38

39 **One Sentence Summary:** Intraluminal accumulation and activation of eosinophils contribute to
40 the clinical properties of airway mucus and may serve as a therapeutic target.

41 **Abstract:** Uncontrolled airway mucus is associated with diverse diseases. We hypothesized that
42 the physical characteristics of infiltrating granulocytes themselves affect the clinical properties of

43 mucus. Surgically obtained nasal mucus from patients with eosinophilic chronic rhinosinusitis
44 (ECRS) and neutrophil-dominant non-eosinophilic chronic rhinosinusitis (non-ECRS) was
45 assessed in terms of computed tomography (CT) density, viscosity, water content, wettability, and
46 granulocyte-specific proteins. In an observational study, we found that nasal mucus from patients
47 with ECRS had significantly higher CT density, viscosity, dry weight, and hydrophobicity than
48 mucus from patients with non-ECRS. The levels of eosinophil-specific proteins in nasal mucus
49 correlated with its physical properties. When isolated human eosinophils and neutrophils were
50 stimulated to induce extracellular traps followed by aggregate formation, we found that cell
51 aggregates showed physical and pathological findings that closely resembled mucus. Co-treatment
52 with heparin (which slenderizes the structure of eosinophil extracellular traps) and DNase
53 efficiently induced a reduction in the viscosity and hydrophobicity of both eosinophil aggregates
54 and eosinophilic mucus. The present study highlights the pathogenesis of mucus stasis in
55 infiltrated granulocyte aggregates from a new perspective. The combination of DNase and heparin
56 might be a novel therapeutic modality against pathologic viscous eosinophilic mucus.

57

58 **Main Text:**

59 INTRODUCTION

60 Airway mucus has a role as a physical barrier to prevent the entry of external pathogens
61 and contributes to the expulsion of foreign substances through mucociliary transport and
62 maintenance of local humidity (1). However, abnormal production, hypercondensation, and
63 decreased clearance of airway mucus can lead to airway obstruction and prolonged inflammation,
64 thereby leading to a poor prognosis (2).

65 In bacterial infection, airway mucus contains abundant neutrophils that migrate into the
66 airways to eliminate pathogens through phagocytosis. These neutrophils also possess
67 anti-microbial capacity in the form of the release of sticky chromatin structures, i.e., neutrophil
68 extracellular traps (NETs). NETs serve as scaffolding for antimicrobial mediators such as histones
69 and granule proteins, and contribute to the entrapment of bacteria and other extracellular
70 pathogens (3). Abundant eosinophil extracellular traps (EETs) were also observed in patients with
71 diverse eosinophilic diseases (4, 5). These extracellular traps (ETs) are major components of
72 inflammatory cell-rich mucus, and contribute to its viscosity.

73 Interestingly, a clinical characteristic of eosinophil-dominant mucus, which is often
74 associated with type 2 inflammation, is that it shows high viscosity. For instance, eosinophilic
75 chronic rhinosinusitis (ECRS) is resistant to conservative treatments using antimicrobial therapies
76 or nebulizers, and frequently requires surgical intervention for mucus removal, which is in contrast
77 to infectious rhinosinusitis (6, 7). Luminal impaction due to viscous mucus is also observed in
78 other eosinophilic upper and lower airway diseases such as eosinophilic otitis media (5), allergic
79 fungal sinusitis (8), allergic bronchopulmonary aspergillosis (9-11), plastic bronchitis (12, 13),
80 and eosinophilic asthma (14-16). Eosinophilic airway mucus has been clinically recognized as
81 allergic mucin, eosinophilic mucin, and mucus plug, and its consistency has been described as
82 being like chewing gum, cottage cheese, axle grease, and peanut butter, which can be a clue to the
83 diagnosis (17-19). The clinical similarity of eosinophil-rich mucus in different airway diseases has
84 been previously discussed (20), although the precise mechanisms leading to its accumulation are
85 less well understood.

86 It is of paramount importance to elucidate the mechanisms and appropriate control of
87 mucus in muco-obstructive airway diseases. The objective of this study was to clarify the

88 contribution of granulocytes to the characteristics of pathological mucus. Using multiple
89 modalities including biophysical approaches, our results highlight the differences between
90 neutrophil- and eosinophil-rich mucus, and the contributions of aggregated extracellular
91 trap-producing granulocytes.

