64 **Abstract (200 words)**

65 Neuroinflammation is both a consequence and driver of overfeeding and weight gain in rodent obesity
66 models. Advances in magnetic resonance imaging (MRI) enable investigations of brain microstructure
67 that suggests neuroinflammation in human obesity. To assess the convergent validity across MRI
68 techniques and extend previous findings, we used diffusion basis spectrum imaging (DBSI) to
69 characterize obesity-associated alterations in brain microstructure in 601 children (age 9-11 years) from
70 the Adolescent Brain Cognitive DevelopmentSM Study. Compared to children with normal-weight, greater
71 DBSI restricted fraction (RF), reflecting neuroinflammation-related cellularity, was seen in widespread
72 white matter in children with overweight and obesity. Greater DBSI-RF in hypothalamus, caudate
73 nucleus, putamen, and, in particular, nucleus accumbens, correlated with higher baseline body mass index
74 (BMI) and related anthropometrics. Comparable findings were seen in the striatum with a previously
75 reported restriction spectrum imaging (RSI) model. Gain in waist circumference over one and two years
76 related, at nominal significance, to greater baseline RSI-assessed restricted diffusion in nucleus
77 accumbens and caudate nucleus, and DBSI-RF in hypothalamus, respectively. Here we demonstrate that
78 childhood obesity is associated with microstructural alterations in white matter, hypothalamus, and
79 striatum. Our results also support the reproducibility, across MRI methods, of findings of obesity-related
80 putative neuroinflammation in children.

81 **1. Introduction**

82 Childhood obesity is a major growing health issue, affecting over 340 million children worldwide
83 in 2016 (World Health Organization, 2021). It is associated with expensive medical costs (Biener et al.,
84 2020), lower quality of life (Killedar et al., 2020), and elevated risk for health complications including
85 adult obesity, type 2 diabetes, and cardiovascular diseases (Liang et al., 2015; Simmonds et al., 2016).
86 Accumulating evidence also identifies childhood obesity as a risk factor for cognitive dysfunction and
87 Alzheimer’s disease in late-life (Tait et al., 2022). Given the brain’s prominent role in regulating feeding
88 and metabolism, it is essential to understand the relationship between obesity and brain health.
89 Determining which brain regions and networks might be involved in the development and maintenance of
90 childhood obesity could help identify targets for obesity prevention and intervention, thereby mitigating
91 short and long-term health consequences.

92 Obesity involves a chronic, low-grade, systemic inflammation affecting multiple organs (Gregor
93 & Hotamisligil, 2011). In rodent models of obesity, high-fat diets induce inflammation in the central
94 nervous system, or “neuroinflammation” (Baufeld et al., 2016; Buckman et al., 2013; De Souza et al.,
95 2005; Décarie-Spain et al., 2018; Valdearcos et al., 2017), which in turn cause memory deficits and
96 anxiodepressive behaviors (Beilharz et al., 2016; Décarie-Spain et al., 2018; Pistell et al., 2010). In
97 humans, post-mortem tissue analyses have revealed associations between obesity and increased gliosis in
98 multiple brain regions, including the hypothalamus, a key regulator of feeding and metabolism (Baufeld
99 et al., 2016; Schur et al., 2015). Aimed at assessing brain health *in vivo*, a number of magnetic resonance
100 imaging (MRI) studies have reported associations between obesity and altered brain structure. In adults,
101 higher body mass index (BMI) and visceral fat are consistently linked to lower cortical thickness and
102 smaller prefrontal and basal ganglia volumes (Fernández-Andújar et al., 2021; Gómez-Apo et al., 2021;
103 Raji et al., 2010; Willette & Kapogiannis, 2015), potentially due to neuronal loss consequent of obesity-
104 related neuroinflammation and/or microangiopathy (Gómez-Apo et al., 2021). These relationships are less
105 clear in children (Willette & Kapogiannis, 2015). Adult obesity has also been associated with
106 compromised white matter integrity, reflected by lower diffusion tensor imaging (DTI)-derived fractional

107 anisotropy (FA) and greater mean diffusivity of water, primarily in frontolimbic tracts and the corpus
108 callosum (Daoust et al., 2021; Kullmann et al., 2015; Verstynen et al., 2012). However, opposite findings
109 of greater white matter DTI-FA in obesity have also been noted (Birdsill et al., 2017; Carbine et al., 2020;
110 Dekkers et al., 2019), and the relationship between obesity and white matter integrity in children remains
111 unknown. Importantly, the standard single-tensor DTI model could be confounded by neuroinflammatory
112 processes such as cellularity and edema (Kullmann et al., 2016; Wang et al., 2011, 2015; Winklewski et
113 al., 2018), which may partially explain the mixed pattern of results.

114 In recent years, studies using multi-compartment diffusion MRI-based methods, though limited in
115 number, have yielded consistent observations of putative neuroinflammation in feeding-related brain
116 regions in obesity (Rapuano et al., 2020, 2022; Samara et al., 2020, 2021). The data-driven multi-tensor
117 diffusion basis spectrum imaging (DBSI) technique models diffusion-weighted signals as a linear
118 combination of discrete anisotropic tensors and isotropic diffusion spectra, enabling the *in vivo*
119 assessment of brain microstructure (Cross & Song, 2017; Wang et al., 2011, 2015). DBSI metrics, though
120 indirectly reflecting true anatomy, have been histopathologically validated as neuroinflammation-
121 sensitive using rodent and human neural tissue in multiple sclerosis (Chiang et al., 2014; Wang et al.,
122 2014; Wang et al., 2011, 2015), epilepsy (Zhan et al., 2018), and optic neuritis (Lin et al., 2017; Yang et
123 al., 2021). Notably, applying DBSI to adults with obesity, we previously observed microstructural
124 alterations in striatal and limbic regions that suggest cellularity, vasogenic edema, and lower apparent
125 axonal and dendritic densities (Samara et al., 2020, 2021), in line with the obesity-related
126 neuroinflammatory phenotype seen in animal and post-mortem human brain studies. In white matter
127 tracts, we found evidence of increased and widespread DBSI-assessed putative neuroinflammation in
128 young and middle-aged adults with obesity across two independent samples (Samara et al., 2020). DBSI
129 has not yet been used to characterize brain microstructure in childhood obesity. However, Rapuano et al.,
130 (2020) used restriction spectrum imaging (RSI), which in contrast to DBSI, models isotropic water
131 diffusion components based on the ratio of radial and axial diffusivities (Palmer et al., 2022; White et al.,
132 2013), and observed associations between greater purported striatal cellular density and higher baseline

133 and future waist circumference and BMI in children in the Adolescent Brain Cognitive DevelopmentSM
134 (ABCD) Study (Rapuno et al., 2020, 2022). Furthermore, using a non-diffusion method, namely
135 quantitative T2-weighted MRI, studies have reported that longer hypothalamic T2 relaxation time and
136 greater T2 signal intensity, both suggestive of reactive microglial and astrocytic gliosis, relate to higher
137 BMI in adults (Schur et al., 2015; Thaler et al., 2012) and children, including a subset from the ABCD
138 Study[®] (Sewaybricker et al., 2019; Sewaybricker, Kee, et al., 2021; Sewaybricker, Melhorn, et al., 2021).
139 Convergent findings amongst MRI methods in the same group of children would support the feasibility
140 and reliability of these techniques to assess putative neuroinflammation in childhood obesity.

