The real-world protection rates of vaccination (VPRs) against the SARS-Cov-2 infection are 7 critical in formulating future vaccination strategies against the virus. Based on a varying co-8 efficient stochastic epidemic model, we obtain seven countries' real-world VPRs using daily 9 epidemiological and vaccination data, and find that the VPRs improved with more vaccine 10 doses. The average VPR of the full vaccination was 82% (SE: 4%) and 61% (SE: 3%) 11 in the pre-Delta and Delta-dominated periods, respectively. The Omicron variant reduced 12 the average VPR of the full vaccination to 39% (SE: 2%). However, the booster dose re-13 stored the VPR to 63% (SE: 1%) which was significantly above the 50% threshold in the 14 Omicron-dominated period. Scenario analyses show that the existing vaccination strategies 15 have significantly delayed and reduced the timing and the magnitude of the infection peaks, 16 respectively, and doubling the existing booster coverage would lead to 29% fewer confirmed 17 cases and 17% fewer deaths in the seven countries compared to the outcomes at the existing 18 booster taking rates. These call for higher full vaccine and booster coverage for all countries. 19

^{*}corresponding authors

The SARS-Cov-2 has been circulating globally with a sequence of emerging variants since 20 the start of the pandemic. Particularly, the Delta and Omicron variants have contributed to surges 21 in the infected cases across the globe due to their high transmissibility^{1,2}. To prevent the spread 22 of COVID-19, vaccines have been rolled out since later 2020, while the booster shots were started 23 since June 2021. Clinical trials or observational studies have been made to evaluate the effects 24 of a vaccine or an arrangement of mixed vaccines³⁻⁹. It is found that the vaccine efficacies of 25 the two-dose vaccination against the original SARS-Cov-2 strain ranged from 50.7% to 95%^{3,4,10}, 26 but waned against Delta and Omicron variants. The vaccine effectiveness ranged from 82.8% to 27 94.5% against Delta and 48.9%-75.1% against Omicron for two doses of Pfizer, AstraZeneca or 28 Moderna vaccines⁸. The vaccine efficacy is defined as one minus the relative risk in the randomized 29 controlled clinical trials¹¹, and the vaccine effectiveness is valued in observational studies, which is 30 one minus the hazard ratio in cohort studies⁶ and one minus the odds ratio in case-control studies⁵. 31 Observational studies were more common in the Omicron era. 32

The booster dose had been shown to increase protection against infection. For homologous 33 or heterologous booster doses of Pfizer, AstraZeneca and Moderna, the effectiveness was 82.3%-34 97.0% against Delta and 55.6%-73.9% against Omicron, with higher effectiveness using Moderna 35 as the heterologous booster dose⁸. The vaccine effectiveness was 51.0% for three doses of Sinovac 36 against Omicron¹², which increased to 63.6% by Sinovac as primary with one Pifzer booster ¹³. 37 See Table S1 in the supplementary for the detailed vaccine efficacy and effectiveness discovered by 38 the existing clinical and observational studies. However, the real-world performance of vaccines 39 at the country's population level which we call the vaccine protection rate is largely unknown. 40

Different from vaccine efficacy and effectiveness, the real-world vaccine protection rate 41 (VPR) is defined as one minus the percentage reduction in the infection rate of the vaccinated rel-42 ative to the unvaccinated population of a country. The VPR measures the combined effectiveness 43 of vaccines administrated in a country at a particular age distribution and nonpharmaceutical in-44 tervention measures against COVID-19. The impacts of these factors are not necessarily evaluated 45 in the homogeneous clinical trials, cohort studies or case-control studies. Indeed, the conventional 46 vaccine efficacies are pegged to a specific vaccine or a mix of vaccines in the clinical trials after ex-47 cluding certain part of the population, which may not conform to the population characteristics of 48 the country. Therefore, the available vaccine efficacy or effectiveness does not necessarily reflect 49 the vaccine immunity level of the whole population against different variants of the SAR-COV-2 50 virus. Hence, it is useful to obtain the real-world VPRs of a country. 51

