## 26 **Structured summary**

### 27 Background

28 Pulmonary tuberculosis (PTB) due to *Mycobacterium tuberculosis* (Mtb) can be challenging  
29 to diagnose because of difficulty obtaining samples, and suboptimal sensitivity of existing  
30 tests. We investigated the performance characteristics and diagnostic accuracy of upper  
31 respiratory tract tests for diagnosing PTB and hypothesised they would have sufficient  
32 accuracy and utility to improve PTB diagnosis.

### 33 Methods

34 A systematic review and meta-analysis was conducted by searching MEDLINE, Cinahl, Web  
35 of Science, Global Health, and Global Health Archive databases up to 31/01/2021, a second  
36 search was conducted for the period 1/1/2021 - 27/5/2022 (subsequently extended to  
37 6/12/2022) to identify studies that reported on the accuracy of upper respiratory tract  
38 sampling for TB diagnosis compared to microbiological reference standards. We used a  
39 random-effects meta-analysis with a bivariate hierarchical model to estimate pooled  
40 sensitivity and specificity, stratified by sampling method. Bias was assessed using QUADAS-  
41 2 criteria. Study registered with PROSPERO (CRD42021262392).

### 42 Findings

43 10,159 titles were screened for inclusion, 274 studies were assessed for full text review, and  
44 71, comprising 119 test comparisons published between 1933 and 2022 were included in the  
45 systematic review (53 in meta-analysis). For laryngeal swabs, pooled sensitivity was 57.8%  
46 (95% CI 50.5-65.0%), specificity was 93.8% (95% CI 88.4-96.8%) and diagnostic odds ratio  
47 (DOR) was 20.7 (95% CI 11.1-38.8). Nasopharyngeal aspirate sensitivity was 65.2% (95%  
48 CI 52.0-76.4%), specificity was 97.9% (95% CI 96.0-99.0%) and DOR was 91.0 (95% CI  
49 37.8-218.8). Oral swabs sensitivity was 56.7% (95% CI 44.3-68.2%), specificity was 91.3%  
50 (95% CI 81.0-96.3%), and DOR was 13.8 (95% CI 5.6-34.0).

51 Interpretation

52 Upper respiratory tract sampling holds promise to expand access to TB diagnosis, including

53 for people who can't produce sputum. Exploring historical methods using modern

54 microbiological techniques may further increase the options for alternative sample types.

55 Prospective studies are needed to optimise accuracy and utility of sampling methods in

56 clinical practice.

57 Funding

58 HRS is funded by the MRC through the MRC DTP programme at LSTM [Grant number

59 MR/N013514/1].

60

61

62 **Research in context**

63 *Evidence before this study*

64 Globally in 2021, an estimated 4.2 million of 10.6 million people with incident tuberculosis  
65 (TB) disease went undiagnosed, emphasising the urgent need for new diagnostic  
66 methodologies. Most TB diagnostics are performed on sputum samples, but people who need  
67 TB tests are often unable to produce sputum. Upper respiratory tract sampling for TB  
68 diagnosis was widely used historically and holds promise to expand non-sputum-based  
69 diagnosis.

70 *Added value of this study*

71 We systematically reviewed and synthesised through meta-analysis diagnostic accuracy  
72 evaluations of upper respiratory tract sampling for TB. Historically, upper respiratory tract  
73 sampling for TB diagnosis was commonly used, with 39/71 studies conducted before 1970,  
74 although in recent years there has been a resurgence of interest in oral sampling. We show  
75 that upper respiratory tract samples have acceptable sensitivity and specificity compared to  
76 sputum culture, and, if testing is optimised using newer molecular and culture-based  
77 methods, may be capable of meeting WHO target produce profiles.

78 *Implications of all the available evidence*

79 Upper respiratory tract sampling methodologies for TB (oral sampling, and sampling from  
80 the larynx and nasopharynx) may hold promise to expand access to TB diagnosis, including  
81 for people who can't produce sputum. These sampling strategies can be optimised using  
82 modern microbiological techniques to increase access to diagnostics for TB.

83

## 84 **Introduction**

85 Pulmonary disease due to *Mycobacterium tuberculosis* (*Mtb*) can be challenging to diagnose  
86 because of lack of access to testing services, difficulty obtaining samples, and suboptimal  
87 sensitivity of tests. In 2021, of the estimated 10.6 million people with incident tuberculosis  
88 (TB) over 4.2 million went undiagnosed (1), and of those diagnosed with pulmonary TB  
89 (PTB) only 63% were bacteriologically confirmed. Bacterial confirmation is important to  
90 ensure correct diagnosis and for identification of drug resistance, so that the most effective  
91 treatment regime can be identified (1).