141 In this study, we used the baseline ABCD Study[®] data from 601 children aged 9-11 years (see
142 **section 2.1** for details on sample selection) to test the *a priori* hypotheses that 1) obesity-associated
143 microstructural alterations, including greater putative neuroinflammation-related cellularity (reflected by
144 greater DBSI restricted fraction (RF)) and lower axonal and dendritic densities (reflected by lower DBSI
145 fiber fraction (FF)) that we had observed in white matter and striatum in adults, and in one novel region
146 not yet assessed using diffusion MRI, i.e., the hypothalamus, would also be present in children, and that
147 2) greater hypothalamic and striatal cellularity (DBSI-RF) would relate to greater baseline waist
148 circumference and BMI metrics in children, similar to the RSI cellular density metric, namely restricted
149 normalized isotropic (RSI-RNI). We also explored associations between baseline DBSI and RSI metrics
150 in the hypothalamus and striatum and one and two-year longitudinal changes in anthropometrics. If our
151 results using DBSI are consistent to those in studies that used RSI and quantitative T2-weighted MRI,
152 they will support the use of non-invasive MRI-based methods to characterize obesity-related putative
153 neuroinflammation *in vivo* in humans, in the absence of histopathological validation.

154

155 **2. Materials and methods**

156 **2.1. Participants**

157 Participants were from the ABCD Study[®], a ten-year, 21-site study tracking brain development in
158 a diverse cohort of U.S. children and adolescents (Casey et al., 2018; Garavan et al., 2018; Jernigan et al.,

159 2018). Participants receive annual physical, sociocultural, and behavioral assessments, as well as
160 neuroimaging and bioassays every two years. Institutional review boards at study sites approved study
161 procedures; parents/caregivers provided written consent and children gave verbal assent. The ABCD
162 Study[®] 2.0.1 release included data from 11,875 participants at baseline and 4,951 participants at one-year
163 follow-up. In addition to the ABCD Study[®] inclusion/exclusion criteria (Garavan et al., 2018), we
164 excluded participants with 1) missing anthropometric or demographic data at baseline or one-year follow-
165 up; 2) current or past diagnosis of neurological (including cerebral palsy, brain tumor, stroke, aneurysm,
166 brain hemorrhage, intellectual disability, lead poisoning, muscular dystrophy, multiple sclerosis, and
167 others) and psychiatric (including schizophrenia, autism spectrum disorder, attention-deficit hyperactivity
168 disorder, and others) conditions and diabetes, similar to Rapuano et al., (2020); and 3) T1 or diffusion-
169 weighted images (DWIs) that did not pass quality control or had clinically significant incidental findings
170 (Hagler et al., 2019; Li et al., 2021). Also consistent with Rapuano et al., (2020), in order to maximize
171 harmonization of MRI data across sites, only scans performed on Siemens 3T Prisma platforms (Siemens
172 Healthineers AG, Erlangen, Germany) were included. As the ABCD Study[®] 4.0 release became available
173 during our study, we further included participants with complete data at two-year follow-up to extend
174 exploratory longitudinal analyses. Lastly, because head motion during MRI scans is known to interfere
175 with diffusion tensor model estimation and give spurious correlations (Ling et al., 2012; Yendiki et al.,
176 2014), we excluded participants with excessive head motion (defined as mean DWI framewise
177 displacement ≥ 2.5 mm) and covaried for mean head motion in statistical analyses.

178 Our inclusion/exclusion criteria selected a total of 1,613 qualifying participants (see
179 **Supplementary Fig. 1** for flowchart). Age and sex-adjusted BMI percentiles at baseline were used to
180 classify participants by weight status (Kuczmarski et al., 2002), including 63 with underweight (BMI < 5th
181 percentile), 1,140 with normal-weight (NW; 5th to < 85th percentiles), 194 with overweight (OW; 85th to <
182 95th percentiles), and 216 with obesity (OB; $\geq 95^{\text{th}}$ percentile). To achieve balanced group sizes as well as
183 reduce computational cost, we randomly selected 216 NW participants (matched to OB group size)
184 stratified by sex, and included all 194 OW and 216 OB participants. After neuroimaging processing, data

185 from 25 participants were excluded due to missing/incomplete T1 or DWI acquisition, missing field
186 maps, mismatch between field map and DWI dimensions, or missing/unclear DWI directions. The final
187 analytical sample therefore included 212 NW, 187 OW, and 202 OB participants, for a total $n = 601$.
188 Such sample size is similar to those in recent literature and should afford sufficient power to detect
189 obesity-related microstructural alterations (see **Supplementary Methods** for power analysis) (Jiang et al.,
190 2023; Sewaybricker, Kee, et al., 2021).

191 **2.2. Obesity-related measures**

192 Participant waist circumference (WC), weight, and height were measured at baseline and one and
193 two-year follow-ups (Barch et al., 2018). Raw BMI was calculated ($\text{weight}_{(\text{lbs})}/\text{height}_{(\text{in})}^2 \times 703$). BMI z -
194 scores corrected for age and sex were computed using the 2000 CDC growth charts (Kuczmarski et al.,
195 2002). These different measures were used to address the concern that a single index may be less
196 reflective of true adiposity and/or sensitive to fat gain in children (Cole et al., 2005; Taylor et al., 2000).

197 **2.3. Neuroimaging**

198 **2.3.1. MRI acquisition**

199 Details on T1 and DWI acquisition and harmonization across sites are published elsewhere
200 (Casey et al., 2018; Hagler et al., 2019). T1-weighted anatomical images were collected as a 3D T1-
201 weighted inversion prepared RF-spoiled gradient echo scan, with voxel resolution = 1 mm^3 isotropic. Spin
202 echo echo-planar imaging was used to acquire multi-shell DWIs with the following parameters: total
203 acquisition time = 7:31, repetition time = 4100 ms, time to echo = 88 ms, matrix size = $140 \times 140 \times 81$,
204 flip angle = 90° , acceleration factor = 3, and voxel resolution = 1.7 mm^3 isotropic. DWIs were imaged
205 with 7 $b = 0$ frames and 96 gradient directions (b 's = 500, 1000, 2000, and 3000 s/mm^2 with 6, 15, 15,
206 and 60 directions, respectively).