Using the daily epidemiological and vaccination data, which include the cumulative numbers 52 of confirmed cases, deaths, recoveries, and people having received the partial, full and booster vac-53 cination, we construct a varying coefficient stochastic epidemic model with eleven compartments 54 (flow diagram in Figure 4) and develop an estimation procedure for the real-world VPRs as well 55 as the key parameters quantifying the dynamic infection, death and recovery rates, which compre-56 hensively reflects the COVID-19 dynamics and nonpharmaceutical interventions (NPI). Compared 57 with existing studies on the effect of vaccination^{14,15}, we do not assume permanent and full immu-58 nity of the vaccines and previous infection while incorporating the stochastic natures of the epi-59 demics with time-varying infection rate due to varying levels of NPI and self protective measures, 60 and allow asymptomatic infection, infection before clinic confirmation, vaccine breakthrough, re-61

⁶² infection and different levels of immunity induced by different vaccine doses. The non-parametric
 ⁶³ time-varying infection rate in our model is better suited for the COVID-19 pandemic as both the
 ⁶⁴ virus transmission rate and the NPI measures change over time.

We considered seven countries that are representative for different types of vaccines with 65 sufficient number of confirmed cases (more than 10% of the total population) after vaccination. 66 Specifically, the results of the US may be used to show the effect of mRNA vaccines (Pfizer 67 and Moderna); the three European countries, UK, Italy and Germany, mainly used a mixture of 68 non-replicating viral vector vaccines (AstraZeneca) and mRNA vaccines; the two south American 69 countries, Brazil and Peru, utilized the inactivated vaccines (Sinopharm and Sinovac), AstraZeneca 70 and Pfizer; Turkey used the inactivated vaccines at the beginning and then started Pfizer. In this 71 paper, the full dose means one dose for Janssen and two doses for the other brands to complete the 72 primary vaccination. Those who have not completed the full vaccination are called partially vac-73 cinated. The booster shot means one dose after full vaccination. The coverage rates of the partial, 74 full and booster vaccines in population are reported in Figure 3 (a), which shows 62.3%–79% of 75 the population in the seven countries have taken the full shots on March 15 2022, but the coverage 76 rates of booster shots were much lower, ranging between 29.1% in the US and 63.4% in Italy. 77

78 **Results**

For each country, we estimate the vaccine protection rates in six consecutive non-overlapping post vaccine periods: the pre-Delta, Intervening I, Delta-dominated, pre-Omicron, Intervening II and

⁸¹ Omicron-dominated periods. Details of these periods are provided in the method section.

Vaccine protection rates. The real-world VPRs for the partial, full and booster vaccination in the 82 seven countries in the six post-vaccine periods are reported in Figure 1 with detailed numerical val-83 ues in Table S3. It shows that before the booster vaccination, both the partial and full vaccination 84 were largely protective against the COVID infection in the pre-Delta period with the VPRs in the 85 seven countries ranging 48%-64% and 68%-95% for the partial and full vaccination, respectively. 86 However, the Delta variant had caused waning VPRs of the partial and full vaccination. Specifi-87 cally, the average VPR of the partial vaccination decreased from 57% (SE: 2%) in the pre-Delta 88 period to 40% (SE: 2%) in the Delta-dominated period, suggesting that only the partial shot was 89 insufficient to protect against the Delta variant. Despite the Delta-variant also reduced the average 90 VPR of the full dose from 82% (SE: 4%) in the pre-Delta period to 61% (SE:3%) in the Delta-91 dominated period, the average VPR of the full vaccination still stayed above the WHO recognized 92 50% level of vaccine efficacy in most countries except Turkey (Figure 1). The coming of Omicron 93 had reduced the VPRs of the partial and full vaccination in the seven countries to less than 50%. 94 In the Intervening II period, the VPRs were 5.5%-34% (Average: 22.2%, SE: 4.0%) for partial 95 vaccination, and 37%-56% (Average: 49.1%, SE: 2.3%) for full vaccination. When the Omicron 96 variant became prevalent, VPRs were even lower, which were 3.8%-28.5% (Average: 11.5%, SE: 97 3.3%) and 26%-45% (Average: 38.6%, SE: 2.4%) for the partial and full vaccination, respectively. 98

