85 in the linear regression analysis was selected for further 159 calculation (Table 1). Next, within the selected period, linear regression analysis was 160 161 performed on the data of the corresponding week/month to calculate the expected mortality during the pandemic. For example, the death data of Januarys from 2009 to 2019 in Singapore 162 were analyzed with linear regression to calculate the expected mortality in January 2021 and 163 2022. 164

165

166 3. Calculation of excess mortality and PEM

Based on expected mortality, excess mortality was calculated using the equation below: 167

Excess mortality = Observed mortality – Expected mortality (15)168

- Accordingly, PEM was calculated using the equation below: 169
- 170

$$PEM = \left(\frac{Excess mortality}{Expected mortality}\right) \times 100\% (15)$$

4. Calculation of percent COVID-excess mortality (PCEM) 171

PCEM is defined as the percentage of COVID-associated deaths divided by expected 172 mortality. Data on COVID-associated deaths were obtained from Google's COVID map 173 (originally from Johns Hopkins University) (17). PCEM was calculated using the equation 174 below: 175

176
$$PCEM = \left(\frac{COVID-associated deaths}{Expected mortality}\right) \times 100\%$$

By comparing PCEM with PEM, we can see the contribution of COVID-associated 177 deaths to the overall excess mortality during the pandemic period. 178

Results 179

Singapore: PEM in Singapore under the ZC policy fluctuated around 0% and did not • 180 exceed 10%. After shifting to the LWC policy, PEM reached over 10% with an average 181 of 24.23% in response to the Delta variant in late 2021. Then Singapore encountered 182 the Omicron outbreaks. The average PEM was 23.98% in early 2022 and 18.53% in 183 late 2022. 184

Singapore had a total population of 5.686 million as of 2020 (18) and a population density of 185 8019 people per square kilometer (19). From January 2020 to July 2021, Singapore effectively 186 implemented the ZC policy, and the total number of deaths from COVID was only 37 (Figure 187 1A). In August 2021, Singapore announced the implementation of the LWC policy. Since then, 188 189 it experienced four rounds of COVID-19 outbreaks. The first one was the Delta epidemic from September to December 2021, with a daily increase of more than 3,000 confirmed cases and 190 10-15 COVID-associated deaths daily at the peak (Figure 1A); the second COVID outbreak 191 192 was the Omicron epidemic starting from the end of January 2022 to April 2022 with a daily increase of 17,000-19,000 confirmed cases but only about 10 daily COVID-associated deaths 193 at the peak (Figure 1A). Omicron and it evolving variants raised the third (July - September 194 2022) and fourth outbreak (starting from the end of September 2022) with a daily increase of 195 5000-12,000 confirmed cases and less than 10 daily COVID-associated deaths (Figure 1A). 196 197 These above low COVID-associated death data posed Singapore as the world model for 198 handling the COVID pandemic. However, the definition of COVID-associated deaths varies from country to country. When PEM was used to evaluate the total mortality burden under the 199 LWC policy, the analysis, as shown below, suggested a different conclusion. 200

Using the monthly mortality data published by the Singapore government (20), a PEM curve 201 from January 2020 to September 2022 was obtained and shown in Figure 1B. PEM in 202 Singapore under the ZC policy before August 2021 fluctuated around 0% and did not exceed 203 10%. After shifting to the LWC policy in August 2021, Singapore encountered the Delta 204 outbreak. Peak PEM was as high as 31.53% (October 2021), and the average during the Delta 205

perpetuity. It is made available under a CC-BY-NC 4.0 International license .

outbreak (September - December 2021) was 24.23% (Figure 1B). The Omicron outbreak began 206 in late January 2022. PEM peaked at 33.94% in March 2022, with an average value of 23.98% 207 (February - April 2022) (Figure 1B). The second Omicron outbreak began in mid-June and 208 lasted until September with a peak and an average PEM of 19.23% (August 2022) and 18.53%, 209 respectively (July – September 2022) (Figure 1B). Data on all-cause mortality after October 1. 210 2022 have not been released by the Singapore government; thus analysis of PEM during the 211 third Omicron Outbreak is out of scope in this paper. The current data showed that PEM 212 increased greatly after the policy transition during both Delta and Omicron outbreaks. In 213 addition, under LWC policy, PEM remained high for Delta and the first Omicron outbreak, 214 while PEM dropped significantly as it progressed into the second half of 2022. Furthermore, 215 PCEM curve was significantly lower than PEM curve (Figure 1B), suggesting a good number 216 of deaths were caused by COVID indirectly under the LWC policy. It may be attributed to the 217 218 overwhelmed medical resources or the under-quantification of COVID-associated deaths. Collectively, the LWC policy in Singapore in the first half of 2022 failed to control the 219 mortality burden well. However, as the COVID variant evolved and became less virulent, as 220 well as an increased rate of vaccine inoculation and potential development of herd immunity, 221 222 PEM decreased significantly overtime but remained above 10%.