207 **2.3.2. DWI and DBSI processing**

208 DWIs were corrected for susceptibility-induced distortion, eddy currents, and head motion using
209 FMRIB Software Library (FSL) *topup* and *eddy* (Smith et al., 2004). Multi-tensor DBSI maps were
210 estimated using an in-house script as previously described (Wang et al., 2011, 2015). Leveraging the

211 multi-shell DWI data, DBSI characterizes brain tissue microstructure by partitioning the total water
212 diffusion signal within each image voxel into isotropic and anisotropic compartments. DBSI modeling
213 produced maps of anisotropic fiber fraction (DBSI-FF; reflects axonal/dendritic density), isotropic
214 nonrestricted fraction ($f(D)$ at apparent diffusion coefficient (ADC) $> 0.3 \mu\text{m}^2/\text{ms}$; reflects vasogenic
215 edema/tissue disintegration/extracellular water), and isotropic restricted fraction (DBSI-RF; $f(D)$ at $0 <$
216 $\text{ADC} \leq 0.3 \mu\text{m}^2/\text{ms}$; reflects intracellular water/inflammation-related cellularity) (Chiang et al., 2014; Sun
217 et al., 2020; Wang et al., 2015). Details on DBSI model specification are provided in **Supplementary**
218 **Methods**. Notably, DBSI-FF and RF are consistently lower and greater, respectively, in adult obesity
219 (Samara et al., 2020, 2021) and serve as the neuroinflammation-related microstructural assessment in the
220 current study. DBSI maps were registered to T1 space first using *epi_reg* and a non-diffusion-weighted
221 image, then by applying the transformation matrix to individual maps using *applyxfm*.

222 **2.3.3. Tract-based spatial statistics (TBSS)**

223 Voxel-wise analyses of white matter DBSI-FF and RF were performed using TBSS (Smith et al.,
224 2006). The DTI model was fitted to preprocessed DWIs using FSL *dtifit*, and DTI-FA maps were eroded
225 by one voxel with end slices removed. Cleaned DTI-FA images were nonlinearly registered to the T1-
226 weighted image of a randomly selected NW participant, averaged, and assigned a threshold at $\text{FA} > 0.2$ to
227 create a white matter skeleton, onto which the DBSI-FF and RF maps were projected.

228 **2.3.4. Segmentation of the striatum and hypothalamus**

229 The nucleus accumbens, caudate nucleus, and putamen were segmented from T1-weighted
230 images using FSL *FIRST* (Patenaude et al., 2011). The hypothalamus was segmented using a novel,
231 automated algorithm developed with deep convolutional neural networks trained on adult data (Billot et
232 al., 2020). To assess the algorithm's accuracy in children, we compared automated and manual
233 hypothalamus segmentations in 20 participants (10 NW and 10 OB, randomly selected within each
234 group). Within this group, the automated and manual segmentations had good spatial overlap (mean Dice
235 similarity coefficient = 0.74, $SD = 0.02$, one-tailed $p < 0.001$ against the conventional threshold of 0.7)
236 and yielded highly correlated volumes ($r = 0.74$, $p < 0.001$). Neither spatial overlap nor volumetric

237 correlation between the automated and manual segmentations was different by weight group (NW vs. OB;
238 p 's = 0.58 and 0.97). Although the automated segmentations had smaller volumes than manual
239 segmentations ($means = 747$ and 887 mm^3 , $p < 0.001$), such volume reduction primarily excluded voxels
240 near the hypothalamic surface, reducing possible contamination of diffusion signal from neighboring
241 cerebrospinal fluid and vasculature (**Supplementary Fig. 2**). Also, the segmented volumes were
242 consistent with literature values (Neudorfer et al., 2020). Taken together, the automated algorithm reliably
243 produced hypothalamus segmentations comparable to manual segmentation. For each subcortical
244 structure, segmentations were visually inspected for accuracy before statistical analyses, and volume and
245 DBSI-FF and RF metrics were each extracted and combined/averaged between hemispheres.

246 **2.4. Statistical analyses**

247 All analyses, except for TBSS, were performed in R version 4.2.1 (R Core Team, 2013).
248 Differences in participant characteristics across NW, OW, and OB groups were assessed using analysis of
249 variance (ANOVA) or chi-square tests.

250 **2.4.1. White matter**

251 For TBSS, we excluded data from 28 randomly selected siblings, eliminating family dependency
252 confounds. Baseline DBSI-FF and RF in white matter tracts were compared amongst unrelated NW ($n =$
253 202), OW ($n = 180$), and OB ($n = 191$) participants using voxel-wise TBSS, first by ANOVAs for main
254 effects of group and second by t -tests for between-group comparisons. FSL *Randomize* (null distribution
255 built from 10,000 permutations; with recommended threshold-free cluster enhancement (TFCE)) was
256 used for these comparisons with spatial family-wise error (FWE) rate corrected at two-tailed $p \leq 0.05$
257 (Winkler et al., 2014). Briefly, the raw statistical image was TFCE-transformed into an output image in
258 which voxel-wise TFCE scores were weighted sums of local clustered signals, such that larger TFCE
259 scores reflected magnitude of cluster-like spatial support greater than a given height (signal intensity) (Li
260 et al., 2017; Smith & Nichols, 2009). We specified the $-T2$ option in *Randomize* (2D optimization for
261 skeletonized data, cluster height weighted by $H = 2$, cluster extent weighted by $E = 1$, voxel connectivity
262 = 26). Voxel-wise analyses using TBSS and TFCE allowed for sensitive detection of regionally-specific

263 obesity-related DBSI-FF and RF effects in white matter, while stringently controlling for multiple
264 comparisons across space. Participant age, sex, race/ethnicity, parental education, household income,
265 parental marital status, pubertal development stage (PDS), mean head motion, and intracranial volume
266 (ICV) were covaried in TBSS. Group differences in white matter skeleton-average values of DBSI-FF
267 and RF were assessed with linear mixed-effects models using the *lme4* package (Bates et al., 2015),
268 where the same set of covariates plus weight group were fixed effects and site was the random effect.

269 **2.4.2. Striatum and hypothalamus**

270 DBSI-FF and RF outliers in the nucleus accumbens, caudate nucleus, putamen, and hypothalamus
271 that were ± 3 SD away from the mean were removed (**Supplementary Table 1**). One and two-year
272 changes in obesity-related measures (i.e., WC, BMI, and BMI z -scores) were calculated by subtracting
273 baseline from respective follow-up. Extreme BMI values (< 10 kg/m² or > 50 kg/m²) and associated BMI
274 z -scores were removed, including 1 NW and 1 OB at one-year and 1 OW at two-year. Distributions for
275 obesity-related measures at and changes between all timepoints are shown in **Supplementary Fig. 3**.