⁹⁹ The booster shot was started in the pre-Omicron period when the Delta was dominant. Our ¹⁰⁰ study shows that it readily restored the VPRs to 78.8%-97% (Average: 83.3%, SE: 2.3%), which

Figure 1: Estimated vaccine protection rates of partial, full and booster vaccination in the seven countries over the six periods with the 95% confidence interval bars. The vaccines used are reported in the parentheses (AZ: AstraZeneca, JS: Janssen, MD: Moderna, NV: Novavax, PZ: Pfizer, SNP: Sinopharm, SNV: Sinovac, TKV: Turkovac).

means that the booster vaccination's VPRs were 20.5%-31.8% (Average: 26.8%, SE: 1.2%) higher
than those of the full vaccination against the Delta variant. In the Omicron-dominated period, the
booster shot's VPRs ranged 55.6%-67.0% (Average: 63%, SE: 1.4%), largely stayed above the
50% threshold. These suggest that the booster shot provided enhanced and effective protection
against both the Delta and Omicron variants.

Impacts of Full and Booster Vaccines. To further evaluate the protection of the COVID-19 vac-106 cination, we investigate the impacts of the full and the booster vaccination on the size of the epi-107 demics and deaths. Five vaccination scenarios were designed: (i) no vaccination at all; (ii) receiv-108 ing the partial but no full vaccination; (iii) receiving the partial and full vaccination but no booster 109 shots; receiving the booster shots only at the half (iv) and twice (v) of the actual daily booster 110 coverage rates. The impacts of these scenarios were projected using the stochastic epidemic model 111 with the estimated parameters for each country. See the specific designs of the scenario analysis 112 (SA) in Section S5 of the supplementary material (SM). 113

The projected cumulative confirmed cases and deaths from the start of vaccination to the start of boosters for the seven countries under the no vaccination (i) and only the partial vaccination (ii) scenarios are shown in Figure 2 (a) and (b) with the detailed numerical values listed in Table S4. It shows that no vaccination at all would bring, respectively, 112918 (CI: 96142-129695, Percentage: 242%) and 825 (CI: 630-1020, Percentage: 83%) thousands increase in the cumulative confirmed cases and deaths in the seven countries relative to the observed values under the actual vaccination arrangement. Under the only partial vaccination, the cumulative confirmed cases and deaths would

Figure 2: Radar plots on the proportions of the projected cumulative numbers of confirmed cases and deaths under two sets of scenario analyses (SA): the pre-booster vaccine periods under no and partial vaccination (a, b) and the post-booster periods under the no, half and twice booster up-take scenarios (c, d), relative to their respective observed values in the seven countries. The 100% gray dashed circles represent the observed situations.

increase by 39697 (CI: 30105-49289, Percentage: 85%) and 218 (CI: 124-312, Percentage: 22%)
thousands, respectively, in the seven countries. These two scenario analyses show the significant
benefit of the partial and the full vaccination.

The less amount of increase in the confirmed cases and deaths under the no and partial 124 vaccination scenarios in Peru was due to its low and slow pace of vaccination, with only 6% and 125 3% of the population having received the partial and full vaccination within the first 100 days 126 of vaccination. In contrast, 13.4%-18.9% and 5.5%-13.9% of the populations had been partially 127 and fully vaccinated in Germany, Italy, Brazil and Turkey, and the US and UK had the highest 128 vaccination rates of 27.7%-48.1% and 15.5%-15.9% for the partial and full vaccination over the 129 same period (Figure 3 (a)). That US and UK had the highest vaccination rates in the first 100 days 130 led to much higher numbers of cases and deaths under the no and partial vaccination scenarios in 131 Figure 2 (a) and (b), as compared with the other countries. 132