92

93 **RESULTS**

94 **Eosinophilic mucus shows high CT density**

95 Microscopically, mucus from patients with ECRS is characterized by the presence of
96 abundant eosinophil accumulations, whereas that from non-ECRS patients is characterized by
97 neutrophil accumulations (**Fig. 1A**). First, we questioned whether, in addition to differences in
98 cellular composition, mucus density would also vary between ECRS and non-ECRS patients. In
99 typical eosinophilic mucus, a unique radiological imaging presentation is high attenuation on
100 computed tomography (CT) (10, 21). Accordingly, as shown in **Fig. 1B**, the mucus in patients with
101 ECRS often shows a high CT attenuation area, unlike that in non-ECRS patients. Surgically
102 obtained mucus was hyperconcentrated as shown by macroscopic images in **Fig. 1C** and **Movie**
103 **S1**. Mucus collected from patients with ECRS was typically highly viscoelastic and thicker than
104 that from patients with non-ECRS. We initially aimed to quantify the CT value of mucus on
105 routine sinus CT imaging; however, mucosal thickening and mucus were indistinguishable. To
106 solve this problem, we conducted an observational study to collect mucus samples from patients
107 with ECRS and non-ECRS who needed surgical treatment, and established *ex-vivo* CT imaging
108 (**Fig. 1D**, **Fig. S1**). The patient demographics are indicated in **Table S1**. As expected, the mean CT
109 value of mucus from patients with ECRS showed significantly higher x-ray attenuation than
110 mucus from patients with non-ECRS (48.5 ± 16.9 Hounsfield units [HU] vs 34.2 ± 6.9 HU,

111 $p < 0.01$, **Fig. 1D**). These results indicate the presence of radiographical differences between
112 eosinophil- and neutrophil-dominant mucus.

113

114 **Biophysical properties of mucus are associated with its CT density**

115 Next, we assessed the rheological properties of mucus samples, measuring their shear
116 viscosity using a rotational viscometer (**Fig. 2A**). With the plate in contact with the mucus sample,
117 the shear viscosity was measured at different values of shear stress. As shown in **Fig. 2B**, the
118 mucus viscosity decreased when the shear rate increased, indicating a non-Newtonian
119 shear-thinning pattern, as found in previous studies on airway mucus (22). As expected, higher
120 shear viscosities were obtained in the mucus from patients with ECRS than in that obtained from
121 patients with non-ECRS. A positive correlation between viscosity and CT values was also
122 observed (**Fig. 2C**). Next, we assessed the dry weight of the mucus using a thermogravimetric
123 analyzer (TGA) (**Fig. 2D**). The weight reduction of ECRS mucus took a longer time than
124 non-ECRS mucus to reach a plateau when the mucus samples were concentrated by gradually
125 heating up to 100°C (**Fig. 2E**), indicating a higher polymer concentration. In a randomly selected
126 sample (because of technical limitations) that we tested, the dry weight of mucus from patients
127 with ECRS was significantly higher than that of patients with non-ECRS ($40.6 \pm 7.0\%$ vs $19.4 \pm$
128 6.2% , $p < 0.01$), and positively correlated with the CT value (**Fig. 2F**). To further determine the
129 wettability of the mucus, the air-dried mucus surface was analyzed with a static water contact
130 angle (**Fig. 2G**). The mucus from patients with ECRS showed significantly higher hydrophobicity
131 than that from patients with non-ECRS ($75.5 \pm 18.3^\circ$ vs $44.9 \pm 18.6^\circ$, $p < 0.0001$, **Fig. 2H**). The
132 mucus-water contact angles and CT values were positively correlated (**Fig. 2I**). These results

133 indicated that the biophysical properties of the mucus were associated with its radiographical
134 findings.

135

136 **Eosinophilic-specific protein contents correlate with the biophysical properties of mucus**

137 To determine whether the biophysical properties of the mucus were associated with the
138 eosinophils in it, we measured the concentrations of the eosinophil-specific proteins galectin-10
139 and eosinophil-derived neurotoxin (EDN). The concentrations of galectin-10 (**Figure 3A**) and
140 EDN (**Figure 3B**) were significantly higher in mucus from patients with ECRS than in that from
141 patients with non-ECRS (galectin-10, 0.26 ± 0.06 vs 0.008 ± 0.005 , $p < 0.01$; EDN, 2.09 ± 0.16 vs
142 1.25 ± 0.12 $\mu\text{g/ml}$, $p < 0.001$). In contrast, the concentration of neutrophil granule protein
143 myeloperoxidase (MPO) was significantly higher in mucus from patients with non-ECRS ($0.11 \pm$
144 0.11 vs 0.33 ± 0.37 $\mu\text{g/ml}$, $p < 0.05$, **Figure 3C**).

145 The correlations between these protein levels and the physical properties or CT values of
146 mucus were analyzed (**Table 1**). Shear viscosity was positively correlated with levels of
147 galectin-10 and EDN, dry weight was positively correlated with levels of galectin-10, contact
148 angle was positively correlated with levels of galectin-10 and EDN but negatively correlated with
149 MPO, and CT values were positively correlated with levels of galectin-10 and EDN. Taken
150 together, these results support the hypothesis that the increased eosinophils in mucus contribute to
151 its biophysical characteristics.

152

153 **Aggregated ETosis cells mimic mucus properties**

154 Unlike apoptosis, which is characterized by DNA fragmentation, activated eosinophils and
155 neutrophils undergo ETosis to release filamentous ETs (23, 24). To investigate the hypothesis that
156 ETotic granulocytes in the mucus are involved in its biophysical properties, isolated human
157 eosinophils and neutrophils were stimulated with phorbol 12-myristate 13-acetate (PMA) to
158 induce ETosis and were aggregated by shear-flow (**Figure 4A**) (25). The macroscopic appearance
159 of cell aggregates showed significant differences; eosinophil aggregates (aggEETs) showed a
160 yellow-brownish eraser-dust-like appearance, whereas neutrophil aggregates (aggNETs) showed a
161 white gel-like appearance (**Figure 4B**). These aggregates consisted of accumulated ETs and cell
162 debris (**Fig. S2**). The sections closely resembled clinical mucus (**Fig. 4C**).