276 Associations between DBSI metrics and baseline or future change in obesity-related measures
277 were assessed using linear mixed-effects models. Age (at baseline, one, or two-year), sex, race/ethnicity,
278 PDS (at baseline, one, or two-year), parental education, household income, parental marital status, mean
279 head motion, and ICV were covaried due to potential confounding (Lawrence et al., 2022; Li et al., 2023;
280 Palmer et al., 2022; Rapuano et al., 2020), and the random effect was family nested within sites. In
281 longitudinal models, baseline obesity-related measures were also covaried. As we had *a priori*
282 hypotheses, and the goal was to describe regionally-specific relations between tissue microstructure and
283 convergent obesity-related measures, multiple comparisons were corrected with each structure treated as a
284 family, at two-tailed $p = 0.05 / (4 \text{ regions} \times 2 \text{ DBSI metrics}) = 0.00625$. Effect size estimates were
285 standardized β 's with 95% confidence intervals (CIs) and partial R^2 's. Models were checked for normality
286 of residuals, homoscedasticity, and low multicollinearity (variance inflation factors were ≤ 2.56). As there
287 were missing data following outlier removal, sample sizes varied and are reported in individual analyses.

288 **2.4.3. Comparison between DBSI and RSI**

289 Mean RSI restricted normalized isotropic (RSI-RNI) metrics in bilateral nucleus accumbens,
290 caudate nucleus, and putamen were obtained from the ABCD Study[®] tabulated dataset (Hagler et al.,
291 2019). The ABCD Study[®] segmented structures using FreeSurfer v5.3; the hypothalamus was not
292 specifically segmented and voxel-wise RSI-RNI maps were not available. RSI reflects cellularity as an
293 increase in the restricted isotropic (originating from intracellular water) diffusion signal, i.e., RSI-RNI
294 (Rapuano et al., 2020, 2022). Associations between RSI-RNI and baseline or future change in obesity-
295 related measures were evaluated using linear mixed-effects models, as in DBSI described in **section 2.4.2**.
296 To further compare model performance, DBSI-RF and RSI-RNI from the nucleus accumbens, caudate
297 nucleus, and putamen were each tested on classifying NW and OB participants using mixed-effects
298 logistic regression, with the same fixed and random effect covariates in linear models. Receiver operating
299 characteristic curves and areas-under-the-curve (AUCs) with 95% CIs were computed using the *pROC*
300 package, and AUCs from DBSI-RF and RSI-RNI were compared using DeLong's test (Robin et al.,
301 2011).

302

303 **3. Results**

304 **3.1. Sample characteristics**

305 Participant demographics, neuroimaging metrics, and obesity-related measures are described in
306 **Table 1**. Qualitatively, the OW and/or OB groups compared to the NW group had more non-White
307 participants, more advanced pubertal development, lower parental education, household income, and
308 proportion of married parents, higher baseline obesity-related measures, and greater one and two-year
309 gain in WC but decrease in BMI *z*-scores. Groups did not differ significantly in striatal or hypothalamic
310 volumes; these volumes were thus not covaried in addition to ICV in analyses.

Variable	Group (total n = 601)			p-value
	NW	OW	OB	
n	212 (35.3% of all)	187 (31.1% of all)	202 (33.6% of all)	N/A
Age (months)	121 ± 8	121 ± 7	120 ± 7	0.89

311 **Table 1. Participant demographics, brain volumes, and obesity-related measures.** Statistics are
312 shown as mean \pm standard deviation for continuous variables and count (frequency) for categorical data.
313 Variables were assessed at baseline unless otherwise noted. Comparisons were performed using one-way
314 analysis of variance or chi-squared tests as appropriate. The “Other” category under race/ethnicity
315 included participants who were parent/caregiver-identified as American Indian, Alaskan Native, Native
316 Hawaiian, other Pacific Islander, mixed, or otherwise not listed. Abbreviations: NW, children with
317 normal-weight; OW, with overweight; OB, with obesity; PDS, pubertal development stage; HS, high
318 school; GED, General Educational Development; ICV, intracranial volume; V, volume; BMI, body mass
319 index; WC, waist circumference. *, $p \leq 0.05$; **, $p \leq 0.01$; ***, $p \leq 0.001$.
320

321 3.2. Comparison of white matter DBSI metrics across groups

322 TBSS ANOVAs indicated significant main effects of weight group for both DBSI-FF and RF.
323 Follow-up TBSS *t*-tests showed that relative to NW, both OW and OB participants had significantly
324 lower DBSI-FF (reflecting lower axonal/dendritic density) and greater DBSI-RF (reflecting elevated
325 cellularity) in widespread white matter tracts (all FWE-corrected $p \leq 0.05$). Qualitatively, group
326 differences in both DBSI-FF and RF appeared more widespread throughout white matter tracts in the OB
327 vs. NW comparisons than in OW vs. NW comparisons (**Fig. 1**); nonetheless, white matter voxel-wise
328 DBSI-FF and RF were not significantly different between OB and OW groups (FWE-corrected $p >$
329 0.054). Consistent with voxel-wise comparisons, relative to NW, both OW and OB groups had lower
330 white matter average DBSI-FF (OW vs. NW, $\beta = -0.39$, 95% CI: -0.60 to -0.18, $p < 0.001$; OB vs. NW, β
331 = -0.33, 95% CI: -0.54 to -0.11, $p = 0.003$) and greater DBSI-RF (OW vs. NW, $\beta = 0.50$, 95% CI: 0.30 to
332 0.70, $p < 0.001$; OB vs. NW, $\beta = 0.36$, 95% CI: 0.16 to 0.56, $p < 0.001$), but these differences were not
333 significant between OW and OB (p 's = 0.65 and 0.14 for DBSI-FF and RF comparisons).

335 **Fig. 1.** Voxel-wise comparisons of white matter DBSI metrics amongst unrelated children with normal-
336 weight (NW; $n = 202$), overweight (OW, $n = 180$) and obesity (OB; $n = 191$). In each panel, axial images
337 are shown from inferior (top left) to superior (bottom right). In *green*: white matter skeleton; in *blue, light*
338 *blue*: NW > OB/OW at family-wise error (FWE) rate-corrected $p \leq 0.05$ and 0.01 ; in *red, yellow*: NW <
339 OB/OW at FWE-corrected $p \leq 0.05$ and 0.01 . Comparisons were adjusted for age, sex, race/ethnicity,
340 parental education, household income, parental marital status, pubertal development stage, mean head
341 motion, and intracranial volume. DBSI, diffusion basis spectrum imaging.