223

Figure 1. COVID-19 pandemic and mortality statistics in Singapore. (A) SARS-CoV-2 confirmed cases (black) and COVID-associated deaths (blue) from January 22, 2020, to Novemver 20, 2022 (17). (B) Percent excess mortality (monthly) from January 2020 to September 2022 and percent COVID-excess Mortality (monthly) during the living-with-COVID policy period from August 2021 to September 2022. The dotted line is the 10% percent excess mortality/percent COVID-excess mortality line.

South Korea: PEM in South Korea under the ZC policy fluctuated around 0%, and 231 most of the time, it did not exceed 10%. After shifting to the LWC policy, PEM 232 exceeded 10% and averaged at 12.83% in response to the Delta variant in late 2021. 233 Then, South Korea faced the Omicron outbreaks with an average PEM of 43.59% in 234 early 2022 and 14.91% in late of 2022. 235

South Korea had a population of 51.836 million as of 2020 (18) and a population density of 236 237 532 people per square kilometer (19). From January 2020 to November 2021, South Korea implemented the ZC policy, and the total number of COVID-19 confirmed cases and the total 238 number of COVID-associated deaths were 368,000 and 2,874, respectively (Figure 2A). On 239 November 1, 2021, South Korea declared to live with COVID. Since then, South Korea 240 experienced a wave of Delta outbreak from November to December 2021, with more than 241 7,000 daily confirmed cases and 70-80 COVID-associated deaths daily at the peak (Figure 2A). 242 Later from February to May 2022, South Korea faced a wave of Omicron outbreak. The daily 243 confirmed cases were about 400,000, and the daily COVID-associated deaths were 350-400 at 244 the peak (Figure 2A). Moving forward to the second half of 2022, South Korea encountered 245 246 another Omicron outbreak (July - September 2022) with a daily increase of 5000-15,000 confirmed cases and around 50 daily COVID-associated deaths (Figure 2A). 247

248 Using the weekly mortality data in South Korea provided by the Human Mortality Database (which has been collated with the data published by the Korean government) (21), a PEM curve 249 250 from January 2020 to September 2022 (week 3, 2020 - week 39, 2022) was obtained and shown in Figure 2B. PEM in South Korea under the ZC policy from January 2020 to November 1, 251 2021 (week 3, 2020 - week 44, 2021) fluctuated around 0%, and most of the time, it did not 252 exceed 10% (Figure 2B). After transitioning to the LWC policy on November 1, 2021, South 253 Korea encountered the Delta outbreak. PEM peaked at 16.70% in December 2021 (week 49, 254 2021), and the average was about 12.83% in November and December 2021 (weeks 44-52, 255 2021) (Figure 2B). Statistically, South Korea performed better than Singapore in Delta 256 prevention under the LWC policy. However, considering the high population density in 257 Singapore, the policies in the two countries cannot be compared by statistics only. 258

PEM in South Korea fell below 0% in January 2022 (Figure 2B. It could be partially due to 259 the decline of COVID-associated death with the temporary pandemic recession and possibly 260 due to the limitation in estimating expected mortality for January 2022. Notably, South Korea 261 262 had a significantly large number of deaths in January 2018, which exceeded 7,000 per week, whereas the number of deaths was less than 6,000 per week in January in years prior to 2018 263 (21). Thus, a large number of deaths in January 2018 shifted the fitting curve upwards and 264 265 increased the estimation of expected mortality. Later from February 2018 until the beginning 266 of the pandemic, South Korea's death toll remained to be similar to that in the previous years. The reason for the sudden increase in the number of deaths in January 2018 remains unknown. 267 268 If the average number of weekly deaths in January 2019-2021 was used to calculate expected mortality, PEM in January 2022 was still below 10%. Thus, the mortality burden in January 269 270 2022 is comparable to that under ZC policy.