163 The CT values of aggEETs were significantly higher than those of aggNETs (**Figure 4D**).
164 Of note, the viscosity of aggEETs was higher than that of aggNETs and comparable to that of
165 clinically obtained mucus from patients with ECRS (**Figure 4E**). In line with the mucus, the
166 rheological properties of aggregated cells indicated a non-Newtonian shear-thinning pattern. The
167 higher adhesion and viscosity of aggEETs were also confirmed using wall slip time-lapse images
168 (**Movie S2**).

169 The weight reduction rate of aggNETs measured using the TGA was larger than that of
170 aggEETs, and reached a plateau more quickly (**Figure 4F**). The final dry weight percentages of
171 aggEETs and aggNETs were $19.5\% \pm 5.7\%$ and $8.0\% \pm 2.8\%$ ($p < 0.01$) respectively (**Fig. 4G**). The
172 interactions between water and polymer molecules of aggEETs and aggNETs assessed by
173 differential scanning calorimetry (26) showed similar patterns (**Fig. S3**), indicating no difference
174 in phase transition behavior and molecular mobility. The wettability assessed by the static water
175 contact angle revealed that aggEETs showed significantly higher hydrophobicity than aggNETs
176 ($82.4^\circ \pm 2.1^\circ$ vs $54.1^\circ \pm 2.8^\circ$, $p < 0.0001$, **Fig. 4H**). These results indicate that in terms of CT value,

177 viscosity, dry weight, and wettability, the aggEETs and aggNETs represented similar physical
178 properties to eosinophil- and neutrophil-dominant mucus, respectively.

179

180 **Heparin enhances DNase-mediated EET degradation**

181 EETs are composed of approximately 30-nm-diameter condensed chromatin structures and
182 are resistant to degradation by deoxyribonuclease 1 (DNase 1), having a longer half-life than NETs
183 (25, 27). As heparin has been reported to relax NETs (28, 29), we treated EETs with heparin and
184 studied their ultrastructure. Interestingly, scanning electron microscopy revealed that heparin had
185 a thinning effect on EETs (**Fig. 5A**). Transmission electron microscopy also revealed that the
186 aggregated nucleosome structure of EETs was decreased after heparin treatment (**Fig. 5B**).

187 Heparin-treated EETs consisted of smooth fibers and a globular domain, similar to the previously
188 reported ultrastructure of NETs (3). The mean diameter of non-treated EETs was $29.8 \pm 0.05 \mu\text{m}$,
189 whereas that of heparin treated EETs was $19.2 \pm 0.03 \mu\text{m}$ (**Fig. 5C**). The relaxation effect of
190 heparin on EETs was observed within 5 minutes and was concentration dependent (**Fig. S4A**).

191 These results indicate the disorganization of the chromatin structure, presumably through a
192 heparin and histone interaction (30). Indeed, the liquid phase interaction of histone and heparin
193 was confirmed by the co-precipitation (**Fig. S4B, C**). Specifically, heparin-induced relaxation of
194 EETs was canceled in the presence of excess histone (**Fig. S4D**).

195 To test whether heparin enhanced the DNase-mediated EET degradation, EETs were
196 treated with DNase with or without heparin, and the amount of free DNA in the supernatant was
197 quantified. Heparin itself did not increase the EET degradation, whereas DNase-induced EET
198 degradation was significantly increased in the presence of heparin (**Fig. 5D**). These data lead us to

199 propose that the heparin-histone interaction relaxed the chromatin structure to promote
200 DNase-mediated DNA degradation.

201

202 **Effect of heparin and DNase on aggEETs and mucus**

203 As aggregated cells were a complex of accumulated EETs and cell debris, we next aimed to
204 study the effect of heparin and DNase 1 on the biophysical properties of aggEETs and aggNETs.
205 In the static condition, we noticed that aggEETs were significantly more resistant to DNase than
206 aggNETs, keeping their structure and DNA contents for 18 hours (**Fig. S5A**). Heparin induced a
207 “swelling” effect on the aggEET structure and enhanced the DNase-mediated DNA degradation
208 (**Fig. 6A, Fig. S5B**).

209 The change in shear viscosity was studied by short (1 hour) exposure of aggEETs to DNase
210 and heparin (**Fig. 6B**). Compared with the control, the most significant decrease in viscosity was
211 observed in the aggEETs co-treated with DNase and heparin. Regarding wettability, we found that
212 the contact angle of the aggEETs treated with DNase, but not those treated with heparin, was
213 significantly less than that of the control. Among the groups, treatment with DNase and heparin
214 induced the most significant decrease in hydrophobicity (**Fig. 6C**). These results indicate that
215 aggregated DNA contributed to the hydrophobicity of aggEETs, leading to DNase-resistant
216 viscosity.