Figure 2 (c) and (d) display the projected cumulative confirmed cases and deaths from the 133 start of booster shots to March 15, 2022 under the scenarios (iii)-(v) regarding the booster vacci-134 nation which kept the observed numbers of the partial and full doses as the baselines; see Table 135 S5 for the detailed numerical values. It is shown that during the post-booster periods, not having 136 the booster shots at all would mean 34860 (CI: 23543-46177) and 143 (CI: 88-198) thousands 137 more confirmed cases and deaths, respectively, in the seven countries, amounting to 36% and 26% 138 increases in the total confirmed cases and deaths, respectively. In the half-booster scenario, the 139 increases in the confirmed cases and deaths would be less than those under the no-booster case, but 140

still translate to 14587 (CI: 8024-21150, Percentage: 15%) and 66 (CI: 29-103, Percentage: 12%)
thousands more confirmed cases and death relative to the observed numbers, respectively, for the
seven countries in the post-booster period.

If the booster taking rates were doubled, we see decreases of 27679 (CI: 21234-34124, Per-144 centage: 29%) and 94 (CI: 62-126, Percentage: 17%) thousands in total confirmed cases and deaths 145 for the seven countries in the post-booster period. It is noted that the relatively large reductions in 146 the confirmed cases and deaths in Germany, Italy, Turkey and UK under the double booster sce-147 nario were due to their actual higher (more than 40%) rates of taking the booster shots by March 148 15, 2022 (Figure 3 (a)). In contrast, the US, Brazil, Peru had lower booster taking rates, which 149 led to smaller amount of reductions in the confirmed cases and deaths as compared to the other 150 countries. 151

To further evaluate the dynamics of the COVID-19 epidemics with respect to different vacci-152 nation strategies, we report in Figure 3 (b) the observed and the projected daily numbers of active 153 confirmed cases (those confirmed infective people who have not recovered or died), to reflect the 154 potential real-time demand on the hospital system under the five scenarios. It shows that, compared 155 to the observed time series of the active confirmed cases, the peaks of the active confirmed cases 156 would be much elevated and happen much earlier under the no and partial vaccination scenarios. 157 In particular, the numbers of active confirmed cases in Germany, Italy, Turkey, the UK and the US 158 would peak when the Delta was dominant. It also shows that the full and the booster shots signifi-159 cantly delayed the timing and flattened the magnitude of the infection peaks in the seven countries, 160

Figure 3: (a) Daily population proportions receiving at least one (red), full (blue) and booster (green) dose of vaccines. The dashed vertical lines mark March 15 and July 17, 2022. (b) The actual (black dashed lines), and the projected daily numbers (in millions) of active confirmed cases (color curves) and their 95% confidence bands (color area) under the five vaccination scenarios.

and in particular, protected the populations in the more lethal pre-Omicron era. As shown in Table S6, the projected numbers of active confirmed cases would exceed the observed peaks for 70-111, 65-156, 23-59 and 0-42 days with the projected peaks being 1.7-9.4 (Mean 4.1, SE 1.1), 1.2-7.0 (Mean 3.5, SE 0.9), 1.2-1.8 (Mean 1.4, SE 0.06) and 1.0-1.3 (Mean 1.1, SE 0.04) times the observed peaks under the no vaccination, partial vaccination, no booster and half booster scenarios, respectively. Those indicate the effect of the vaccination potentially avoided severe runs on the health system of the seven countries.

Comparing the actual observations with the three scenarios regarding the booster shot taking, the peak values of active confirmed people in the seven countries would increase by 23%-78% (Mean: 43%, SE: 6%) under the no booster scenario, and decrease by 26%-63% (Mean: 41%, SE: 5%) relative to the observed peaks under the twice booster scenario, which verifies the booster does can further relieve the pressure on the healthcare system in the Omicron era due to its higher VPRs against the Omicron variants as reported in Figure 1.