The Omicron outbreak occurred from February to May 2022. PEM peaked at about 78.33% in 271 February 2022 (week 12, 2022), and the average was 43.59% from February to May 2022 272 273 (weeks 7-19, 2022) (Figure 2B). In the second half of 2022, South Korea experienced another round of Omicron outbreak from July to September 2022 (weeks 27-39, 2022) with a peak and 274 average PEM of 25.93% (week 37, 2022) and 14.91% (Figure 2B). Analysis of PEM in months 275 276 beyond October 1, 2022 was unavailable until the government's further release of data on all-277 cause mortality. The current data showed that PEM increased greatly after the policy transition 278 during both Delta and Omicron outbreaks. In addition, under the LWC policy, the mortality

perpetuity. It is made available under a CC-BY-NC 4.0 International license.

burden decreased significantly in response to two Omicron outbreaks that occurred in the first 279 and second half of 2022. Furthermore, PECM curve was significantly lower than PEM curve 280 during the Omicron outbreak (Figure 2B), suggesting that a good number of deaths were caused 281 by COVID indirectly under the LWC policy when encountering the Omicron variant. It might 282 be attributed to the overwhelmed medical resources or the under quantification of COVID-283 associated deaths. Collectively, the LWC policy in South Korea in early 2022 failed to control 284 the mortality burden well. However, later in the second half of 2022, the average PEM, 285 although it remained above 10%, dropped drastically. Decreasing mortality burden might be 286 due to less virulent variants and the potential development of herd immunity. 287

299

Australia: PEM in Australia under the ZC policy fluctuated around 0%, and most of the time, it did not exceed 10%. After shifting to the LWC policy, Australia encountered two subsequent Omicron outbreaks. PEM reached an average of 39.85% in early 2022 and decreased to 35.68% in late 2022.

Australia had a population of 25.693 million as of 2020 (18) and a population density of 3 300 people per square kilometer (19). From January 2020 to October 11, 2021, Australia effectively 301 implemented the ZC policy. The total confirmed cases of COVID-19 were 131,000, and the 302 total COVID-associated deaths were 1,461 (Figure 3A). On October 11, 2021, Australia 303 announced the beginning of the LWC policy, which coincided with the Delta outbreak, leading 304 to a daily increase of more than 2,000 confirmed cases and daily COVID-associated death of 305

perpetuity. It is made available under a CC-BY-NC 4.0 International license .

10-15 (Figure 3A). Since then, Australia has experienced two waves of Omicron outbreaks.
The first wave lasted from the end of December 2021 to March 2022, with more than 100,000
confirmed cases per day (Figure 3A) and more than 80 COVID-associated deaths per day. The
second wave started at the end of February 2022, while the first wave had not completely
subsided until August 2022. During the second wave of Omicron, there was a daily increase of
more than 50,000 confirmed cases and a large fluctuation of daily COVID-associated deaths
of about 20-50 (Figure 3A).

Using the Australian weekly death data provided by the Human Mortality Database (which has 313 314 been collated with the data published by the Australian government) (21), a PEM curve from January 2020 to July 2022 (week 3, 2020 – week 30, 2022) was obtained and shown in Figure 315 316 3B. Australia only published data on all-cause mortality for 2015-2019, and the annual death data fluctuated significantly, so it was impossible to perform any effective linear fitting. 317 Therefore, in this study, the average number of yearly deaths for 2016-2019 was used to 318 estimate expected mortality. As shown in Figure 3B, PEM in Australia under the ZC policy 319 320 before October 11, 2021 (week 40, 2021) fluctuated around 0% and was below 10% most of the time. After transitioning to the LWC policy on October 11, 2021, Australia experienced a 321 Omicron outbreak beginning in late December 2021, and PEM rose to nearly 10% in the last 322 two weeks of 2021. As Australia continued its LWC policy, the impact of Omicron was 323 324 significantly enhanced, with a peak PEM at about 56.12% in January 2022 (week 3, 2022) and an average of 39.85% from January and March 2022 (weeks 1-13, 2022). The second wave of 325 the Omicron outbreak (March - August 2022) achieved a peak PEM of 44.65% (Week 24, 2022) 326 327 and an average PEM of 35.68% (Weeks 11-30, 2022) (Figure 3B). The second Omicron outbreak lasted until the end of August 2022. However, all-cause death data beyond August 1, 328 329 2022, was not released by the government, so PEM analysis in this study covered up to July 2022. The current data showed that PEM increased significantly after the policy transition 330 during two waves of the Omicron outbreak. In addition, under the LWC policy, average PEM 331 decreased in response to two Omicron outbreaks. Furthermore, PCEM curve was significantly 332 333 lower than PEM curve (Figure 3B), suggesting that a good number of deaths were caused by COVID indirectly under the LWC policy. It might be attributed to the overwhelmed medical 334 335 resources or the under quantification of COVID-associated deaths. Collectively, the LWC policy in Australia failed to control the mortality burden well. Average PEM decreased slightly 336 in response to two subsequent Omicron outbreaks that occurred in early and late 2022, which 337 might be due to a decreasing virulence of the virus and the potential development of herb 338 immunity through acquired immunity and vaccine inoculation. 339