92 The most common sample used for PTB diagnosis is sputum, which can be tested by smear  
93 microscopy, culture, or using nucleic acid amplification tests (NAAT) such as Xpert  
94 (Cepheid) or Truenat (Molbio). These methods rely on people producing a sputum sample for  
95 analysis. However not everyone being investigated for PTB can produce sputum. For adults  
96 in the WHO consolidated guidelines on TB (2) sputum or induced sputum are the  
97 recommended sample types for diagnosis of PTB and, if HIV positive, urine using the  
98 ALERE-LAM. No alternative non-sputum options are recommended for a microbiological  
99 diagnosis of PTB to allow confirmation and resistance testing.

100 Children commonly do not produce sputum and therefore the WHO recommends alternative  
101 sample types for diagnosis of PTB, these include induced sputum, gastric aspirate, gastric  
102 lavage, nasopharyngeal aspirate (NPA) and stool (3). Gastric aspirate has a sensitivity of 73%  
103 (Xpert MTB/RIF) compared to microbiological reference standard (32% compared to  
104 composite reference standard), but is invasive, requires fasting and early morning testing with  
105 low caregiver acceptability (2,3). NPA is less invasive however still requires specialist  
106 equipment (for suction) and has moderate caregiver acceptability, sensitivity against a  
107 microbiological reference standard is 46% (Xpert MTB/RIF, based on four studies) (2,3).

108 Stool is a newly recommended specimen type in the 2021 update, has high acceptability, and  
109 is non-invasive; sensitivity of stool Xpert MTB/RIF is 61% against microbiological reference  
110 standard (16% against clinical reference standard) (2,3). However stool testing requires  
111 waiting for a bowel movement.

112 Alternative accessible sample types that can be processed with both existing and novel tests,  
113 are patient-centred, and can be collected at the time of consultation, are urgently required.

114 WHO Target Product Profiles (TPPs) have defined the minimal and optimal diagnostic  
115 accuracy standards for tests to diagnose TB in clinical settings, as well as defining desirable  
116 characteristics, including using non-sputum samples such as urine, stool, oral mucosal  
117 transudates, saliva, exhaled air, or blood from a fingerstick (4). Apart from stool, currently  
118 available alternative sample types, such as gastric aspirate or in adults broncho-alveolar  
119 lavage are invasive, need fasting and often admission to a hospital with specialist equipment.  
120 This can be a barrier to microbiological diagnosis both in terms of availability of the tests,  
121 costs, and accessibility.

122 In Europe in the early 1900s, physicians investigating patients for TB encountered similar  
123 concerns and laryngeal swabs were investigated as an alternative sample type for diagnosis of  
124 PTB (5–7); however with the decline of TB in Europe this practice fell out of use. More  
125 recently, when looking for alternatives to sputum in children, NPA (a procedure where a  
126 catheter is inserted into the nostril and suction applied to produce a sample) has been used,  
127 and oral mucosa specimens (samples taken by swabbing either the inside of the cheek or the  
128 tongue) from South Africa, Moldova and Kenya have successfully been used to diagnose TB  
129 (8–10). Sampling of the upper respiratory tract (from the mouth and nose, tonsils, down to the  
130 level of the larynx/vocal cords) which is non/minimally invasive, and can be performed

131 quickly as an outpatient, offers a potential alternative to expand access to microbiological TB  
132 diagnosis in those that cannot produce sputum.

133 We therefore set out to systematically appraise the evidence for the performance  
134 characteristics and diagnostic accuracy of upper respiratory tract sampling for diagnosing  
135 active PTB disease. We hypothesised that upper respiratory tract tests would have sufficient  
136 accuracy and utility to increase access to TB diagnosis.

### 137 **Methods**

138 We undertook a systematic review and meta-analysis; the published protocol is available  
139 online ([https://www.crd.york.ac.uk/prospero/display\\_record.php?RecordID=262392](https://www.crd.york.ac.uk/prospero/display_record.php?RecordID=262392)). We  
140 developed a search strategy with information specialists at the Liverpool School of Tropical  
141 Medicine library (Supplemental Table S1). We searched the following databases up to  
142 31/01/2022, then a further search was carried out for the period 1/1/2021 - 27/5/2022  
143 (subsequently extended to (6/12//2022): MEDLINE; Cinahl; Web of Science; Global Health;  
144 and Global Health Archive.