342

343 3.3. Associations between striatal and hypothalamic DBSI metrics and obesity-related measures

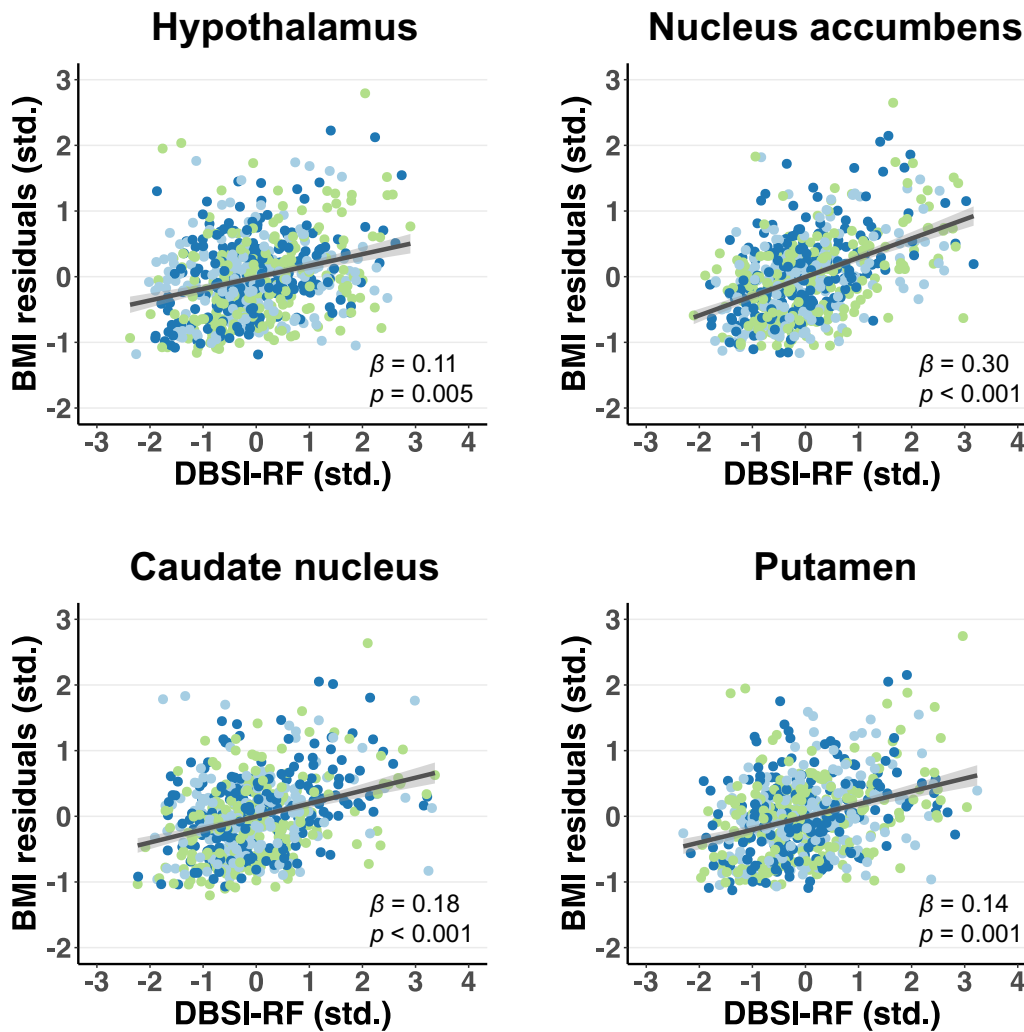

344 3.3.1. Baseline

345 Greater BMI at baseline was significantly associated with greater DBSI-RF in the hypothalamus
346 ($\beta = 0.11$, 95% CI: 0.04 to 0.19, partial $R^2 = 0.014$, $p = 0.005$), nucleus accumbens ($\beta = 0.30$, 95% CI:
347 0.22 to 0.39, partial $R^2 = 0.096$, $p < 0.001$), caudate nucleus ($\beta = 0.18$, 95% CI: 0.08 to 0.27, partial $R^2 =$
348 0.034, $p < 0.001$), and the putamen ($\beta = 0.14$, 95% CI: 0.06 to 0.22, partial $R^2 = 0.021$, $p = 0.001$) (**Fig.**
349 **2A**). These results were consistent with WC and BMI z -scores as obesity-related measures. Further,

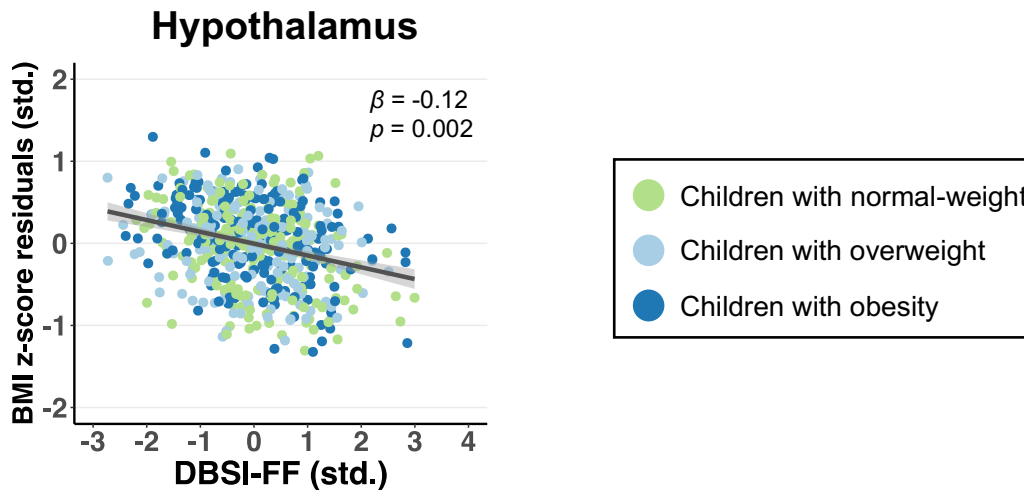

350 greater baseline BMI z -scores were significantly related to lower DBSI-FF in the hypothalamus ($\beta = -$
351 0.12, 95% CI: -0.20 to -0.05, partial $R^2 = 0.016$, $p = 0.002$) (**Fig. 2B**). Similar associations, at nominal but
352 not multiple comparison-adjusted significance, were seen between lower DBSI-FF in the hypothalamus
353 and WC ($\beta = -0.08$, $p = 0.038$) and BMI ($\beta = -0.09$, $p = 0.024$); in the nucleus accumbens and WC ($\beta = -$
354 0.10, $p = 0.009$); and in the putamen and BMI ($\beta = -0.08$, $p = 0.048$) and BMI z -scores ($\beta = -0.08$, $p =$
355 0.048). Detailed statistics for all models are reported in **Supplementary Table 2**. Follow-up analyses
356 revealed no DBSI metric by hemisphere interaction in relating to baseline obesity-related measures (i.e.,
357 no laterality effect; p 's ≥ 0.30).

358 Beyond DBSI metrics, variables that were associated with greater obesity-related measures at
359 baseline included older age, lower parental education, and more advanced pubertal stage. As we did not
360 specifically power or hypothesize for demographics-related effects, these findings are exploratory and are
361 noted in **Supplementary Table 3**. In total, our linear-mixed effects models explained 18-25% of the
362 variance in baseline obesity-related measures.

