Key Words: Tuberculosis; gender; care seeking; barriers; engagement; Zambia

1 **Abstract**

2 **Background:** Men and women with undiagnosed tuberculosis (TB) in high burden countries
3 may have differential factors influencing their healthcare seeking behaviors and access to TB
4 services, which can result in delayed diagnoses and increase TB-related morbidity and mortality.

5
6 **Methods:** A convergent, parallel, mixed-methods study design was used to explore and
7 evaluate TB care engagement among adults (≥ 18 years) with newly diagnosed,
8 microbiologically-confirmed TB attending three public health facilities in Lusaka, Zambia.
9 Quantitative structured surveys characterized the TB care pathway (time to initial care-seeking,
10 diagnosis, and treatment initiation) and collected information on factors influencing care
11 engagement. Multinomial multivariable logistic regression was used to determine predicted
12 probabilities of TB health-seeking behaviors and determinants of care engagement. Qualitative
13 in-depth interviews (IDIs; n=20) were conducted and analyzed using a hybrid approach to
14 identify barriers and facilitators to TB care engagement by gender.

15

16 **Results:** Overall, 400 TB patients completed a structured survey, of which 275 (68.8%) and 125
17 (31.3%) were men and women, respectively. Men were more likely to be unmarried (39.3% and
18 27.2%), have a higher median daily income (50 and 30 Zambian Kwacha [ZMW]), alcohol use
19 disorder (70.9% [AUDIT-C score ≥ 4] and 31.2% [AUDIT-C score ≥ 3]), and a history of smoking
20 (63.3% and 8.8%), while women were more likely to be religious (96.8% and 70.8%) and HIV-
21 positive (70.4% and 36.0%). After adjusting for potential confounders, the adjusted probability
22 of delayed health-seeking ≥ 4 weeks after symptom onset did not differ significantly by gender
23 (44.0% and 36.2%, $p=0.14$). While the top reasons for delayed healthcare-seeking were largely

24 similar by gender, men were more likely to report initially perceiving their symptoms as not being
25 serious (94.8% and 78.7%; $p=0.032$), while women were more likely to report not knowing the
26 symptoms of TB before their diagnosis (89.5% and 74.4%; $p=0.007$) and having a prior bad
27 healthcare experience (26.4% and 9.9%; $p=0.036$). Notably, women had a higher probability of
28 receiving TB diagnosis ≥ 2 weeks after initial healthcare seeking (56.5% and 41.0%, $p=0.007$).
29 While men and women reported similar acceptability of health-information sources, they
30 emphasized different trusted messengers. Also, men had a higher adjusted probability of stating
31 that no one influenced their health-related decision making (37.9% and 28.3%, $p=0.001$). IDIs
32 largely corroborated the quantitative findings while offering more context and in-depth
33 understanding of the factors that affected initial health seeking decisions, diagnoses, and
34 treatment experiences across each step of men's and women's TB care pathways. To improve
35 TB detection, men recommended TB testing sites at convenient community locations, while
36 women endorsed an incentivized, peer-based, case-finding approach. Sensitization and TB
37 testing strategies at bars and churches were highlighted as promising approaches to reach men
38 and women, respectively.

39

40 **Conclusions:** Men and women with TB differ with respect to TB risk factors, TB care
41 engagement experiences and determinants, and broader health influences. These differences
42 suggest that gender-tailored TB health promotion and case-finding strategies may be needed to
43 improve TB diagnosis and care engagement in high burden settings.

44

45

46

47 **Background**

48 In 2020, more than 4 million persons with tuberculosis (TB) globally remained undiagnosed or
49 went unreported,¹ suggesting that a large proportion never received life-saving treatment. That
50 same year, 56% of all TB notifications were among men, notwithstanding significantly higher
51 gaps in case detection when compared to women.¹ These data are consistent with a meta-
52 analysis of TB prevalence surveys from 28 countries that found a 2.2-times higher prevalence
53 of TB disease among men than in women.² Further, men with TB may demonstrate lower rates
54 of sputum conversion and cure,^{3,4} and are more likely to die.^{5,6} In some settings, gender
55 disparities in TB-related outcomes, in part, appear to be underpinned by men's late(r)
56 presentation to TB services, as well as poorer retention in TB treatment services.⁷⁻⁹ Thus
57 strategies to increase TB case detection require targeted approaches grounded in gendered
58 differences in the TB epidemic and care pathway.

59 In order to design interventions and healthcare improvement strategies to better reach,
60 appeal to, and overcome unique barriers faced by both men and women with undiagnosed TB,
61 it is crucial to better understand the factors influencing TB care seeking and engagement in high
62 burden settings, and whether they differ by gender. Across different settings, both men and
63 women with undiagnosed TB may face substantial challenges seeking care for their illness and
64 accessing TB diagnostic services.^{5,8-10} These may include insufficient TB-related knowledge
65 (including its symptoms, where to go for services and the benefits of early diagnosis and
66 treatment), insufficient time and/or money for transport and/or services (especially among the
67 socioeconomically vulnerable), geographic inaccessibility, a lack of social support and self-
68 efficacy, TB- (and HIV-) related stigma, privacy concerns, prior bad experiences with healthcare
69 (including rude providers), or in the case of men, traditional views of masculinity that impede

70 healthcare seeking. The determinants influencing engagement in TB care services in sub-
71 Saharan Africa among men and women may be distinct, but to-date gender-specific differences
72 across the TB care pathway, if present, are not well-characterized.

73 We undertook a mixed-methods study in Lusaka, Zambia, to explore and characterize
74 care journeys for men and women with newly diagnosed TB. We sought to (a) evaluate TB risk
75 factors, (b) understand barriers and facilitators to healthcare seeking after symptom onset,
76 getting TB illness diagnosed, and starting TB therapy, and (c) to explore preferences for being
77 reached with health information and potential strategies to improve TB detection. The primary
78 objective of this study was to determine if and how these differ for men and women with TB. In
79 the discussion section we use insights on similarities and differences to suggest gender-tailored
80 strategies that may be needed to improve the key steps within the TB care pathway (**Fig 1**) and
81 address any gender-specific inequities.