217 To extend our findings to clinical samples, we examined the effect of DNase and heparin
218 on the viscosity and wettability of mucus from patients with ECRS. As expected, eosinophilic
219 mucin treated with DNase and heparin showed reduced shear viscosity (**Fig. 7A**). Treatment with
220 DNase or heparin alone did not affect the wettability of eosinophilic mucin, although co-treatment

221 with DNase and heparin significantly reduced the hydrophobicity (**Fig. 7B**). Collectively, these
222 data indicate the therapeutic potential of heparin for facilitating DNase-induced enzymatic
223 degradation of EETs.

224

225 **DISCUSSION**

226 The current study identified that intraluminal accumulation and activation of granulocytes
227 contributes to the clinical properties of hyperconcentrated airway mucus and may serve as a
228 therapeutic target. Airway mucus is a complex mixture of the following components: 1) mucus
229 glycoprotein (mucin) derived from airway epithelial goblet cells and submucosal glands; 2)
230 detached or migrated cell components and substances released from them; 3) serum-derived
231 proteins such as leached albumin; 4) pathogens such as bacteria and viruses; 5) dust; 6)
232 electrolytes; 7) substances associated with infection such as secretory IgA and other
233 immunoglobulins, lactoferrin, lysozymes, and defensins (31). Of these components, studies on the
234 viscosity of mucus have largely focused on the hypersecretion of mucin and biological changes to
235 it, whereas recent evidence has revealed that granulocyte-derived ET polymers contribute to the
236 physical characteristics of inflammatory mucus (32, 33).

237 Granulocytes are the front-line cells of innate immunity, have a short lifespan, and do not
238 divide once they mature. They are produced in large numbers in the bone marrow and can rapidly
239 accumulate at inflammatory sites from the blood circulation. Once entering the airways, activated
240 granulocytes can capture pathogens by causing ETosis, and then kill them with cytotoxic
241 protein-containing ETs (34). Unlike neutrophilic inflammation, the majority of eosinophilic
242 airway diseases are caused by sterile allergic reactions and have pathological implications.
243 Utilizing the granulocyte-rich mucus from patients with chronic rhinosinusitis and blood-derived

244 cells, our data indicated that the presence of aggregated ETotic eosinophils influences the
245 biophysical characteristics of mucus. The CT values of sinus mucus were directly related to the
246 presence of eosinophilic inflammation and its biophysical properties, supporting the utility of CT
247 values for diagnosis and pathological evaluation in clinical practice.

248 Fixed airway obstruction due to eosinophilic mucus is a hallmark phenomenon of diverse
249 eosinophilic upper and lower airway diseases. The water contact angle experiments indicated the
250 hydrophobic properties of eosinophil-dominant mucus. Biochemically, water is the most abundant
251 constituent in airway mucus, composing about 98% of it under normal conditions. When the water
252 content is below 90%–93%, mucus inhibits the motility of cilia, producing mucus stasis (35). In
253 the current study, the mucus from patients with ECRS and non-ECRS was highly dehydrated
254 (59.4% and 80.6% water, respectively), far exceeding that required to inhibit mucociliary
255 clearance. Poor mucus clearance directly causes reduced quality of life for patients. For instance,
256 the presence of eosinophilic mucin is reported to be associated with recurrence after endoscopic
257 sinus surgery for chronic rhinosinusitis (7). Granule proteins, cytokines, histones, and other
258 alarmins released from inflammatory cells may cause epithelial damage and tissue remodeling
259 when they remain intraluminally localized, generating muco-inflammatory positive feedback
260 (35-37).

261 To study the effects of eosinophils and neutrophils on the biophysical properties of mucus,
262 we utilized blood-derived granulocytes. Using ETotic cell aggregates, we were able to reproduce
263 similar physical properties as those clinically observed in eosinophil- and neutrophil-dominant
264 mucus. While the mechanisms of inflammation have been investigated using molecular and
265 genetic approaches, we believe that our cell population-based approach provides a better
266 understanding of the biophysical phenomena. Although the current study focused on the properties

267 of the mucus, a significant difference between hydrophilic aggNETs and hydrophobic aggEETs
268 might account for formation of pathological features of diseased tissue such as neutrophilic
269 abscess (38) and eosinophilic granuloma (39). Our results provide a strong argument for targeting
270 excess granulocyte accumulation and ET formation as causes of tissue dysfunction.

271 Aerosolized recombinant human DNase 1 (dornase alpha) is an established treatment for
272 patients with cystic fibrosis, where it promotes the hydrolysis of NETs in airway secretions (40,
273 41). EETs have a well-conserved chromatin structure and are more aggregated than NETs,
274 resulting in greater stability against DNase (25, 42). The current study is the first demonstration of
275 the relaxing effect of heparin on EETs. Negatively charged heparin has a high affinity for
276 positively charged histones, and it can disorganize chromatin fiber by liberating histones (29, 43).
277 Heparin has pleiotropic effects, such as preventing the cytotoxic effects of extracellular histone
278 (44) and eosinophil granule proteins (45, 46). Our data support the combined use of heparin and
279 DNase by inhalation, endoscopic injection, or irrigation, with the potential to remove EETs to
280 decrease the viscosity and hydrophobicity of eosinophil-dominant mucus (**Fig. 7C**). This simple
281 mucus modification strategy could be a better approach than targeting the mucin hypersecretion
282 pathway, which is subject to adverse consequences (47).