347

 New Zealand: <u>PEM in New Zealand under the ZC policy fluctuated around 0%, and</u> most of the time, it did not exceed 10%. After shifting to the LWC policy, New Zealand encountered Omicron outbreaks. <u>PEM averaged at 9.48% and 7.67% in early and late</u> 2022, respectively.

New Zealand had a population of 5.090 million as of 2020 (18) and a population density of 19 352 people per square kilometer (19). From January 2020 to November 2021, New Zealand 353 effectively implemented the ZC policy. The total confirmed cases were nearly 120,000, and 354 the total COVID-associated deaths were 44 during this ZC policy period (Figure 4A). On 355 December 3, 2021, New Zealand implemented the LWC policy. Then it encountered two waves 356 of Omicron outbreak. The first began in February 2022 and lasted until the end of April 2022, 357 with more than 20,000 daily confirmed cases (Figure 4A) and 10-20 daily COVID-associated 358 deaths. The second Omicron outbreak (June - August 2022) experienced 5000-10,000 daily 359 360 confirmed cases and about 10 daily COVID-associated deaths (Figure 4A).

Using the weekly death data in New Zealand provided by the Human Mortality Database (which has been collated with the data published by the New Zealand government) (21), a PEM curve from January 2020 to October 2022 (week 3, 2020 - week 43, 2022) was obtained and shown in Figure 4B. PEM under the ZC policy before December 2021 fluctuated around 0%

perpetuity. It is made available under a CC-BY-NC 4.0 International license .

and remained below 10% (Figure 4B). After transitioning to the LWC policy on December 3, 365 2021, New Zealand experienced a relatively long period of a steady phase from December 366 2021 (week 47) to late-February 2022 (week 9) until the beginning of the Omicron outbreak. 367 Starting in week 10 in 2022, PEM exceeded 10% and continued to rise to a peak at about 16.53% 368 in week 12. The average PEM during the Omicron outbreak (weeks 8-20, 2022) was 9.48% 369 (Figure 4B). The second Omicron outbreak began in June 2022 and lasted until August 2022, 370 and the peak PEM was 18.77% (Week 30, 2022), and the average PEM was only 7.67% (Weeks 371 372 21-33, 2022) (Figure 4B).

In our analysis, New Zealand is the only country that achieved approximately 10% average PEM during the Omicron outbreak under the LWC policy, which might be a result of the ultrahigh vaccination rate, especially among the elderly. There was no significant difference between PCEM and PEM curves (Figure 4B), suggesting that data on COVID-associated deaths well reflected the mortality burden attributed to COVID-19. Collectively, the LWC policy in New Zealand in the examined period acceptably succeeded in controlling the mortality burden.

380

Figure 4. COVID-19 pandemic and mortality statistics in New Zealand. (A) SARS-CoV-2 confirmed cases (black) and COVID-associated deaths (blue) from January 22, 2020, to November 20, 2022 (17). (B) Percent excess mortality (weekly) from week 3, 2020 to week 43, 2022 and percent COVID-excess mortality (weekly) during the living-with-COVID policy period from week 47, 2021 to week 43, 2022. perpetuity. It is made available under a CC-BY-NC 4.0 International license .

 Hong Kong: <u>PEM under the ZC policy before 2022 fluctuated and remained</u> approximately about 10% most of the time. However, during the outbreak of the Omicron variant, the average PEM was 71.14% in the first half of 2022 and decreased to 9.19% in the second half.