It is noted that in Italy the projected peak under the partial vaccination scenario was higher than that under the no vaccination in the Intervening II period. This was due to that a considerable proportion of population would have been infected in the Delta-dominated period under the no vaccine scenario, and Italy had the highest rate of partial vaccination before the Intervening II period among the seven countries (Figure 3 (a)). However, the immunity acquired from the partial vaccination gradually expired without further injected immunity from the full dose. This would lead to a rebound in the numbers of susceptibles, even exceeding those under the no vaccination scenario as

shown in Figure S1. This result suggests the importance of acquiring additional immunity through
full and booster doses.

183 Discussion

This study targets the population protection rates of vaccines. Although the vaccine efficacies are 184 different between different age groups, our results reveal the overall protection rates of a country, 185 which are informative on the total infection size and the demand on the health resources of a coun-186 try. It is shown that the real-world vaccine protection rates (VPRs) of the partial, full and booster 187 vaccination decreased with time. The full vaccination was effective before Omicron with the VPRs 188 stayed above 50%, which became insufficient when the Omicron was dominant. The booster shot 189 was effective in slowing down the epidemics in both the Delta and Omicron-dominated periods 190 with the average VPRs well above the 50% threshold. Our results on the real-world VPRs were 191 consistent with the vaccine effectiveness in the existing cohort or case-control studies ^{9,12,16}. The 192 necessity of the full and the booster vaccination are further highlighted by significant reductions in 193 daily numbers of active confirmed cases in the scenario analyses. 194

¹⁹⁵ Two sets of sensitivity analyses have been conducted to explore the impact of the uncertainty ¹⁹⁶ associated with model parameters for the daily asymptomatic rate $1 - \theta_t$ and the average time ¹⁹⁷ duration μ_r from recovery to loss of natural immunity (average duration for reinfection) on the ¹⁹⁸ estimated VPRs. The sensitivity analyses show that the average absolute differences between the ¹⁹⁹ VPRs by using different values of the daily asymptomatic rate and the average duration for rein-

fection were 1.26% (SE: 0.23%) and 0.94% (SE: 0.17%), respectively, indicating the robustness of
the estimated VPRs with respect to the two key parameters.

Despite the effectiveness of the booster shot in the Omicron era, the booster vaccine coverage 202 had a rather slow pace of growth with less than 9% increase from March 15 2022 to July 17 2022 203 in Italy, Turkey, the UK and the US, as shown in Figure 3 (a). The booster coverage was 37.6% 204 on July 17, 2022 in the US, which was only increased by 8.5% over the four months since March 205 15 2022, and the UK's increased only 3.1% over the same period. Thus, there is ample room 206 for vigorous promotion of booster shots in all countries to realize their benefits in reducing both 207 the size of the epidemics and death. The encouraging effects of the booster shots also encourage 208 consideration for another dose after the booster shot to cope with the continuing evolution of the 209 SARS-Cov-2 viruses. 210

211 Methods

The study period in this research is from the start of the vaccine in a country to March 15, 2022, 212 while part of the pre-vaccine period was considered for model parameter estimation. For each 213 country, we divide the post-vaccine era into six consecutive non-overlapping periods: the pre-214 Delta period from the start of vaccination till the Delta variant was first detected in the country, the 215 following intervening period (Intervening I) until the Delta variant became predominant (more than 216 50% of the daily detected cases), the Delta-dominated period when the majority of the cases were 217 caused by the Delta variant till the start of booster shots, the pre-Omicron period from the start 218 of booster shots till the Omicron variant was first detected, the intervening period (Intervening II) 219

till Omicron became predominant, the Omicron-dominated period when the majority of the cases were caused by the Omicron variant. It is noted that the dominated variant was still Delta in the pre-Omicron period in the seven countries. Since the start of the booster shot (June 21, 2021) was close to the date (June 29, 2021) when the Delta variant began to dominate in Turkey, we merged its Delta-dominated period and pre-Omicron period, which makes Turkey have only five periods. The key dates of these periods are provided in Table S2 in the SM.