283 Limitations of the current case-control study include the heterogeneity of chronic
284 rhinosinusitis. In both ECRS and non-ECRS, chronic rhinosinusitis is classified according to the
285 JESREC scoring system, although the pathogenesis is a mixture of inflammation by neutrophils
286 and eosinophils in varying degrees (48). Nevertheless, the concentrations of eosinophil-specific
287 galectin-10 and EDN in mucus were associated with their properties, suggesting the importance of
288 eosinophil density. Considering the limitations of our experimental study, we could not exclude
289 the possibility of the presence of EET-independent granulocyte viscosity. AggEETs and aggNETs

290 are composed of condensed cell debris including actin polymer, which may cause viscosity (22).
291 Since neutrophils contain abundant protease that may degrade organized proteins (25), it is
292 conceivable that neutrophil cell debris has a much more disintegrated structure. Other possibilities
293 include cytolytic eosinophil production of *de novo* polymers such as Charcot-Leyden crystals (49),
294 and amyloid-like aggregation of granule protein (4, 45, 50). The difference between neutrophil and
295 eosinophil debris may be related to pathological differences, and further investigation is
296 warranted.

297 In conclusion, our study revealed the characteristics of mucus and aggregated cells using
298 radiographical, biophysical, pathological, and molecular approaches. The current study also
299 highlights the utility of cell-population-based biophysical analysis. Intraluminal granulocyte
300 accumulation and the activation of these granulocytes to form aggregated ETs are processes
301 involved in the clinical features of mucus. The combination of DNase and heparin may be a
302 promising therapeutic modality against highly viscous eosinophilic mucus.

303

304 **MATERIALS AND METHODS**

305 **Study design**

306 This was a case-control study comparing the CT values and physical properties of
307 clinically obtained sinus mucus from age- and gender-matched ECRS and non-ECRS patients
308 (**Table S1**). The sample size was based on preliminary data from our laboratory. Sinus mucus was
309 obtained from patients with non-ECRS and those with ECRS treated by routine endoscopic sinus
310 surgery between February 2017 and July 2019. Samples were immediately frozen at -30°C and
311 shipped to Akita University on dry ice and stored at -80°C . Patients with ECRS were diagnosed

312 according to the diagnostic criteria of the JESREC study score (51). This scoring system assesses
313 unilateral or bilateral disease, the presence of nasal polyps, blood eosinophilia, and dominant
314 shadow of ethmoid sinuses on CT scans. For a definitive diagnosis of ECRS, a score of 11 or
315 higher and a mean number of 70 or higher infiltrated eosinophil counts in sectioned tissue in the
316 three densest areas of cell infiltration in high power fields ($\times 400$, hematoxylin-eosin staining) is
317 required. Patients who did not meet the diagnosis of ECRS were classified as non-ECRS. Patients
318 with an established immunodeficiency, coagulation disorder, diagnosis of classic allergic fungal
319 sinusitis, eosinophilic granulomatosis with polyangiitis, fungal sinusitis, or cystic fibrosis, and
320 those who were pregnant, were excluded from the study. All patients scheduled for surgery had
321 previously failed to respond to adequate trials of conservative medical therapy administered to
322 control their symptoms. All patients were free of systemic steroids for at least two months prior to
323 surgery. Preoperative demographics and medical history including sex and age were obtained for
324 each patient. For the mucus studies, the experiments were conducted with the investigator blinded
325 to the details of the samples.

326 The purpose of the experimental study using mucus from patients with ECRS and cell
327 aggregates separately dominated by neutrophils or eosinophils was to investigate the mechanism
328 behind the highly viscous eosinophilic airway mucus with a view to developing a rationally
329 designed treatment. For the cell-based studies, measurements were made over at least three
330 experiments. All experiments were approved by the Akita University institutional review board,
331 protocol approval No. 994, 1965. Written informed consent was obtained from all participants in
332 accordance with the principles laid out in the Declaration of Helsinki.

333

334 **Cell purification**

335 Eosinophils were isolated from peripheral blood from medication-free donors using a
336 MACS™ system (Miltenyi Biotec, Bergisch Gladbach, Germany) with CD16-negative selection
337 (anti-CD16 antibody-conjugated microbeads, #130-045-701, Miltenyi Biotec), as described
338 previously (52, 53). The purity of the isolated eosinophils was >98% of nucleated cells and the
339 viability >99%. Neutrophils (>95% neutrophils, viability >98%) were obtained by positive
340 selection using the same system. The viability and purity of the cells were analyzed via trypan blue
341 exclusion.