392 Hong Kong had a population of 7.481 million as of 2020 (18) and a population density of 7,126 people per square kilometer (19). Hong Kong has implemented the ZC policy since January 393 2020. Before Omicron struck at the beginning of February 2022, Hong Kong underwent a 394 period of a stationary state of the pandemic with total confirmed cases of nearly 15,000 and 395 total COVID-associated deaths of 213 (Figure 5A), proving the effectiveness of the ZC policy. 396 397 Then, from March to the mid-May 2022, Hong Kong experienced a major wave of Omicron outbreak, with over 1.2 million confirmed cases and more than 9000 COVID-associated deaths 398 total (Figure 5A). Then Hong Kong experienced a second wave in August and September 2022, 399 400 with 400,000 confirmed cases and more than 600 COVID-associated deaths total (Figure 5A).

Using the monthly death data published by the Hong Kong government for analysis (22), a 401 PEM curve from January 2020 to September 2022 was obtained and shown in Figure 5B. PEM 402 under the ZC policy before February 2022 fluctuated and remained approximately about 10% 403 404 most of the time. The periods with about 20% PEM mainly corresponded to several waves of 405 SARS-CoV-2 in the first two years of the pandemic. Considering the high population density in Hong Kong, the containment measures against COVID-19 executed by the government 406 407 before February 2022 were acceptable. However, a major wave of the Omicron variant 408 breached the long streak of the stationary phase with a peak PEM of 102.77% in March 2022 and an average PEM of 71.14% (March-May 2022) (Figure 5B). Then, in August and 409 September, Hong Kong experienced another wave of Omicron outbreak with a peak and an 410 average PEM of 18.17% (September 2022) and 9.19% (August -September 2022) (Figure 5B). 411 Data on all-cause mortality from October 1, 2022, onwards were still unavailable from the 412 government website. Even under the ZC policy, Hong Kong failed to control the spread of the 413 Omicron variant in early 2022. The Omicron surge could be attributed to its high population 414 density, the low vaccination rate among the elderly (23), the highly contagious variant, and 415 increased social mixing during the lunar new year. The outbreak in Hong Kong aroused endless 416 417 debates on the ZC policy and its effectiveness in preventing a variant as contagious as Omicron. 418 The current data showed that PEM increased greatly in response to the Omicron outbreak in early 2022. However, PEM decreased significantly in late 2022 when encountering another 419 420 wave of Omicron outbreak. Furthermore, PCEM curve was considerably higher than PEM 421 curve in February and March 2022 (Figure 5B), suggesting that a good number of reported COVID-associated deaths might be overreported. It might be because Hong Kong counted 422 patients who "died with COVID" into the pool of "COVID-associated deaths." Then, PEM 423 curve became higher than PCEM curve, indicating an under quantification of COVID-424 associated deaths. Collectively, the specialized ZC policy in Hong Kong was unsuccessful in 425 controlling the mortality burden during the Omicron outbreak in the first half of 2022. Average 426 427 PEM decreased as progressed into the second half of 2022 due to the reduced pathogenicity of the virus and the potential development of herd immunity. 428

436

Discussion 437

The goal of this study is to delineate a threshold of PEM as a criterion to assess the effectiveness 438 of different anti-pandemic policies in response to different variants of viruses. During the 439 implementation of the ZC policy, PEM in various countries did not exceed 10% most of the 440 time. Occasionally it fluctuated around 10% for a short time and then quickly declined. After 441 shifting to the LWC policy, PEM increased significantly and exceeded 10% in early 2022. 442 Detailed summary of PEM data for each country/region is listed in Table 2. Thus, when PEM 443 is kept roughly at or below 10%, the mortality burden during the COVID pandemic could be 444 considered acceptable to the public, government officials, and healthcare professionals, etc. 445 Therefore, the PEM threshold of 10% might be set as a criterion to assess the effectiveness of 446 anti-pandemic policies in controlling the mortality burden. Furthermore, the policymakers are 447 suggested to control the PEM within 10% during outbreaks. 448

The four countries analyzed in this study can be classified into two groups: Singapore and 449 South Korea, which are high in population density, influenced by Confucian culture, and are 450 located in the northern hemisphere, as group A; while Australia and New Zealand, which are 451

- low in population density, influenced by Anglo-Saxon culture and are located in the southern 452
- hemisphere, as group B. Countries in group A dealt with both Delta and Omicron variants while 453

medRxiv preprint doi: https://doi.org/10.1101/2022.08.31.22279422; this version posted November 28, 2022. It is made available under a CC-BY-NC 4.0 International license .