We estimate the real-world VPR by building a stochastic epidemiological model with elevencompartments to quantify the epidemic process and developing a novel estimation procedure for its parameters.

Figure 4: Compartments and their structure flows of the proposed epidemiological model, where the compartments V_0 and V_e constitute state $S = V_0 + V_e$ of currently uninfected people without immunity, and φ_1 , φ_2 and φ_3 are the parameters representing vaccine protection rates.

Stochastic epidemiological model. The stochastic epidemiological model describes the spread 229 of the SARS-CoV-2 virus and the daily increase of infected cases in a country. The compart-230 ments and flows between compartments are shown in Figure 4. The model allows non-permanent 23 vaccine and natural immunity, breakthroughs in vaccinated people, and being asymptomatic and 232 infectious before clinical diagnosis (pre-symptomatic). The susceptible population are divided into 233 five compartments, the ones with no, partial, full and booster vaccine immunity and the ones who 234 have been vaccinated but lost vaccine immunity or have recovered from previous infection but 235 lost natural immunity, in the top row of Figure 4. The currently uninfected compartment without 236 vaccine or natural immunity consists of unvaccinated people, the vaccinated people with expired 237 vaccine immunity and the recovered with expired natural immunity; see the SM for the specific ar-238 rangement on the vaccine expiration parameters μ_1 , μ_2 and μ_3 , and the parameter of losing natural 239 immunity μ_r . The latter is responsible for reinfection. The uninfected individuals may catch the 240 virus by contacting with the infected which are divided into three compartments: asymptomatic, 241 pre-symptomatic and diagnosed. Asymptomatic cases represent the ones show no symptoms and 242 do not take a test. The pre-symptomatic period stands for the period after infection but before lab 243 confirmation. The pre-symptomatic cases would be diagnosed at the rate $\alpha \in (0, 1)$, where $1/\alpha$ 244 represents the average days between being infected and lab diagnosis. 245

Following the set up of the infection rates for different stages of infections¹⁷, we assume the pre-symptomatic compartment is five times more infectious than the asymptomatic and diagnosed compartments, as diagnosed cases would take precautions and quarantine at home, and asymptomatic cases have no symptoms and should be less infectious. Let M be the total population size,

 β_t denote the time-varying infection rate of the pre-symptomatic cases, and $\tilde{I}(t)$ be the standard-250 ized total infection load, which is equal to the size of the pre-symptomatic compartment divided by 25 M plus those of the asymptomatic and diagnosed compartments divided by 5M. Allowing time-252 varying infection rate (β_t) is needed as government and citizens' responses to COVID-19 change 253 over time and the virus itself keeps mutating. We assume the daily new infections from the sus-254 ceptible groups without vaccine or natural immunity, and with partial, full and booster vaccine im-255 munity follow conditional Poisson distributions with means equal to $\beta_t \tilde{I}(t)$, $\varphi_1 \beta_t \tilde{I}(t)$, $\varphi_1 \varphi_2 \beta_t \tilde{I}(t)$ 256 and $\varphi_1 \varphi_2 \varphi_3 \beta_t \tilde{I}(t)$ multiplying the size of the corresponding group, respectively, which are shown 257 in Figure 4. And a new infection has $1 - \theta_t$ probability being asymptomatic, which is modelled 258 by a binomial distribution. The specification of θ_t is given in the SM, which is based on exist-259 ing studies¹⁸⁻²⁰ on the proportion of asymptomatic cases over different periods of the pandemic. 260 The vaccine effects are reflected by $\varphi_1, \varphi_2, \varphi_3 \in (0, 1)$, where the individuals having partial, full 261 and booster vaccine immunity are less likely being infected comparing to the those without vac-262 cine immunity by the factors φ_1 , $\varphi_1\varphi_2$ and $\varphi_1\varphi_2\varphi_3$, respectively. The VPRs for the three vaccine 263 compartments are $1 - \varphi_1$, $1 - \varphi_1 \varphi_2$ and $1 - \varphi_1 \varphi_2 \varphi_3$, respectively. 264

Estimation. Given the above model arrangement, we estimate the diagnosis rate α , time-varying infection, recovery and death rates, and the VPR parameters φ_1 , φ_2 and φ_3 of a country by a multistep multi-time range procedure via minimizing certain criterion functions using different periods of data for different variants of SARS-CoV-2 virus, and a nonparametric regression method for the time-varying parameters.