A. Associations with DBSI restricted fraction (RF)

B. Associations with DBSI fiber fraction (FF)

364 **Fig. 2.** Significant associations **(A)** between baseline body mass index (BMI) and DBSI-RF in the
365 hypothalamus and striatum and **(B)** between baseline BMI *z*-scores and DBSI-FF in the hypothalamus in
366 children. BMI or BMI *z*-score residuals (adjusted for age, sex, race/ethnicity, parental education,
367 household income, parental marital status, pubertal development stage, mean head motion, intracranial
368 volume, and family nested by site) and DBSI metrics were standardized (std.). Standardized β regression
369 coefficients were reported with 95% confidence intervals (shaded). DBSI, diffusion basis spectrum
370 imaging.

371

372 **3.3.2. One and two-year change**

373 Greater DBSI-RF in the hypothalamus at baseline, at nominal significance not surviving multiple
374 comparison correction, predicted greater gain in WC over two years, accounting for baseline WC ($\beta =$
375 0.09, 95% CI: 0.01 to 0.18, partial $R^2 = 0.008$, $p = 0.035$; **Supplementary Fig. 4**). However, such effect
376 was not seen at one-year follow-up, or with changes in BMI or BMI *z*-scores as obesity-related measures
377 (p 's = 0.79 and 0.52). Other one or two-year changes in obesity-related measures were not associated with
378 baseline DBSI metrics (**Supplementary Tables 4 and 5**).

379 **3.4. Associations between striatal RSI-RNI and obesity-related measures**

380 **3.4.1. Baseline**

381 Consistent with a previous study using ABCD Study[®] baseline data ($n = 5,366$; Rapuano et al.,
382 2020), greater baseline BMI was associated with higher RSI-RNI in the nucleus accumbens ($\beta = 0.36$,
383 95% CI: 0.27 to 0.44, partial $R^2 = 0.125$, $p < 0.001$), caudate nucleus ($\beta = 0.15$, 95% CI: 0.07 to 0.23,
384 partial $R^2 = 0.025$, $p < 0.001$), and putamen ($\beta = 0.17$, 95% CI: 0.09 to 0.26, partial $R^2 = 0.030$, $p < 0.001$)
385 in the current, smaller sample. Results were similar with WC and BMI *z*-scores. Detailed statistics for all
386 linear mixed-effects models are reported in **Supplementary Table 6**.

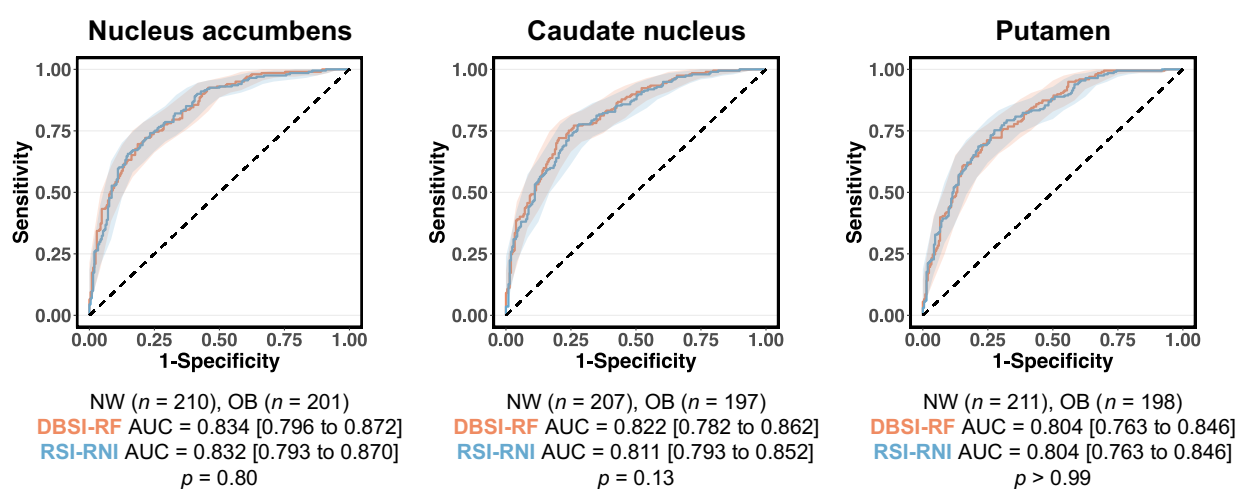

387 **3.4.2. One and two-year change**

388 Greater baseline RSI-RNI in the nucleus accumbens and caudate nucleus were respectively
389 associated, not surviving multiple comparison correction, with one-year gain in WC, accounting for
390 baseline levels (nucleus accumbens: $\beta = 0.10$, 95% CI: 0.00 to 0.20, partial $R^2 = 0.008$, $p = 0.042$; caudate
391 nucleus: $\beta = 0.11$, 95% CI: 0.02 to 0.19, partial $R^2 = 0.011$, $p = 0.017$; **Supplementary Fig. 5**). These

392 associations were not seen at two-year follow-up or with changes in BMI or BMI z-scores
393 (Supplementary Tables 7 and 8).

394 3.5. Comparison between DBSI and RSI on classifying NW and OB groups

395 Striatal DBSI and RSI metrics reflective of neuroinflammation-associated cellularity and cellular
396 density, i.e., DBSI-RF and RSI-RNI, showed similar sensitivity and specificity in classifying NW and OB
397 children (p 's ≥ 0.13 ; Fig. 3). Across the striatum, DBSI-RF was positively and strongly correlated with
398 RSI-RNI (r 's ≥ 0.60 , p 's ≤ 0.001 ; Supplementary Fig. 6).

399 **Fig. 3.** Receiver operating characteristic curves comparing striatal DBSI restricted fraction (RF) and RSI
400 restricted normalized isotropic (RNI) performance in classifying children with normal-weight (NW) and
401 obesity (OB). AUC, area-under-the-curve; DBSI, diffusion basis spectrum imaging; RSI, restriction
402 spectrum imaging.
403

404 4. Discussion

405 4.1. Overview

406 Here we present both novel findings and support for the reproducibility of previous neuroimaging
407 studies that observed microstructural alterations suggestive of neuroinflammation in key feeding and
408 reward-related brain regions in childhood obesity. First, we demonstrate that elevated DBSI-assessed
409 cellularity, i.e., putative inflammatory marker, in the striatum relates to higher WC, BMI, and BMI z-
410 scores in 601 children aged 9 to 11 years from the ABCD Study[®], reproducing observations made by
411 Rapuano et al., (2020) that used another diffusion-based RSI model in the same dataset. Quantitatively,
412

413 DBSI-RF and RSI-RNI were associated with obesity-related measures in similar magnitudes, and the two
414 methods exhibited comparable performance in classifying NW vs. OB children. Such convergence of
415 findings underpins the sensitivity and utility of diffusion MRI-based techniques in characterizing brain
416 microstructural alterations in obesity.