82

83 **Methods**

84 A convergent, parallel, mixed-methods design was used to yield a more complete understanding
85 of complex experiences and multi-level barriers to care engagement among individuals with
86 undiagnosed TB, by combining quantitative and qualitative data to construct complementary
87 perspectives.^{11,12}

88

89 **Setting and participants**

90 The study was conducted at three public health facilities in Lusaka, Zambia from September
91 2019 to June 2020. Kanyama and Matero first-level hospitals have extremely busy outpatient

92 TB clinics (1,263 and 1,522 TB notifications, respectively in 2021) and serve as the primary
93 health facility for adjacent, densely populated, peri-urban townships; University Teaching
94 Hospital (UTH), is a tertiary health facility serving Lusaka, and a referral hospital for Zambia.
95 Quantitative data collection took place at Kanyama and University Teaching Hospitals, and
96 qualitative data collection at all three facilities.

97

98 Persons with TB (i.e., TB patients) were eligible to participate in either quantitative or qualitative
99 study activities if they were at least 18 years of age and had microbiologically-confirmed TB
100 diagnosed in the last three weeks (to improve recall). An approximately equal number of
101 participants were purposefully sampled from each of the three facilities, balanced for sex and
102 HIV status. Recruitment for the quantitative data collection phase took place from September
103 18, 2019 to January 17, 2020, and closed once the pre-specified sample size was reached
104 (~n=400 participants); recruitment for the qualitative data collection phase took place from
105 February 20th 2020 to June 6th 2020, and closed once data saturation was reached (10 men and
106 10 women for n=20).¹² There were no individuals who participated in both the quantitative and
107 qualitative data collection phases.

108

109 **Ethics, consent, and permissions**

110 All participants provided written or verbal (for phone interviews) informed consent in their
111 preferred language (Nyanja, Bemba or English). The University of Zambia Biomedical Research
112 Ethics Committee (#010-014-19) and the institutional review board of the University of California,
113 San Francisco (#18-26028) approved this study.

114

115 **Data collection**

116 Both quantitative and qualitative data collection tools sought to explore and characterize men's
117 and women's TB care journeys (**Fig 1**).¹³ For the quantitative phase of the study, all participants
118 completed a structured survey (**S1 Appendix**). In addition to socio-demographic and clinical
119 details, surveys captured information related to their pathway to TB care services, including
120 timing of symptom onset, factors that may have influenced care-seeking and diagnosis, where
121 and when they sought care, and their experience and satisfaction with TB services; whenever
122 possible, validated measures for the survey were utilized.^{14–16} Surveys were administered via a
123 touchscreen tablet using District Health Information Software 2 (DHIS2) with the help of a study
124 team member. TB diagnosis and treatment details, as well as HIV status (reflecting either self-
125 report or test result status if previously unknown) were extracted from routine, facility-specific,
126 TB registers.

127 For the qualitative study phase, since recruitment took place around the start of the
128 COVID-19 epidemic, the 20 TB patients completed in-depth interviews (IDIs) by phone to protect
129 the safety of both the patients and study staff.¹⁷ A semi-structured guide, developed and
130 structured according to key steps in TB care pathways,^{18,19} was used for the IDIs (**S2 Appendix**).
131 The guide used open-ended questions and incorporated probes based on the Capability,
132 Opportunity, Motivation, Behavior (COM-B) theory of behavior change to clarify responses and
133 encourage elaboration.²⁰ Four experienced Zambian research assistants (RAs) collected the
134 data after being trained in the study data collection methods. During training, the interview guide
135 was practiced in the three interview languages (Nyanja, Bemba and English) to elicit participant
136 experiences in the manner intended. During interviews, the interviewer captured the key points

137 and developed the notes into a semi-structured memo immediately after the interview. Each IDI
138 was audio-recorded and lasted 40-90 minutes.

139

140 **Data analysis and definitions**

141 Alcohol use disorder was defined as an AUDIT-C score of ≥ 4 among men and ≥ 3 among
142 women.²¹ For both quantitative and qualitative data analyses, we refer to gender-specific
143 differences because we explored and characterized health-related behaviors and choices and
144 the factors influencing those behaviors and choices (including social, cultural, and gender
145 norms) among men and women with TB, rather than any differences that may be due to biology
146 due to biology.²²

147

148 **Quantitative analysis**

149 For quantitative data analysis, because we were *a priori* interested in evaluating whether there
150 were differences between men and women with TB, all analyses were undertaken overall and
151 stratified by gender. Fisher's exact, Pearson's chi-squared, or Wilcoxon rank-sum tests were
152 applied to compare socio-demographic characteristics among indicators with few responses,
153 categorical covariates, and continuous covariates, respectively. Multinomial multivariable logistic
154 regression was then used to determine the adjusted, predicted probabilities of specific TB health-
155 seeking behaviors and determinants of care engagement for men and women. A directed acyclic
156 graph (**S1 Figure**) was used to identify a minimally sufficient adjustment set of confounders and
157 this informed the final multivariable model;²³ in addition to the dependent TB healthcare-seeking
158 determinant variable and the independent variable of interest, gender (male or female), models
159 were adjusted for age, enrolment site, HIV status, education level, daily income, relationship

160 status, alcohol use disorder status (AUDIT-C positive), history of prior TB, and knowing friends
161 or family members who have had TB. Complete case analysis was conducted including only
162 individuals for which complete survey data was recorded. All statistical tests were two-sided at
163 alpha=0.05 and were conducted using Stata version 17.0 (StataCorp LLC, College Station, TX,
164 USA).

165

166 **Qualitative analysis**

167 Interviews were transcribed verbatim and directly translated into English. The RAs quality
168 checked their own transcripts and CM quality checked all the transcripts. All the transcripts and
169 memos were uploaded into Dedoose v7.0.23 (SocioCultural Research Consultants, Los
170 Angeles, CA, USA) for coding. A hybrid process of inductive and deductive thematic analysis
171 was followed.^{24,25} First, ADK created deductive codes from prior research evaluating gendered
172 differences in TB care engagement.^{5,9} Next, CM, ADK and KC reviewed four transcripts and
173 inductively developed codes (**S3 Appendix**). CM and ADK coded two transcripts each to refine
174 the codes, followed by another two transcripts each to achieve consistency in coding. All
175 transcripts were then coded by CM and ADK through an iterative process and categorized into
176 themes. Analysis and interpretation of the data was categorized by gender to capture similarities
177 and differences in perceptions, behaviors, experiences, and preferences.