342

343 **Ex vivo CT value measurement**

344 Nasal mucus and cell aggregates were stored in microtubes and scanned three times using
345 an Aquilion ONE CT scanner (**Fig. S1**, Canon Medical Systems, Otawara, Japan). The scanning
346 parameters were 120 kVp, 240 mA, 0.5-s exposure time, and 350-mm field of view. The raw data
347 were reconstructed with an FC 21 kernel to generate 512×512 matrix images with 0.5-mm slice
348 thickness ($0.67 \times 0.67 \times 0.5$ -mm voxel resolution). Each voxel had a CT value that represented the
349 x-ray attenuation of a substance where 0 Hounsfield units (HU) is the attenuation of water
350 (1g/cm^3) and -1000 HU is the attenuation of air (0g/cm^3). The microtubes were excluded from the
351 obtained CT images by applying a cut-off CT threshold of -100 HU and the mucus was extracted.
352 The CT values of the mucus were measured on each of the three scans and then averaged.

353

354 **Preparation and characterization of ETosis cell aggregates**

355 Isolated neutrophils and eosinophils ($10\text{--}100 \times 10^6$ cells) were stimulated with phorbol
356 12-myristate 13-acetate (PMA; Sigma, 10 ng/ml) in 6-well flat-bottom tissue culture plates, in

357 0.3% bovine serum albumin (BSA) containing phenol red-free RPMI 1640. After 18 hours (>99%
358 cell death with ETosis), culture plates were shaken (600 minutes^{-1} , 20 minutes) with an MS1 plate
359 shaker (IKA Works, Wilmington, NC) to induce aggregates. The aggregates were collected using
360 a cell scraper and tweezers. In some experiments, they were fixed in 10% formalin and embedded
361 in paraffin, followed by hematoxylin-eosin staining. For liquid phase stability, aggregates were
362 stained with SYTOX green (1:5000) and viewed by an inverted microscope (Eclipse TE300,
363 Nikon, Tokyo, Japan) equipped with a cooled color digital camera (Spot 1.3.0, Diagnostic
364 Instruments, Sterling Heights, MI) in conjunction with IP Lab image analysis software
365 (Scanalytics, Fairfax, VA). Additional characterization is provided in **Fig. S2**.

366

367 **Measurement of shear viscosity**

368 The rheological experiments were carried out using an MCR302 rotational rheometer
369 (Anton Paar Japan, Tokyo, Japan) with a cone–plate system (CP25-2) for shear fixation.
370 Frequency sweep tests were performed from 0.1 rad/s to 100 rad/s . The shear thinning behavior
371 of secretions and cell aggregates was characterized over a range of 0 to 100 s^{-1} . The viscosity of
372 the sample against shear rate was measured. All rheology studies were performed at 36°C . In some
373 experiments, the shear viscosity was also measured with added DNase 1 (40 U/ml, New England
374 Biolabs, Ipswich, MA) and/or heparin (300 $\mu\text{g/ml}$, Sigma-Aldrich, St. Louis, MO). DNase and/or
375 heparin were added in sufficient quantities to soak the samples in the tubes and the tubes were
376 incubated for one hour at 37°C . Before measurement of the shear viscosity, 20 mg of each sample
377 was prepared.

378

379 **Thermogravimetric analysis (TGA)**

380 A sample of each of the cell aggregates or mucus (5 mg) was placed in an alumina crucible
381 and heated in a thermogravimetric analyzer (STA 7300, Hitachi High-Technologies, Tokyo,
382 Japan). Samples (originally at 25°C) were heated at a rate of 10°C/minute up to a maximum of
383 100°C and were maintained at this temperature for 30 minutes in a stream of dry nitrogen. The
384 percentage weight change was evaluated, and the final weight was considered as the dry weight.

385

386 **Water contact angle analysis**

387 Mucus or cell aggregates were uniformly smeared onto a slide and dried in ambient air for
388 6 hours. For measurement of the contact angle, a 4- μ l water droplet was placed using a
389 manipulator and imaged using a digital camera 30 s after the release of the droplet. The contact
390 angle values of the droplets were recorded using the ImageJ contact angle plug-in
391 (<https://imagej.nih.gov/ij/>). In some experiments, we also measured the contact angle of samples
392 treated overnight with DNase 1 (40 U/ml) and/or heparin (300 μ g/ml, Sigma-Aldrich, St. Louis,
393 MO). Prepared samples were smeared onto a slide and the contact angle was measured as
394 described above.

395

396 **Measurement of the levels of EDN, galectin-10, and MPO**

397 Ten microliters of 0.1% dithiothreitol were added to 10-mg mucus samples, which were
398 then stirred for 15 minutes before being quickly frozen in liquid nitrogen. The samples were
399 crushed with a multi-bead shocker (Yasui Kikai, Osaka, Japan) at 250 bpm for 10 s and then with
400 an ultrasonic crusher (Bioruptor, BM Equipment Co., Ltd. Tokyo, Japan). The supernatant was

401 collected by centrifugation (10 000× g, 10 minutes). The levels of EDN, galectin-10, and MPO
402 were measured using ELISA assay kits (EDN: 7630, MBL, Nagoya, Japan; galectin-10:
403 Cloud-Clone Corp., Katy, TX, MBL, Aichi, Japan; MPO: Enzo Life Sciences Inc, Farmingdale,
404 NY).