417 Second, we observed associations between obesity and increased purported cellularity consistent
418 with neuroinflammation in brain white matter tracts and hypothalamus, which were not assessed by
419 Rapuano et al., (2020). Our results in the hypothalamus align with reports of putative gliosis in this
420 region, assessed by quantitative T2 MRI, in both childhood and adult obesity (Schur et al., 2015;
421 Sewaybricker et al., 2019; Sewaybricker, Kee, et al., 2021; Sewaybricker, Melhorn, et al., 2021; Thaler et
422 al., 2012). Here, our findings add diffusion MRI-derived evidence of obesity-related putative
423 neuroinflammation in the hypothalamus in children. Furthermore, to our knowledge, our study is the first
424 to investigate and report overweight and obesity-associated white matter microstructural alterations in
425 children, in line with our earlier studies of DBSI-assessed putative white matter neuroinflammation in
426 adults (Samara et al., 2020). Collectively, our findings and those previously reported suggest that young
427 children manifest obesity-related differences in brain microstructure that are consistent with
428 neuroinflammation seen in animal and post-mortem human brain studies (Baufeld et al., 2016; Buckman
429 et al., 2013; De Souza et al., 2005; Décarie-Spain et al., 2018; Schur et al., 2015; Valdearcos et al., 2017).
430 Such brain differences may affect current and future susceptibility for weight gain and its comorbidities
431 including cognitive impairment, type 2 diabetes, and late-life dementia (Liang et al., 2015; Simmonds et
432 al., 2016; Tait et al., 2022).

433 **4.2. Links between obesity, neuroinflammation, and brain function**

434 The highly vascularized hypothalamus responds to feeding-related hormones, neuronal signals,
435 and nutrients derived from the bloodstream (Velloso & Schwartz, 2011). As a “metabolic sensor”, the
436 hypothalamus is vulnerable to overfeeding and obesity-related elevations in peripheral pro-inflammatory
437 molecules including cytokines and saturated fatty acids (Jais & Brüning, 2017). Overfeeding also causes
438 the blood-brain barrier to break down, further enabling inflammatory factors to infiltrate brain tissue

439 (Guillemot-Legris et al., 2016; Guillemot-Legris & Muccioli, 2017; Stranahan et al., 2016). Our finding
440 that DBSI-assessed cellularity (DBSI-RF) in the hypothalamus is greater in childhood obesity is
441 consistent with the neuroinflammatory phenotype encompassing the recruitment, proliferation, and
442 activation of astrocytes and microglia (i.e., reactive gliosis) seen in this brain region in rodents fed with
443 high-fat diets (Buckman et al., 2013; De Souza et al., 2005). While such immune response may initially
444 be neuroprotective, chronic gliosis leads to dysregulated neuroinflammatory processes that disrupt
445 hypothalamic metabolic regulation and contribute to overfeeding, leptin and insulin-resistance, and
446 development of obesity (Gómez-Apo et al., 2021; Sochocka et al., 2017; Valdearcos et al., 2017).
447 Persistent neuroinflammation could also cause axonal damage and loss (Frischer et al., 2009; Kempuraj et
448 al., 2016), which may explain our observed association between obesity and lower DBSI-assessed
449 axonal/dendritic density (DBSI-FF).

450 The striatum plays a key role in reward processing and appetitive behavior (Stice et al., 2011).
451 Striatal activity, primarily dopamine neurotransmission, is influenced by homeostatic signals from the
452 hypothalamus and by circulating feeding-related hormones, both acting on receptors on midbrain
453 dopaminergic cells (Abizaid et al., 2006; Figlewicz, 2016; Hommel et al., 2006; King et al., 2011).
454 Altered dopamine neurotransmission has been noted in obesity (Geiger et al., 2009; Wang et al., 2001;
455 Wu et al., 2017). Beyond the hypothalamus, neuroinflammation in the striatum may further contribute to
456 obesogenic behavior. Indeed, our observation of heightened DBSI-assessed cellularity across the striatum
457 in childhood obesity matches the microstructural changes characteristic of diet-induced reactive gliosis in
458 the nucleus accumbens in rodents (Décarie-Spain et al., 2018; Molina et al., 2020). Taken together, MRI-
459 based assessments of hypothalamic and striatal microstructure by us and others consistently suggest
460 putative neuroinflammation in these regions in childhood obesity, in agreement with studies in rodent
461 models and human adults.

462 Longitudinally, greater DBSI-assessed cellularity in the hypothalamus weakly predicted two-year
463 gain in WC, aligning with a recent T2 MRI-based report of putative hypothalamic gliosis being associated
464 with weight gain in children (Sewaybricker, Kee, et al., 2021). Further, greater RSI-RNI in the nucleus

465 accumbens and caudate nucleus were linked to one-year WC gain, reproducing findings in Rapuano et al.,
466 (2020). However, these findings were at nominal but not multiple comparison-corrected significance, and
467 did not generalize across different obesity-related measures or MRI techniques. As our sample size was
468 not intended to power for the weaker longitudinal effects observed in Rapuano et al., (2020), these
469 findings require confirmation in larger studies involving more longitudinal observations as the ABCD
470 Study[®] continues to release data. Nonetheless, given evidence that striatal neuroinflammation causally
471 contribute to overfeeding in rodents (Décarie-Spain et al., 2018), plus emerging reports that putative
472 nucleus accumbens cellularity may mediate the relationships between eating behavior and obesity in both
473 adults and children (Rapuano et al., 2022; Samara et al., 2021), chronic neuroinflammation should be
474 evaluated as a potential contributing factor to obesity maintenance.

475 **4.3. Brain microstructure in childhood vs. adult obesity**

476 Overall, the pattern of our results in children agrees with DBSI-assessed microstructural
477 alterations seen in adult obesity (Ly et al., 2021; Samara et al., 2020, 2021). Obesity-associated decrease
478 in apparent axonal/dendritic density and increase in cellularity have been observed in white matter in both
479 adults and children. However, the pattern of results in the striatum differs by age. For example, greater
480 putative cellularity in the nucleus accumbens is associated with higher BMI and related metrics in
481 children, but such effect is absent in adults (Samara et al., 2021). Interestingly, it has been noted that in
482 adults, higher BMI is associated with smaller nucleus accumbens volumes (Dekkers et al., 2019; García-
483 García et al., 2020), whereas in children, such association is reversed (García-García et al., 2020;
484 Rapuano et al., 2017) or absent, as is in the current study and another analysis of the ABCD Study[®] data
485 (Adise et al., 2021). It is possible that as early reactive responses to obesity, striatal cellularity and gliosis
486 would manifest as microstructural but not volumetric alterations in children, while chronic
487 neuroinflammation would over time contribute to vasogenic edema and atrophy seen in adults (Dorrance
488 et al., 2014; Sochocka et al., 2017), as in multiple sclerosis (Kamholz & Garbern, 2005). Furthermore, as
489 executive control regions such as the prefrontal cortex mature later relative to the striatum (Spear, 2000),
490 striatal disruptions may lead to a more dysregulated reward system that influences obesogenic behavior

491 more strongly in children than in adults. As the ABCD Study[®] collects biennial neuroimaging scans in the
492 same participants from childhood through adulthood using harmonized MRI sequences, future research
493 should capitalize on this longitudinal dataset to delineate obesity-related brain microstructural changes
494 over development.