178

179 **Triangulation**

180 After analysis of the qualitative and quantitative data sets separately, ADK and CM compared
181 the quantitative findings with the descriptive findings from the qualitative data for convergence.
182 To relate and reflect on the gender-specific differences and suggested gender-tailored

183 interventions, the quantitative statistical results were compared with the interpretation of each
184 theme from the qualitative findings. The first authors reviewed and discussed the contradictions
185 and the corroborated findings with related explanations.

186

187 **Results**

188 **Overview of participants and characteristics by sex**

189 Among 483 adults with confirmed TB approached by the study, 76 (15.7%) did not wish to
190 participate (reasons were not collected), and 7 (1.4%) had incomplete survey data; therefore
191 400 (82.8%) were included in the quantitative data analysis. Overall, participants had a median
192 age of 34 (IQR: 27-43) years, 275 (68.8%) were male, and 187 (46.8%) were HIV-positive (**Table**
193 **1**). The 20 TB patients who participated in the IDIs had a median age of 44 years (range, 23-
194 67), 10 (50%) were male and female, respectively, and 10 (50%) were HIV-positive, 8 (40%)
195 HIV-negative and 2 (10%) had an unknown HIV status.

The characteristics of survey participants stratified by gender did not differ by age, education, or prior history of TB (**Table 1**) . However, men with TB were more likely to report never being married (39.3% and 27.2%), higher median daily income (50 and 30 Zambian Kwacha (ZMW]) and being the primary household provider (73.5% and 51.6%). Conversely, women with TB were much more likely to report that they were religious (96.8% and 70.8%) and be HIV-positive (70.4% and 36.0%) than men with TB.

Men were also substantially more likely to have evidence of alcohol use disorder (i.e., AUDIT-C positive; 70.9% and 31.2%) and report a history of tobacco smoking (63.3% and 8.8%); of 234 participants with alcohol use disorder, 155 (79.5%) men and 8 (20.5%) women had a tobacco smoking history. Men were also much more likely to attend bars/taverns at least weekly (54.6% vs 16.8%) and 29.1% of men and 12.0% of women with TB reported going to a bar/tavern every day. Men were also more likely than women to say that they knew someone who had been previously diagnosed with TB (52.2% and 36.8%) and to suspect TB (not yet diagnosed) in a friend and/or family member (29.9% and 19.2%).

227 In the IDIs, men frequently attributed their TB disease to alcohol consumption and smoking
228 'behavior':

229 P: "I had TB as a result of my behavior."

230 I: "If I may ask, what do you mean 'as a result of' what you were doing?"

231 P: "I was smoking." (**Male, HIV negative**)

232

233 "I don't know how it (TB) started. I think it's just the issue of drinking alcohol and smoking.

234 I used to drink a lot and smoke whenever I went out." (**Male, HIV positive**)

235

236

237 **TB health-seeking delays and care seeking experiences**

238 **Barriers to healthcare seeking**

239 There was no gender-specific difference in the probability of delayed initial health-seeking ≥ 4
240 weeks after symptom onset (**Table 2**; 44.0% and 36.2%, $p=0.14$). Men and women were
241 similarly likely to report that while they had considered getting help for their TB symptoms sooner,
242 they consciously delayed healthcare seeking (53.6% and 54.6%, $p=0.85$). The top reasons
243 provided for delayed care seeking were largely similar according to gender (**Fig 2a, S1 Table**).
244 Both men and women commonly reported that they thought their symptoms were due to
245 environmental causes such as pollution, that they preferred to try self-medication first, and that
246 they lacked time to seek evaluation for their symptoms. However, men were more likely to report
247 that they thought their symptoms were not serious initially and would spontaneously get better
248 (94.8% and 78.7%, $p=0.032$), while women had a higher probability of stating that they did not
249 know the symptoms of TB prior to their diagnosis (89.5% and 74.4%, $p=0.007$). While not a
250 commonly cited reason for delayed health care seeking, women were also more likely than men
251 to report prior bad healthcare experiences (26.4% and 9.9%, $p=0.036$).

252

253
254
255

Table 2. Tuberculosis care seeking behaviors and healthcare experiences among men and women with newly diagnosed tuberculosis in Lusaka, Zambia. Values represent adjusted predicted probabilities and associated 95% confidence intervals.