405

406 **Scanning electron microscopy (SEM)**

407 Eosinophils were added to round coverslips in culture plates and stimulated with PMA (10
408 ng/ml) for 3 hours or more to induce EET formation, with or without heparin (300 µg/ml, 30
409 minutes). They were then immediately fixed in a mixture of freshly prepared aldehydes (1%
410 glutaraldehyde and 1% paraformaldehyde) in 0.1 M phosphate buffer (pH 7.4) for 1 hour at room
411 temperature and processed for SEM. Coverslip-adherent cells were postfixed with 1% osmium
412 tetroxide in water for 1 hour and dehydrated in an ascending ethanol series from 50% (vol/vol) to
413 absolute ethanol (10 minutes per step). Cells were then critical point dried in carbon dioxide.
414 Coverslips were mounted on aluminum holders, sputtered with 5-nm gold, and analyzed in a
415 scanning electron microscope (Thermo Fisher Scientific FEI Quanta 3D FEG Dual Beam
416 (SEM/FIB)], which enabled excellent high resolution surface imaging.

417 Qualitative analyses were performed on 70 electron micrographs (n=35 for each group) at
418 different magnifications. For quantitative analyses of EETs, a total of 20 electron micrographs
419 from cytolytic eosinophils showing EETs (10 from untreated and 10 from heparin-treated cells)
420 were analyzed at 80 000×. The diameters of 20 EET fibers randomly selected from each electron
421 micrograph were measured, with a total of 400 fibers being analyzed (n=200 fibers in each group).
422 The mean diameter of the EET fibers was then determined for each group.

423

424 **Transmission electron microscopy (TEM)**

425 Eosinophils were seeded on Aclar film (Nishin EM, Tokyo, Japan), stimulated with 10
426 ng/ml of PMA for 3 hours, and then immediately fixed in a mixture of freshly prepared aldehydes
427 (1.25% glutaraldehyde and 1% paraformaldehyde) in 0.1 M cacodylate buffer. After incubation
428 for 2 hours in 0.1 M cacodylate buffer containing 1% OsO₄, the specimens were dehydrated in an
429 ethanol series, passed through propylene oxide, and embedded in epoxy resin. Ultrathin sections
430 (80 nm) were collected on copper grids and stained for 20 minutes in 4% uranyl acetate and 0.5%
431 lead citrate. The specimens were viewed with a Hitachi H-7650 transmission electron microscope
432 at 100 kV.

433

434 **EET and aggEET dissolution assays**

435 Isolated eosinophils were induced to ETosis by stimulation with PMA (10 ng/ml) for 18
436 hours. The medium was replaced with 100 µl of Ca²⁺-containing Hank's balanced salt solution
437 with Picogreen (Thermo Fisher Scientific, Waltham, MA, 1:100) and incubated with or without
438 DNase 1 (20 U/ml) and heparin (5 mg/ml). The plate was shaken gently (400 rpm) for 5 minutes at
439 room temperature. After pipetting, 100 µl of medium was aspirated and centrifuged (500× g, 5
440 minutes). The fluorescence intensity of the supernatant was immediately measured to quantify the
441 free DNA using a GloMax-Multi detection system (Promega, Madison, WI). In the static
442 condition, aggEETs were incubated at 37°C (0.3% BSA/RPMI medium) in the presence of DNase
443 1 (40 U/ml). To visualize DNA, SYTOX was added to the medium. Fluorescent images were

444 obtained at indicated time points under an inverted microscope (Eclipse TE300, Nikon, Tokyo,
445 Japan) equipped with a cooled color digital camera.

446

447 **Statistical Analysis**

448 Results are expressed as mean \pm SD. The data analysis in this study was performed using
449 GraphPad Prism software, Version 7 (GraphPad, San Diego, USA). The Wilcoxon signed rank test
450 or Welch's *t* test were used to evaluate differences between two groups. Multiple comparison tests
451 were used to compare means between groups. Correlation analysis was performed using
452 Spearman's rank correlation. A *p*-value of <0.05 was considered statistically significant.

693 **Figure legend**

694

695 **Fig. 1. Eosinophil-rich mucus from patients with ECRS showed high CT x-ray attenuation.**

696 (A) The microscopic appearance of sectioned mucus in patients with ECRS and non-ECRS
697 (400×, hematoxylin-eosin staining, scale bar=50 μm). (B) Coronal sinus CT images of
698 patients with ECRS (right) and non-ECRS (left). Red arrowheads indicate high CT
699 attenuation areas in the maxillary sinus. (C) Macroscopic images of surgically-obtained
700 sinus mucus from patients with ECRS and non-ECRS. (D) Comparison of mucus CT
701 values between ECRS and non-ECRS groups (ECRS: n=40; non-ECRS: n=26, mean ± SD,
702 **p<0.01, Welch's *t* test).