those in Group B only dealt with the Omicron variant. Peak PEM in Group A was 16-30% and 454 30-70% in response to the Delta and the Omicron variants, respectively. Regarding countries 455 456 in Group B and their responses to the Omicron variant, Australia had a PEM of about 10% at the beginning of the outbreak, which later exceeded 10% and reached over 50%. New Zealand 457 maintained a low average PEM of almost 10%, with a peak of 16.69%. Collectively, it is 458 relatively challenging for Group A countries to control the PEM below 10% during the 459 Omicron era. From the mortality burden standpoint, Group A countries/regions may implant 460 the LWC policy without sufficient preparation, which will lead to a high mortality burden in 461 early 2022. While for Group B countries, New Zealand set a good model of exercising LWC 462 policy during omicron outbreaks, which could be learned by other countries/regions with low 463 464 population density.

PEM during the omicron outbreak was not less than that during Delta outbreaks in Group A 465 countries (Figure 1B, 2B). The difference in PEM in response to the Omicron variant between 466 Group A and New Zealand was mainly due to differences in population density (24). In addition, 467 the higher PEM in Group A countries can be largely attributed to the following factors. First, 468 469 influenced by the Confucian culture, multigenerational households are more common, which leads to over-crowdedness and increase the risk of COVID-19 transmission and infection (25). 470 Second, the northern hemisphere was experiencing winter during the Omicron outbreak, which 471 was associated with a surge of COVID-19 infections and deaths (26). Such association can be 472 attributed to biological factors, including the susceptibility of COVID viruses to heat and UV-473 radiation (27, 28), and behavioral factors, such as the tendency to have more gatherings in 474 475 crowded indoor areas in cold weather.

Hong Kong has been implementing a ZC policy throughout the entire period of the pandemic. 476 477 The spread of the virus was well controlled in the first two years of the pandemic until the Omicron outbreak. The surge of Omicron in Hong Kong was partially due to low vaccination 478 479 coverage, especially among the elderly population. By December 23, 2021, 52% of vaccine-480 eligible individuals received at least one dose, and 49% received at least two doses, of which 481 only 7% received a booster dose for those aged 60 years and above, (23). 96% of COVIDassociated deaths during January 6 – March 21, 2022, happened to those elders aged \geq 60 years, 482 483 while 70% of this age group were unvaccinated (23). In contrast, New Zealand, as the only country with an average PEM of 10% during the Omicron outbreak under the LWC policy in 484 our analysis, benefited from the ultrahigh vaccination rate, especially among the elderly (96.5% 485 were fully vaccinated for elders above 60 years old and > 90% were boosted for these above 486 70 years old) (29) (Data were extracted on May 3, 2022). In agreement with multiple studies, 487 a high vaccination rate is associated with low excess mortality and is an essential indicator of 488 adjusting anti-pandemic policy (4, 30). The underlying reasons for the low vaccination in Hong 489 Kong rate remained unclear. Still, it was possibly due to vaccine hesitancy caused by the 490 491 inefficiency in vaccination promotion and the widespread misunderstandings of the side-effects of COVID vaccines (23, 31). In addition, the Chinese Lunar new year, which coincided with 492 the Omicron outbreak, facilitated the spread of the virus owing to increased gatherings among 493 families and friends. Also, although both were named the "ZC policy," the precautionary 494 495 measures implemented by Hong Kong were different and less strict than those in mainland 496 China, which might also fail to control the Omicron surge.

Since the emergence of the Omicron variant, there have been endless debates on public health 497 498 policies. As most countries transitioned to the LWC policy, countries/regions that insisted on the ZC policy were thrust into the limelight. Numerous parties have criticized government 499 officials' authoritarian rules imposed on the general public and blamed that the ZC policy 500 501 lacked basic humanity without considering the specific local conditions, such as population density, population structure, vaccination coverage, availability of healthcare resources, and 502

perpetuity. It is made available under a CC-BY-NC 4.0 International license .

culture, etc. To ease the evaluation process, we proposed a PEM threshold of 10% as a standard 503 to assess the effectiveness of any anti-pandemic policy from the perspective of whether the 504 mortality burden of the pandemic was tolerable to the society. The analysis of PEM was simple 505 yet efficient and provided a preliminary evaluation of the feasibility of the policy. Although 506 collectively named the LWC policy, the content and stringency highly varied among 507 countries/regions. Thus, it is not a matter of implementing which policy but rather of rules and 508 regulations that can effectively minimize the mortality burden on society during the pandemic. 509 510 We suggest that anti-pandemic policies be adjusted to achieve a PEM of 10%.