	Overall (95%CI)	Male (95%CI)	Female (95%CI)	Gender-specific difference* (95%CI)
TB Health-Seeking				
Health-seeking delay category (Time from symptom onset to first seeking care for illness)				
<4 weeks	58.5 (54.1,63.0)	56.0 (50.4,61.6)	63.8 (55.5,72.0)	-7.8 (-18.3, 2.7)
4-7.9 weeks	30.6 (26.4,34.8)	33.1 (27.6,38.6)	25.7 (18.4,33.0)	7.4 (-2.2, 17.1)
≥8 weeks	10.9 (7.8,13.9)	10.9 (7.0,14.8)	10.6 (5.0,16.2)	0.3 (-6.9, 7.6)
Location where participants first visited for care related to their illness				
Public clinic or hospital	86.6 (83.4,89.7)	88.0 (84.4,91.5)	83.2 (74.3,92.0)	4.8 (-5.0, 14.6)
Private clinic or hospital	4.5 (2.4,6.5)	3.5 (1.4,5.7)	7.0 (1.9,12.1)	-3.5 (-9.3, 2.3)
Pharmacy	7.8 (5.3,10.4)	7.8 (4.9,10.7)	8.0 (1.5,15.6)	-2.9 (-7.7, 7.1)
Herbalist/traditional healer	1.0 (-)	0.8 (-)	1.8 (0,6.5)	-1.0 (-5.6, 3.7)
TB Diagnosis				
Diagnostic delay category (Time from initial care-seeking to TB diagnosis)				
<2 weeks	54.4 (49.6,59.2)	59.0 (53.3,64.8)	43.5 (34.4,52.7)	15.5 (4.1, 26.9)
2-3.9 weeks	25.4 (21.1,29.7)	23.6 (18.4,28.7)	28.7 (19.4,38.0)	-5.1 (-16.3, 6.1)
≥4 weeks	20.2 (16.4,24.0)	17.4 (13.1,21.7)	27.8 (18.5,37.1)	-10.4 (-21.7, 0.3)
Diagnostics and treatment received for TB illness prior to diagnosis				
Antibiotics	75.6 (20.3, 28.6)	74.9 (69.6, 80.2)	77.0 (69.2, 84.7)	-2.0 (-11.9, 7.9)
Blood test	81.1 (77.6, 84.6)	80.8 (76.6, 85.2)	81.9 (76.4, 85.2)	1.1 (-7.5, 9.6)
Chest x-ray	74.3 (70.4, 78.2)	74.3 (69.6, 79.0)	74.4 (65.8, 83.0)	-0.2 (-10.4, 10.1)
Traditional remedy	8.6 (5.9, 11.3)	9.4 (5.8, 12.9)	6.7 (1.9, 11.5)	2.7 (-3.7, 9.0)
Number of visits to providers/facilities prior to diagnosis				
1	56.2 (51.3,61.0)	58.1 (52.1,64.2)	51.9 (42.2,61.5)	6.2 (-5.8, 18.2)
2	35.5 (30.9,40.2)	33.8 (28.0,39.6)	39.2 (29.8,48.6)	-5.4 (-17.1, 6.2)
≥3	8.3 (5.7,11.0)	8.1 (5.0,11.3)	8.9 (3.0,14.8)	-0.8 (-7.8, 6.2)
Time to diagnostic facility from home				
<30 minutes	40.1 (35.4,44.7)	40.0 (34.2, 45.7)	40.1 (40.7, 49.4)	-0.1 (-11.7, 11.4)
30-60 minutes	41.3 (36.6,46.0)	43.3 (37.3, 49.3)	37.4 (28.5, 46.3)	6.0 (-5.4, 17.3)
>1-2 hours	18.6 (14.9,22.4)	16.7 (12.2, 21.3)	22.5 (14.6, 30.5)	-5.8 (-15.5, 3.9)
TB Treatment				
Treatment delay category				
0-2 days	91.4 (88.8, 94.1)	91.0 (87.7, 94.3)	92.7 (87.5, 97.9)	-1.7 (-8.1, 4.7)
3-5 days	4.8 (2.7, 6.9)	4.6 (2.1, 7.0)	5.4 (0.8, 10.0)	-0.8 (-6.3, 4.6)
>5 days	3.8 (2.0, 5.6)	4.4 (2.1, 6.8)	1.9 (0, 4.6)	2.5 (-11.7, 6.2)

*Positive values indicate a higher probability among men, while negative values indicate a higher probability among women.

256
257
258

259 Many IDI participants, irrespective of gender, corroborated the survey findings and reported “not
260 worrying” about their cough and initially self-medicating with herbs and cough medicines based
261 on advice from their peers, or their own initiative. They continued to take these medications,
262 which temporarily alleviated some of their symptoms, and only visited the health facility when
263 their symptoms did not improve, or they experienced additional symptoms, such as prolonged
264 coughing fits, blood in their sputum, worsening chest pain, and excessive weight loss.

265 “I didn’t even know what was happening. I was sweating after even having a bath. I tried
266 drinking all sorts of medication for a cough, I thought I would get better and what misled
267 me was the cough medicine. I was drinking [the medicine] but the cough was not finishing.
268 That is when I decided to go to the clinic and they told me that my lungs were not fine and
269 that is how I was put on TB medication” (**Female, HIV negative**)

270
271 Women, particularly those who were HIV-negative, disclosed that they lacked knowledge about
272 TB symptoms and delayed seeking care because they “did not know what the problem was at
273 that time and never thought about it [TB].”

274 I: “Before being found with TB, what did you know about TB?”

275 P: “I really did not know about TB (...); when I was diagnosed with it, that is when I was
276 taught about (TB).” (**Female, HIV negative**)

277
278 Men discussed delaying care seeking because of confusing their TB symptoms, such as a cough
279 or weight loss, with the effects of excessive smoking and alcohol use. After onset of symptoms,
280 they tried to first cut back on their smoking and alcohol intake. They only visited the health facility
281 when symptoms persisted:

282 “I used to smoke, and when I would cough, I would feel pain, and when I would talk about
283 what I was feeling, I was told to stop smoking or else I would get TB” (**Male, HIV negative**)

284
285 “So, people would say, ‘Ah big man! You have lost weight, are you not eating?’ Then I
286 would say I have been drinking a lot of beer that is why. But when I reduced on beer,
287 the same problem persisted, then I knew I had to go to the hospital.” (**Male, HIV**
288 **negative**)

289

290 Some men who delayed seeking help cited conflicting work obligations as their reason. They
291 believed that despite feeling unwell, men acted “fit” to keep their work commitments:

292 “You just know how men behave; you keep on thinking you are fit and yet you are not
293 okay. So, you’ll find that I would force myself to go for work even when I’m not feeling
294 okay.” (Male, HIV negative)

295
296 “For most men, one of the reasons [for delayed care seeking] is because they are the
297 ones that work and take care of their families. Even if he is not feeling well and stays
298 home, all eyes will be on him, because he needs to provide for his family. So even if he
299 is not feeling well, he would rather go to work and keep on telling himself I’ll go to the
300 clinic next time.” (Male, HIV positive)

301
302 Notably, some HIV-positive participants, regardless of gender, delayed seeking care because
303 they thought their symptoms were related to HIV antiretroviral therapy (ART) side effects:

304 I: “At that point that you lost weight, what did you think was happening to your body?”
305 P: “I just thought the medicine [ART] was rejecting me (...), that is when I went to talk to
306 my doctor. But it was not immediate, it took me almost a month.” (Female, HIV positive)

307

308 **Factors influencing initial healthcare-seeking behaviors and location**

309 Both men and women cited similar top reasons for ultimately seeking care for their TB illness
310 (Fig 2b, S1 Table) including to stay healthy, being worried it was something serious,
311 encouragement from worried loved ones and friends to get help, feeling debilitated, or no longer
312 being able to work.