495 **4.4. Comparison between DBSI and RSI findings**

496 Although DBSI and RSI differ in their modeling of brain microstructure, their measures of
497 restricted water diffusion have been interpreted similarly such that the isotropic intracellular water
498 fraction (DBSI-RF and RSI-RNI) is thought to ultimately reflect the degree of neuroinflammation-related
499 immune cell infiltration or tissue cellularity (Cross & Song, 2017; Rapuano et al., 2020, 2022; Wang et
500 al., 2011, 2015). Indeed, in our study, DBSI and RSI-assessed striatal cellularity related similarly to
501 obesity-related measures and strongly with each other, and classified obesity status with comparable
502 performance. A true head-to-head comparison of the microstructural properties reflected by DBSI-RF and
503 RSI-RNI would however warrant a controlled phantom or immunohistological gold standard. In general,
504 the agreeing findings from DBSI and RSI highlight that diffusion MRI-based techniques are sensitive to
505 characterizing obesity-associated microstructural alterations in children, adding a novel neuroimaging
506 tool that assesses putative neuroinflammation *in vivo*.

507 **4.5. Limitations**

508 Limitations and future directions include, first, the lack of longitudinal timepoints besides one
509 and two-year follow-ups. It is possible that obesity-related neuroinflammation affects clinical and
510 behavioral outcomes on a timescale larger than two years. Second, as the ABCD Study[®] does not record
511 obesity duration, we could not assess when and to what extent brain microstructural changes occur
512 relative to obesity onset. Further research tracking children moving from normal-weight to obesity would
513 be useful. Third, as we focused on assessing associations between brain microstructure and obesity-
514 related measures, factors such as sex and socioeconomic status (SES) that likely impact child
515 development and complicate said associations, though controlled for in analyses, were not tested. In terms
516 of sex, girls have greater fat mass and more concentrated trunk adiposity than boys, even at similar BMIs

517 (Wisniewski & Chernausek, 2009). Further, though obesity is associated with elevated serum leptin levels
518 in both sexes, such effect is stronger in girls, who also demonstrate increases in leptin during puberty as
519 opposed to decreases in boys (Falorni et al., 1997). In terms of SES, socioeconomic adversity is a known
520 risk factor for childhood obesity (Hemmingsson, 2018; Vazquez & Cubbin, 2020), with physical
521 inactivity, unhealthy diet, and stress as proposed mediating mechanisms (Caprio et al., 2008;
522 Gebremariam et al., 2017; Hemmingsson, 2018; Mekonnen et al., 2020). Studies have also noted that girls
523 from disadvantaged neighborhoods are more susceptible to obesity compared to boys (Kranjac et al.,
524 2021), and that girls and boys experience differential dietary influences and weight expectations from
525 parents and peers (Caprio et al., 2008; Shah et al., 2020). Regarding brain microstructure, recent analyses
526 using the ABCD Study[®] data have shown that girls demonstrate greater RSI-assessed cell and neurite
527 density in white matter compared to boys (Lawrence et al., 2022), and lower SES interacts with greater
528 BMI in relating to putative white matter neuroinflammation and smaller brain volumes (Adise et al.,
529 2022; Dennis et al., 2022; Li et al., 2023). Collectively, these results suggest that there exist complex
530 associations between sex, sociocultural forces, and brain microstructure, and future research should adopt
531 an integrative framework to investigate how they may individually and interactively shape obesity
532 development. On a related note, we emphasize growing concerns that current practices of MRI acquisition
533 and quality control may inadvertently exclude participants in less accessible rural areas, from lower SES
534 families, and of racial/ethnic minorities (Ricard et al., 2023). The exclusion of neuroimaging data with
535 excessive head motion, in particular, poses a challenge in obesity research, as greater BMI is causally and
536 genetically linked to increased motion (Beyer et al., 2020). It is possible that our findings may not
537 generalize to children of all sociodemographic backgrounds, and confirmation in large samples of
538 marginalized populations is needed.

539 Finally, we note the limited interpretability of diffusion MRI-derived microstructural metrics.
540 While DBSI assessments have been histopathologically validated as neuroinflammation-sensitive in
541 inflammatory neurological diseases including human and rodent models of multiple sclerosis (Chiang et
542 al., 2014; Wang et al., 2011, 2015), and rodent optic neuritis (Lin et al., 2017; Yang et al., 2021),

543 validation remains ongoing for obesity. Although the cellularity and axonal density effects inferred from
544 DBSI-modeled water diffusivity agree with the neuroinflammatory phenotype seen in animal models and
545 human post-mortem brain of obesity (Baufeld et al., 2016; Buckman et al., 2013; De Souza et al., 2005;
546 Décarie-Spain et al., 2018; Schur et al., 2015; Valdearcos et al., 2017), we recognize that DBSI, as any
547 MRI technique, is an indirect marker of brain microstructure and could reflect neural development that
548 otherwise do not involve neuroinflammation (Palmer et al., 2022). On a related note, it is challenging to
549 determine whether feeding-related regions such as the hypothalamus and striatum are the only ones
550 involved in obesity-related neuroinflammation, since a true control region in which this phenomenon is
551 definitively absent has not been identified. Such limitation invites future research to evaluate
552 microstructure throughout gray matter as well as study potential interactions between gray and white
553 matter alterations in obesity. The confidence in the validity of MRI-based assessments of obesity-related
554 neuroinflammation could be explored with rodent models and/or human studies using positron emission
555 tomography methods for measuring neuroinflammatory indicators (e.g., astrocyte and microglia
556 activation).

557 **5. Conclusions**

558 With DBSI, we observed microstructural alterations in white matter, hypothalamus, and striatum
559 in children with overweight and obesity. Agreement between DBSI and RSI suggested that diffusion MRI
560 is a sensitive and useful tool for assessing obesity-related putative cellularity in children. Given that
561 childhood and adolescence involve substantial brain development, further longitudinal work is warranted
562 to elucidate how early changes in brain microstructure may contribute to obesity and its comorbidities in
563 the long run.