703

704

705 **Fig. 2. Biophysical properties of mucus and their associations with CT density. (A)**

706 Measurement of dynamic viscosity against the shear rate of mucus samples using a

707 rotational viscometer. **(B)** The change in shear viscosity according to the shear rate (orange

708 line: ECRS, n=27; blue line: non-ECRS, n=15). **(C)** Correlation between shear viscosity at

709 a shear rate of 10 s^{-1} and the CT values of each sample (orange: ECRS, n=37; blue:

710 non-ECRS, n=25). Coefficient of correlation, $R^2 = 0.45$ **(D)** Measurement of dry weight

711 of the mucus using a thermogravimetric analyzer (TGA). **(E)** The weight reduction rate of

712 the sample measured using TGA. Samples were gradually heated from 0 to 7.5 minutes and

713 then kept at 100°C . Lines and colored areas indicate mean and $\pm \text{SD}$, respectively (orange:

714 ECRS, n=4; blue: non-ECRS, n=6). **(F)** Correlation between dry weight and CT values

715 (orange: ECRS, n=4; blue: non-ECRS, n=6). Coefficient of correlation, $R^2 = 0.69$ **(G)**

716 Measurement of the contact angle (θ) between water and mucus surface. **(H)** Comparison

717 of contact angle (orange: ECRS, n=40; blue: non-ECRS, n=27, ****p<0.0001,

718 Mann-Whitney U test). **(I)** Scatter plot shows correlation between contact angle and CT

719 values of the samples (orange: ECRS, n=40; blue: non-ECRS, n=27). Coefficient of

720 correlation, $R^2 = 0.15$.

721

722

723

724 **Fig. 3. Eosinophil- and neutrophil-specific protein contents in mucus.** The concentrations of

725 (A) galectin-10, (B) eosinophil-derived neurotoxin (EDN), and (C) myeloperoxidase

726 (MPO) in mucus from patients with ECRS and non-ECRS (ECRS, n=37; non-ECRS,

727 n=25; mean \pm SE, * p<0.05 ** p<0.01 *** p<0.001, Welch's *t* test.).

728

729

730 **Fig. 4. The characteristics of cell aggregates.** (A) Preparation of aggEETs and aggNETs.

731 Isolated human eosinophils and neutrophils were stimulated with PMA to induce ETosis.

732 After plate shaking, aggregated cells were collected. (B) Macroscopic images of aggEETs

733 and aggNETs. (C) Microscopic appearance of sectioned aggEETs and aggNETs (400×,

734 hematoxylin-eosin staining, scale bar: 50 μm). (D) Comparison of CT values between

735 aggEETs and aggNETs (n=3, repeated measures, Welch's test, ****p<0.0001). (E) The

736 change in shear viscosity of cell aggregates according to shear rate (orange line: aggEETs,

737 n=3; blue line: aggNETs, n=3). (F) Mass reduction rate of cell aggregates using TGA

738 (orange: aggEETs, n=6; blue: aggNETs, n=6). Lines and colored area indicate mean and ±

739 SD, respectively. (G) Comparison of dry weights (aggEETs, n=6; aggNETs, n=6; *p<0.05,

740 Welch's test). (H) Comparison of contact angles (aggEETs, n=14; aggNETs, n=14;

741 ****p<0.0001, Welch's test).

742

743

744

745 **Fig. 5. The effect of heparin and DNase on EETs.** (A) Scanning electron microscope (SEM)

746 images of non-treated control and heparin treated EETs (Scale bar=1 μ m). The EETs

747 consist of smooth stretch and globular domains (red arrowheads). (B) Transmission

748 electron microscope images of non-treated or heparin treated EETs. White arrowheads

749 indicate globular domain. (C) Comparison of fiber diameters of extracellular traps assessed

750 by SEM (n=200, ****p<0.0001, Welch's *t* test). (D) Measurement of free dsDNA detected

751 in the culture supernatant briefly treated with heparin and/or DNase 1 (n=4, ****p<0.0001,

752 Tukey's multiple comparisons test).

753

754

755 **Fig. 6. Heparin enhances the effect of DNase on aggEETs.** (A) Morphological change in
756 aggEETs under the effect of DNase and/or heparin was assessed by SYTOX DNA dye
757 using inverted fluorescence microscopy (scale bar=200 μm , $\times 20$ objective). (B) The cell
758 aggregates were treated with DNase and/or heparin for 2 hours and shear viscosity was
759 assessed by a rotational rheometer (n=3 for each group, mean \pm SD). (C) Comparison of
760 contact angle of cell aggregates treated with DNase and/or heparin (n=3, *p<0.05,
761 **p<0.01, ***p<0.001, Kruskal-Wallis test: p<0.01).

762

763

764 **Fig. 7. The effect of heparin on mucus in patients with ECRS. (A)** The change in shear
765 viscosity of mucus obtained from patients with ECRS (n=7 for each group, mean \pm SD).
766 **(B)** Comparison of contact angle of mucus treated with DNase and/or heparin (each group:
767 n=4, ****p<0.0001, Kruskal-Wallis test: p<0.01). **(C)** Illustration of the effects of heparin
768 on aggEETs in mucus. Airway mucus contains large amounts of aggEETs that contribute
769 to viscosity. Heparin relaxed their condensed chromatin structure and enhanced the effect
770 of DNase.