313

314 IDI participants similarly emphasized that they would visit a doctor if they had a serious illness.

315 Both men and women indicated that symptoms, particularly a persistent cough with chest pain,
316 “blood discharge” (i.e., hemoptysis), shortness of breath, and progressive weakness, led them
317 to seek medical attention. Men were more likely to mention seeking treatment because they had
318 lost too much weight, while women often mentioned having a persistent cough and being too
319 weak to carry out their everyday tasks:

320 “The only thing that made me go [to the clinic] was I was just noticing that I was lacking
321 strength to do things and it was becoming so hard for me to even cut vegetables, and I
322 would just sleep. I was failing even to fetch water in a bucket.” (**Female, HIV positive**)
323

324 Social support played a large role in influencing both men’s and women’s care seeking, with
325 friends and families strongly encouraging them to seek help for their symptoms. Men were more
326 likely to note that their spouses supported them by accompanying them to the health facility.

327 “It’s the pain that I was having and the people who love me organized themselves and
328 came to get me and I didn’t refuse. They came in and parked the vehicle because even
329 when they were talking to me on phone my voice was very weak. So, we just went to the
330 hospital so we could know the truth.” (**Male, HIV positive**)
331

332 Among men and women living with HIV, encouragement from their support network of peers,
333 also living with HIV, was mentioned as a facilitator for seeking care:

334 “There are some friends who are on medication (ART) and I even phoned them to ask if
335 they also felt the same at some point and they encouraged me to visit the hospital
336 because of how I was feeling.” (**Male, HIV positive**)
337

338 Notably, both male and female participants were highly likely to report they first presented to
339 public health clinic or hospital for their TB illness (88.0% and 83.2%, $p=0.33$) **Fig 2c, Table 2**);
340 additional sites of initial presentation (e.g., private health facilities, pharmacies, and traditional
341 healers) were uncommon and did not differ by gender. Men and women noted similar factors
342 that influenced the first site and/or provider they sought for help with their TB illness (**Fig 2d, S1**
343 **Table**); the most important reasons included proximity to home, perceived high quality services,
344 privacy and confidentiality, inexpensive services, and because their friends/colleagues went
345 there. Men were more likely than women to choose a facility because its providers were nice
346 and polite (42.0 and 30.3%, $p=0.014$; **Fig 2d**).

347

348 Similarly, men and women in the IDIs often shared that they chose health facilities that were
349 close to their homes to avoid transport costs and based on recommendations from friends and
350 family members:

351 I: "...Why did you go to xxx clinic?"

352 P: "Because it is our nearest clinic and easiest to get there." (**Female, HIV positive**)

353

354 On the other hand, some IDI participants said they avoided their local health facilities in favor of
355 private clinics and higher-level government institutions to access specialized services, and to
356 avoid poor perceived service, long queues, a purported lack of medical testing capacity and
357 medication stockouts.

358 "I wanted to go to xxx but people were saying the machines don't work well they can't
359 even detect malaria. That is how I went to yyy and they tested me." (**Male, HIV positive**)

360

361 "I went there [private facility] because it is faster to get results there, at xxx queues are
362 long. Just for you to be seen is a problem, and [t is] worse still if you are not feeling well.
363 I wanted to be tested and told the results faster so that I could be told what I was suffering
364 from to start medication." (**Female, HIV negative**)

365

366

367 **TB diagnostic delays and experiences**

368 After first seeking evaluation and care for the illness, women had a higher likelihood than men
369 of experiencing more than 2-weeks of delay in being diagnosed with TB (56.5% and 41.0%,
370 $p=0.007$, **Table 2**); notably 27.8% of women had diagnostic delays exceeding 4-weeks
371 compared to 17.4% among men ($p=0.06$). There was no gender-specific difference in the
372 likelihood of reporting visits to either 2 or 3-plus providers/facilities prior to their TB diagnosis
373 being made (**Table 2**). Men and women also had a similarly high probability of reporting that
374 they received antibiotics and underwent blood tests, and chest radiography as part of their TB
375 diagnostic journey (**Table 2**); use of traditional remedies was uncommon and didn't differ by sex.
376 There were few gender-specific differences in TB symptomatology (**S2 Table**), with only eight

377 sweats being slightly more likely among men (93.8% and 80.9%, $p=0.007$). Notably, the
378 likelihood of reporting cough ≥ 2 weeks was similar between men and women (77.8% and 83.2,
379 $p=0.23$), as was the probability of reporting ≥ 4 TB symptoms (92.5% and 91.6%, $p=0.39$).

380
381 In IDIs, both men and women corroborated findings of delayed TB diagnosis despite making
382 multiple clinic visits. While they received cough medication, antibiotics, or prescriptions to
383 purchase symptom-relieving medicines, they were tested for TB only when symptoms persisted.
384 For example, a female participant claimed her TB remained undiagnosed for about two months
385 while pregnant:

386 “I was pregnant and developed a really bad cough that I had for almost two months and
387 that’s how I ended up giving birth to a premature baby because (...) it was difficult for
388 them to find the TB. They would just give me Amoxil and say it’s just a cough and even
389 when I finish the medication, it would not feel any better. I went to the hospital two times.”
390 **(Female, HIV positive)**

391
392 Contrary to the survey, a few men and women disclosed initially seeking assistance from
393 traditional healers, but that they found it unsatisfactory and later went to health facilities when
394 they felt their symptoms were not improving:

395 “Well at first, I tried the Traditional Healer but what he was saying was contrary to what I
396 was feeling. So, I sat and thought that this problem could be sorted at the hospital and
397 that is how I went to the hospital.” **(Male, HIV positive)**

398 399 **TB treatment delays and experiences**

400 Overall, TB treatment delays were uncommon and did not differ by gender – where the
401 probability of starting on TB therapy within 2 days of diagnosis (as confirmed by the TB register)
402 was 91.0% and 92.7% for men and women, respectively ($p=0.61$; **Table 2**).