511

In addition, we found that PEM during Omicron outbreaks in early 2022 was not less than that 512 during Delta outbreaks, suggesting that Omicron should not be the key reason for the policy 513 transition towards LWC. However, PEM decreased significantly from early to late 2022 in all 514 studied countries/regions, suggesting that the mortality burden in response to the Omicron 515 outbreak fell, which might be due to the following factors. First, herd immunity was developed 516 along the pandemic's progression as more individuals acquired immunity through infection or 517 vaccination (32). Second, the COVID virus variant evolved with reduced pathogenicity, 518 significantly decreasing deaths and severe cases (33). Third, the government was more prompt 519 520 in adjusting anti-pandemic policies, including enhanced regulation on infectious individuals, to encounter each COVID outbreak. The mortality burden caused by COVID-19 was reduced 521 over time, laying a great foundation to call for further relief of LWC policy in the near future. 522 523 In the long run, the world may eventually have to coexist with the COVID virus. Still, the preconditions of transitioning to a LWC policy need to be examined, and high vaccination 524 coverage is a crucial requirement. PEM can serve as a reference, but further research to identify 525 526 more dimensions to assess the impact of the disease is needed for better policy-making and implementation. 527

528

There are some limitations in this study. First, PEM is calculated using the all-cause mortality 529 reported by official statistics. Therefore, the practicality and validity of PEM-based analysis 530 depend on the infrastructure and capacity to record and report mortality in each location. In 531 addition, the frequency of data reporting affects the accuracy of data as monthly death reports 532 533 tend to even out any fluctuations in weekly death reports and result in underestimation. Second, to simplify the evaluation, we did not consider the impact of the economy on health and 534 mortality in the long run. Studies from other angles like economy and life quality are needed 535 to help develop appropriate policies during the pandemic. 536

Figure 1 COVID-19 pandemic and mortality statistics in Singapore. (A) SARS-CoV-2 confirmed cases (black) and COVID-associated deaths (blue) from January 22, 2020, to Novemver 20, 2022 (17). (B) Percent excess mortality (monthly) from January 2020 to September 2022 and percent COVID-excess Mortality (monthly) during the living-with-COVID policy period from August 2021 to September 2022. The dotted line is the 10% percent excess mortality/percent COVID-excess mortality line.

Figure 2 COVID-19 pandemic and mortality statistics in South Korea. (A) SARS-CoV-2 confirmed cases (black) and COVID-associated deaths (blue) from January 22, 2020, to November 20, 2022 (17). (B) Percent excess mortality (weekly) from week 3, 2020 to week 39, 2022 and percent COVID-excess mortality (weekly) during the living-with-COVID policy period from week 44, 2021 to week 39, 2022. The dotted line is the 10% percent excess mortality/percent COVID-excess mortality line.

Figure 3 COVID-19 pandemic and mortality statistics in Australia. (A) SARS-CoV-2 confirmed cases (black) and COVID-associated deaths (blue) from January 22, 2020, to November 20, 2022 (17). (B) Percent excess mortality (weekly) from week 3, 2020 to week 30, 2022 and percent COVID-excess mortality (weekly) during the living-with-COVID policy period from week 40, 2021 to week 30, 2022. The dotted line is the 10% percent excess mortality/percent COVID-excess mortality line.

Figure 4 COVID-19 pandemic and mortality statistics in New Zealand. (A) SARS-CoV-2 confirmed cases (black) and COVID-associated deaths (blue) from January 22, 2020, to November 20, 2022 (17). (B) Percent excess mortality (weekly) from week 3, 2020 to week 43, 2022 and percent COVID-excess mortality (weekly) during the living-with-COVID policy period from week 47, 2021 to week 43, 2022. The dotted line is the 10% percent excess mortality/percent COVID-excess mortality line.

Figure 5 COVID-19 pandemic and mortality statistics in Hong Kong. (A) SARS-CoV-2
confirmed cases (black) and COVID-associated deaths (blue) from January 22, 2020, to
November 20, 2022 (17). (B) Percent excess mortality (monthly) in Hong Kong from January
2020 to September 2022 and percent COVID-excess mortality (monthly) from January 2022
to September 2022. The dotted line is the 10% percent excess mortality/percent COVID-excess
mortality line.