²⁷⁰ The recovery and death rates are estimated by the kernel smoothing regression of daily new

recovery and death numbers on the total size of active confirmed infections at time t. If the recovery 271 data are not available, we set it as 1/14, meaning 14 days as the average recovery time since 272 diagnosis²¹. Let $I_p(t)$ be the size of the pre-symptomatic compartment and $\Delta N(t)$ be the new 273 confirmed cases at day t. Adopting a multi-step estimation procedure, we use the B-splines to fit the 274 infection rate β_t , and minimize the criteria function $\sum_{t \in S} \left\{ \alpha \hat{\mathbf{E}}^{\alpha, \varphi_1, \varphi_2, \varphi_3} \{ I_p(t) | \mathcal{F}_{t-1} \} / \Delta N(t) - 1 \right\}^2$ 275 with respect to α , φ_1 , φ_2 , φ_3 and the coefficients of the B-splines over an estimation period S. 276 Here $\Delta N(t)/\alpha$ stands for an imputation for $I_p(t)$ and $\hat{E}^{\alpha,\varphi_1,\varphi_2,\varphi_3}\{I_p(t)|\mathcal{F}_{t-1}\}$ is a simulation-277 based estimate of the conditional expectation of $I_p(t)$ given data up to t-1 by averaging the 278 simulated trajectories under the proposed model at each α , φ_1 , φ_2 , φ_3 and β_t . This estimation 279

²⁸⁰ approach can be viewed as a minimum distance method that minimizes the distance between the ²⁸¹ trajectories implied by the model and the observed data of daily new confirmed cases. However, ²⁸² due to the unobservable compartments, imputation is needed as well as a decentralized strategy ²⁸³ that estimates different parameters over different time periods. The mathematical expressions of ²⁸⁴ the proposed model and the detailed estimation procedure are provided in the SM.

Sensitivity analysis. The number of reported cases are influenced by the severity of symptoms, public willingness to do testing and the testing capacity. These factors determine the pre-symptomatic proportion θ_t and the diagnosis rate α of the pre-symptomatic cases in our model. While α is empirically estimated by the proposed method, θ_t is determined from existing studies. Murray et al. (2022)²⁰ suggested the asymptomatic cases accounted for 80-90% of COVID-19 infections in the Omicron era. In the main analysis, the probability for new infections being asymptomatic since the detection of Omicron variant was assumed to increase linearly from 40% to 90%. To explore the

sensitivity of this specification, we conducted a sensitivity analysis which assumed the probability 292 of being asymptomatic for new infections after the Omicron increased linearly from 40% to 80%. 293 The estimated VPRs in the intervening II and the Omicron-dominated periods for the seven coun-294 tries are reported in Table S7, which shows that the magnitude of the differences between VPRs 295 by altering the daily asymptomatic rates $1 - \theta_t$ was no more than 8.6% and the average of the 296 absolute differences was 1.26% (SE: 0.23%). We have also conducted a sensitivity analysis on the 297 estimated VPRs with respect to μ_r , the time duration from recovery to loss of natural immunity. 298 It shows that the differences between the estimated VPRs in the seven countries with μ_r being 16 299 months as in the main analysis and those with μ_r being 6 months were at most 5% apart with the 300 average absolute differences being 0.94% (SE: 0.17%). Table S7 contains the details for the two 301 sets of sensitivity analyses. 302

Reporting summary. Further information on research design is available in the Nature Research
 Reporting summary linked to this article.

305 Data availability

The daily epidemiological and vaccination data that support the findings of this study are available in a public repository "Our World in Data", ["https://covid.ourworldindata.org/"].