403

404 In IDIs, both men and women corroborated that once diagnosed, they were quickly started on
405 TB treatment. They reported that, in most cases, the results of TB tests were available the
406 following day and that treatment was initiated the same or following day of TB diagnosis:

407 I: “How long after being diagnosed did you start treatment?”

408 P: “They gave me medication the same day I was diagnosed.” (**Female, HIV negative**)

409

410 IDI participants revealed that they had received information on the TB prevention, care, and
411 treatment process after being diagnosed. Men said they had been told to give up smoking and
412 drinking:

413 ‘When I reached, they told me you will start taking drugs and I took some even there
414 and they oriented me about TB, how its spread and how to prevent it from [spreading to]
415 people. This was through a video.’ (**Male, HIV positive**)

416

417 “I was told things like in the case of beer drinking I had to stop and also smoking had to
418 stop.” (**Male, HIV positive**)

419

420 Both men and women expressed acceptance of the diagnosis and the need to take medication
421 due to a desire to get well:

422 “I just accepted [it] and moved on, and I make sure I take my drug. It’s life, there is
423 nothing you can do.” (**Female, HIV positive**)

424

425 However, after receiving a TB diagnosis, some men and women disclosed experiencing
426 “depression” and ‘fear’ of having TB, sometimes because they associated TB with HIV:

427 “I was scared ... I was so scared, I just wondered where I contracted it from since I
428 frequently test for HIV.” (Female, HIV negative)

429

430 “At the time [of TB diagnosis], I felt depressed and could think a lot. Then afterward, I
431 realized the solution was just to follow instructions because you can’t keep thinking
432 about where you got it from, or who gave it to you, because it is too late.” (**Male, HIV
433 positive**)

434

435 In the survey, men and women had a similar probability of reporting that they were satisfied with
436 the TB services they received (95.1% and 95.4%, $p=0.93$) and that the facility met their health-
437 related needs (92.9% and 88.9%, $p=0.29$) (**S3 Table**). However, women were more slightly likely

438 than man to say that they would recommend the TB facility to a friend or loved one (96.1% and
439 91.0%, $p=0.045$).

440

441 Among IDI participants, men and women corroborated the above and expressed a high degree
442 of satisfaction with their experiences with receiving TB services. They perceived health workers
443 as kind and helpful in guiding them through the clinic processes. As a result, both men and
444 women stated that they intended to advise and encourage their friends and family to visit the
445 medical facilities for treatment if they felt ill.

446 “They just welcomed us very well; they don’t shout or insult, even when going to get
447 medicine for TB, they welcome us very well.” (Female, HIV negative)

448

449 **Designing TB care engagement strategies for men and women**

450 **Preferred health channels and trusted sources of health information**

451 Among survey respondents, most communication channels for health-related information were
452 highly acceptable to both men and women with TB (**Fig 3a, S4 Table**). The most popular
453 mediums for reaching participants with health-related information included community-based
454 plays, brochures, radio, television, and billboards – only television was more likely to be reported
455 by women (88.6% and 81.6%, $p=0.046$). Notably, men had a higher probability than women of
456 reporting that no one influenced or helped them make health-related decisions (37.9% and
457 28.3%, $p=0.001$). Among persons who reported that someone influenced health-related
458 decisions, men and women had a similarly high likelihood of reporting family members, friends,
459 health care workers and spouses as persons who helped them make health-related decisions
460 (**Figure 3b, S4 Table**). However, men had a higher probability of reporting that coworkers
461 (54.4% and 31.9%, $p=0.002$) and neighbors (50.4% and 35.7%, $p= 0.042$) influenced their

462 health-related decisions, while women had a higher probability of reporting that religious leaders
463 (62.9% and 47.7%, $p=0.044$) influenced their health-related decisions (**Figure 3b, S4 Table**).

464

465 Both men and women in the IDIs also agreed that radio, television, SMS, and newspapers were
466 effective tools for "educating" people about TB transmission and symptoms, as well as
467 encouraging people to seek treatment for TB symptoms. In order to "reach" everyone who might
468 not have access to radios and televisions, they also highlighted the importance of community-
469 based engagement strategies:

470 "It will be good for people to sensitize in the community because not everyone has a
471 television and radio." (**Male, HIV positive**)

472

473

474 **Recommendations for improving TB detection among men and women**

475 IDI participants were asked to consider three different potential strategies for improving TB
476 detection in their community and state which one they thought might be most successful (**Table**
477 **3**). About half of participants chose putting stands and mobile clinics offering TB testing in
478 community places like markets and bus stations as the best strategy to improve TB detection;
479 this was also the most preferred strategy among men, especially because of its convenience if
480 one is simply "passing by" and is sick. Participants, especially women, also felt a promising
481 strategy was to provide a small incentive to reach out to and encourage TB testing among peers
482 that may have TB; this was because of their lived experience and ability to credibly teach others
483 about TB. Few participants preferred a strategy that would provide persons with a small incentive
484 to undergo TB testing at the local health facility.

485 **Table 3. Perspectives and preferences of newly diagnosed tuberculosis patients for**
486 **three potential strategies to improve tuberculosis diagnosis in their community (n= 17).**

Strategy and description	Number who stated that this strategy was most likely to be effective	Quotes
<p>1. Place a mobile clinic or stand at a convenient location in the community (e.g., market, minibus stand), to provide rapid TB testing</p>	<p>Overall: 8 Men: 5 Women: 3</p>	<p>“What is important is putting mobile clinics because they will be near people and when someone is just passing (by) they may think of testing for TB. Just like people go for cervical cancer, you will find that one is just coming from the market, but once they see the mobile clinic, they will turn and test, so it helps. (Male, HIV positive)</p> <p>“The suggestion to open a mobile clinic is a good idea because some people will give reasons like not being able to go to the clinic to get tested because sometimes there are long distances to get to the clinic...” (Male, HIV negative)</p> <p>“The best is that one of going into like the market or bus stops, because people are scared to go to the clinic, so you go and test them from there.” (Female, HIV positive)</p>
<p>2. Provide a small amount of money to get tested for TB at the health facility</p>	<p>Overall: 2 Men: 1 Women: 1</p>	<p>“Yes! ... You know people, where there is money, they can accept anything. You offer some money, packets of sugar, some drinks... you know this poverty in Zambia.” (Male, HIV negative)</p> <p>“It’s good because some people become suffer(ing) from TB and (become) so sick that they have no means of looking for food.” (Female, HIV positive)</p>
<p>3. Provide brief training to current TB patients and give them a small amount of money to reach out to their peers that may have TB to encourage testing</p>	<p>Overall: 7 Men: 2 Women: 5</p>	<p>“If you give (training and incentives) to TB patients, they will also teach others who are seem(ing) to be sick. They will go and teach them and encourage them, tell them to go to the clinic and get tested... It is very much number one because they are able to encourage someone of their status, like what that friend of mine did to me, just because she went through it...” (Female, HIV positive)</p> <p>“If we teach the current (TB patients) and give them something, they might be able to assist those people who are with the same disease.” (Male, HIV positive)</p> <p>“You know what it does to you, so you want also others to know fast what it does.” (Female, HIV negative)</p>

Note: 2 men did not provide responses to this question as their interviews were ended early, and 1 woman did not provide clear opinion for which strategy she thought may be most effective

487
488
489

490 IDI participants also recommended door-to-door household testing campaigns in the
491 community to identify more persons with TB.

492 ‘Yes, I think like I said, the door-to-door campaign, it can work. For example, you have
493 this program for polio whereby nurses go door-to-door, and also put-up points where they
494 give vaccinations for polio and other medicine to prevent blindness. Even TB you can do
495 the same.’ (Male, HIV negative)
496

497 Participants further recommended that undertaking case finding in bars and taverns could help
498 better reach and diagnose TB among men, as they spend a lot of time there:

499 I: “What ways can be used to reach men for them to be diagnosed early?”

500 P: Okay men are found in the taverns, if you start going around the community taverns,
501 that would help.” (Male, HIV negative)
502

503 Women on the other hand were said to be ‘into church’ and approaching them at churches
504 would help in reaching them and detecting TB sooner:

505 “Women are not a problem. They normally meet in groups at church on certain days, so
506 we can do well to follow them on those days to sensitize them about TB.” (Female, HIV
507 positive)
508

509 Discussion

510 In this mixed-methods study among more than 400 newly diagnosed TB patients in Lusaka,
511 Zambia, we identified several important gender-specific differences influencing TB diagnosis and
512 care (**Fig 1**). Of note, a larger proportion of men engaged in behaviors that increased their risk
513 for developing TB disease (e.g., high levels of alcohol consumption and smoking), while women
514 more often reported experiencing substantial delays in the diagnosis of their TB disease after
515 initially seeking help for their symptoms. Furthermore, we identified gender-specific differences
516 in factors affecting men’s and women’s healthcare seeking behaviors, trusted persons who
517 influence their health, and preferences for improving TB detection in their community. These

518 differences have important implications for the design of future strategies to improve TB
519 diagnosis and care engagement for both men and women living in high TB burden settings.

520

521 Except for one study among multi-drug resistant TB patients from South Africa, the
522 prevalence of alcohol use disorder among persons with TB in our study was much higher than
523 prior prevalence estimates among TB patients in sub-Saharan Africa.²⁶ Alcohol use has a dose-
524 response relationship with TB, where larger consumption amounts - likely through several
525 mechanisms²⁷ – is associated with an increasing risk of both developing^{28–30} and dying from
526 TB.^{29,31} Smoking is also an important risk factor for developing TB,^{32,33} and combined with
527 alcohol use, may portend to an even higher TB risk through a synergistic relationship.³⁴ In high
528 TB burden settings, like Zambia, there is clearly an important need to address harmful alcohol
529 use (found among 63% of the men) and smoking (among 80% of men with alcohol use disorder)
530 as a strategy for preventing TB and improving treatment outcomes.^{26,31,35} One potentially
531 promising strategy to better reach men could include outreach at bars, taverns, and betting halls,
532 as also suggested by our interviewees, to provide alcohol use and smoking use education and
533 support resources as part of a broader TB sensitization and control strategy; however, this and
534 other strategies require further study to determine their acceptability, feasibility and potential
535 effectiveness.

536

537 Prior studies have reported variable gender-specific differences in patient-related delays
538 in healthcare seeking for TB symptoms.^{5,7} Among both men and women, lack of knowledge and
539 disease recognition (e.g., cough) as well perceptions of disease causation (environment, curse)
540 and severity led to self-medication, lifestyle changes and use of herbalists/ traditional healers,

541 which delayed care-seeking. These findings suggest an important need for ongoing community-
542 based TB education and sensitization campaigns to reach men and women alike. Such
543 campaigns should leverage regular opportunities for persons living with HIV engaged in care –
544 emphasizing their increased risk of TB, its associated symptoms, and the need for timely
545 evaluation even if they suspect their illness is due to other causes.

546

547 Our results provide important insights into the optimum ways to reach men and women
548 with TB and other health related information. Motivations and nudges such as staying strong
549 and healthy, concern and encouragement from loved ones, and the inability to continue working
550 may be leveraged in future TB communication strategies to promote timely healthcare seeking
551 among both men and women. Plays in the community, brochures/pamphlets, and the radio made
552 for appealing edutainment to both men and women. Interpersonal communication should
553 leverage the influence of co-workers (workplace) and neighbors by providing group education
554 in the workplace and neighborhood for men, and that of religious leaders through church-based
555 outreach approaches that include religious leaders as key stakeholders and trusted messengers
556 for health initiatives targeted at women. Examples of such strategies in the TB literature are
557 limited,^{36,37} but there has been demonstrated success associated with including religious leaders
558 in campaigns to bolster COVID-19 vaccination coverage in different settings.^{38–40} It was notably
559 that male participants were far more likely to state that no one influenced their healthcare
560 decisions; understanding what TB-related messages are the most resonant and motivating, and
561 what channels are most likely to reach men impervious to interpersonal influence requires
562 preference research methods; best-worst scaling, are well suited for this purpose.⁴¹

563

564 In our study, men were similarly likely as women to cite lack of time as a factor contributing
565 to delayed healthcare seeking, despite being the primary breadwinner for their household. Being
566 the main income provider may be tied to masculine identity and is often cited as an important
567 reason for prolonged delays in healthcare seeking for TB among men.^{5,9,42,43} Notably, few men
568 and women reported cost as a barrier to healthcare seeking for TB despite reporting a lower
569 average daily income. This suggests that unlike other settings, women's financial dependency
570 did not result in them demoting their healthcare-related needs and delaying access to TB
571 diagnostic services.⁹ TB detection strategies that offer convenience and timeliness – such as
572 community-based testing locations, after hours testing availability, or fast-track access points at
573 facilities are likely to appeal to both men and women. In interviews, men preferred TB testing
574 services at community locations such as minibus stands or at the market for their convenience
575 while women preferred a peer-based strategy in which brief training and a small incentive were
576 provided to recently diagnosed TB patients to reach out to and recommend that their family
577 members, friends and other close contacts get tested. Testing in community locations should be
578 further explored for patient-centeredness, convenience, and overcoming barriers to timely TB
579 diagnosis, especially as more sensitive, rapid, point-of-care, and non-sputum-based diagnostics
580 become available in the future.^{44,45} Several pilots and implementation research projects have
581 shown that community testing, peer-led, and social-network based TB case finding strategies,^{46–}
582 ⁵¹ are promising approaches - although their epidemiologic impact may be limited.⁵²
583 Nonetheless, interventional implementation studies and/or quasi-experimental studies are
584 needed to understand how feasible and effective they and other community-based case-finding
585 strategies may be as part of existing TB control programs.⁵³

586

587 Public healthcare facilities provided the settings for health seeking behavior for both men
588 and women based on proximity, quality of services, privacy and confidentiality, and (lack of) cost.
589 The role of actors, i.e., providers, was important to men who valued polite and respectful
590 interactions, which has been previously identified an important determinant for HIV care
591 engagement and retention in Zambia.^{54,55} Emphasizing the convenience, quality, privacy of TB
592 services and politeness of providers should be incorporated into future communication and
593 quality improvement strategies to increase care engagement among both men and women.

594

595 Though found in many different high burden settings,^{8,9,56,57} including a prior study from
596 Lusaka, Zambia,⁵⁸ it is not immediately clear what underpinned the prolonged time to diagnosis
597 among women with TB in our study. Both men and women presented with similar symptoms and
598 frequently to a public health facility where TB diagnostic services (or specimen referral) are
599 routinely available. While it is possible that TB education post-diagnosis led to over-reporting of
600 symptoms, another possible explanation is low-risk perception for TB in women (especially those
601 that are HIV negative) among healthcare workers, which led them to consider alternative
602 etiologies even when women presented multiple times with classic TB symptoms.⁷ To further
603 investigate this finding and explanatory causes, the use of standardized patient visits may be
604 considered,⁵⁹ that could then inform appropriate quality improvement efforts, including provider
605 trainings. Further, the implementation of systematic TB testing for all symptomatic persons
606 presenting for any reason to health facilities in high burden community (i.e., intensified case
607 finding), could help overcome any gender-related clinical biases, if present.⁶⁰⁻⁶²

608

609 Strengths of our study were the inclusion of a large number of consecutively enrolled,
610 microbiologically-confirmed TB patients from two different health facilities. Further, the
611 integration of qualitative data from TB patients helped to provide greater insight and rich context
612 for men's and women's converging and diverging experiences, and factors influencing TB care
613 engagement. However, our study did have some limitations. While our study findings are likely
614 representative of Lusaka province, which notifies more than 40% of annual TB cases in
615 Zambia,⁶³ some barriers, behaviors – which may be tied to local cultural norms – and healthcare
616 experiences, are likely to be context-specific and thus may not be generalizable to other urban
617 and peri-urban African settings. Additionally, our study was conducted directly prior to and at the
618 very outset of the COVID-19 pandemic; it is not clear how this world altering event has and will
619 continue to influence and modify men's and women's TB engagement behaviors and
620 experiences. However, a prior study during the early COVID pandemic in Zambia appeared to
621 demonstrate that men and women continued to seek care for TB illness despite substantial
622 uncertainties and fear.¹⁷ Further, because we recruited persons shortly after diagnosis, we were
623 unable to explore determinants of TB therapy adherence and retention in treatment services;
624 while findings to date across settings are heterogenous, males may be more likely to non-
625 adherent and have poor TB treatment outcomes.⁵ Finally, many variables we utilized were by
626 self-report, including alcohol use, smoking, seeking help from traditional healers, and delays in
627 initial healthcare seeking after TB symptom onset; given the potentially stigmatizing nature of
628 these behaviors and social desirability bias, which may differ by gender, the true prevalence may
629 have been underestimated.

630

631 **Conclusions**

632 We identified several important and marked gender-related differences among men and women
633 with TB in Zambia, including a high prevalence of alcohol use disorder and tobacco smoking
634 among men, excess diagnostic delays among women, as well as differential determinants of
635 healthcare-seeking, trusted messengers, and preferred strategies for improving TB detection.
636 Collectively, this suggests that gender tailored strategies, acknowledging men's and women's
637 unique challenges, needs, and preferences, may be needed to improve TB diagnosis and care
638 engagement in high burden settings.

639 **Author contributions:** ADK, MM, and AS designed the study with input from CM and KAC.
640 CM, SN, KM, NS, MK, LC, and MM helped with project administration and data collection. ADK
641 was responsible for funding acquisition. ADK and CM was responsible for the database. ADK,
642 CM, JMP, KAC, and AS, designed the analyses and ADK and CM performed the analyses. All
643 authors commented on drafts and approved the final version of the article. ADK takes
644 responsibility for the integrity of this study and decision to publish these data.

645

646 **Funding:** This research was supported by a grant from the National Institutes of Health,
647 UCSF-Gladstone Center for AIDS Research, P30AI027763 (ADK). ADK is supported by the
648 National Institute of Allergy and Infectious Diseases (K23AI157914). KAC is supported by THE
649 by the National Institute of Allergy and Infectious Diseases (K24 AI167805).

650 **Role of funder:** The funders had no role in study design, data collection and analysis, decision
651 to publish, or preparation of the manuscript

652

653 **Acknowledgments:** We would like to acknowledge and thank the study staff, the staff at the
654 individual health facilities, and the study participants who made this work possible.

655

656 **Competing interests:** ADK is an Academic Editor for PLOS Global Public Health. JMP is a
657 guest editor for PLOS Global Public Health. KAC has received investigator-initiated research
658 support from and served as a medical advisory board member for Gilead Sciences. The
659 authors otherwise declared that no competing interests exist.

660

661 **Data Availability:** Data files will be made available upon publication from the Dryad database.