145 We included studies that evaluated the accuracy of upper respiratory tract sampling (index  
146 tests) for a microbiological (culture and nucleic acid amplification tests [NAAT] including  
147 automated platforms and laboratory PCR) diagnosis of TB disease, compared to a  
148 microbiological reference standard using either sputum or gastric lavage. We included cohort,  
149 cross-sectional, and randomised controlled studies (either published in peer-reviewed  
150 manuscripts, or as pre-prints) that recruited participants from any community or clinical  
151 setting; we placed no restrictions on publication language. We excluded: studies where the  
152 index or reference standard used histological or biomarker-based testing; post-mortem

153 studies; studies in non-human animal species; case reports; clinical guidelines; and studies  
154 testing for latent TB infection (where active TB disease was not tested for).

155 Titles and abstracts were imported into a Rayyan.ai database(11), and screened by one  
156 reviewer (HRS), with a random subset of 10% checked for agreement by a blinded second  
157 reviewer (HMR or RMB). The full text of selected manuscripts was then independently  
158 assessed by two reviewers (two of HRS, HMR, RMB) for inclusion; in cases of  
159 disagreement, the third reviewer acted as an arbitrator. Risk of bias was assessed using the  
160 QUADAS-2 tool (12).

161 Data were extracted using a piloted extraction form into a study database. Manuscripts  
162 published in languages other than English were translated prior to full text review and data  
163 extraction.

164 For each included manuscript, we extracted data on: year; author; country; type of  
165 publication; original language; report variable if multiple data sets; study design; setting;  
166 population; swab/device used; technique of sampling; site of sampling; number of samples  
167 per participant; timing of swabs; swab preparation; transport; storage; method of testing; test  
168 cut-off; participants; inclusion criteria; number of samples sets taken; number included in  
169 analysis; sex; HIV status; median age; index test positive; index test negative; missing result;  
170 reference test positive; reference test negative; missing result; true positive; control  
171 population; number of samples sets taken, index test positive, and index test negative.

172 If a manuscript contained multiple index tests, reference tests or cohorts of patients, each data  
173 set was included as a separate report. As participants within a particular study may have been  
174 included in more than one index test comparison, we reported the number of sample sets  
175 included in the analysis for each test comparison undertaken.

176 **Data synthesis and analysis**

177 We summarised study characteristics and, separately for each upper respiratory tract  
178 sampling methodology, graphed forest plots and calculated the pooled sensitivity and  
179 specificity of the index test compared to reference standards using a bivariate hierarchical  
180 random effects model, fitted using the lme4 package in R (version 4.2.1) based on the  
181 Cochrane handbook for Systematic Reviews of Diagnostic Test Accuracy (13). If studies  
182 were of children a second model, using a composite reference standard, including  
183 microbiological and clinical cases of PTB was performed (as in the recent WHO consolidated  
184 guidelines (2,3)). Definitions of how clinical cases were defined are provided in the  
185 Supplementary Material. Data and code to reproduce analysis are available at:  
186 <https://osf.io/9nuvq/>. This study was registered in PROSPERO (CRD42021262392).

187 **Funding source**

188 HRS is funded by the MRC through the MRC DTP programme at LSTM [Grant number  
189 MR/N013514/1]. This research was funded in whole, or in part, by the Wellcome Trust  
190 [Grant number 200901/Z/16/Z]. This work was supported by UK Foreign, Commonwealth  
191 and Development Office (“Leaving no-one behind: transforming gendered pathways to health  
192 for TB”) and partially funded by UK aid from the UK government (to MS, BR, LEC, and  
193 PM); however, the views expressed do not necessarily reflect the UK government’s official  
194 policies. RMB and HMR are supported by Wellcome PhD Fellowships (203905/Z/16/Z and  
195 225482/Z/22/Z). For the purpose of open access, the author has applied a CC BY public  
196 copyright license to any Author Accepted Manuscript version arising from this submission.

197 The funder of the study had no role in study design, data collection, data analysis, data  
198 interpretation, or writing of the report.

199 **Results**

200 9680 studies were identified during the initial search period up to 31/01/2021, and a further  
201 1364 when extended to 6/12/2022 (Figure 1). We removed 885 duplicates, leaving 10,159  
202 studies that were screened for inclusion. We reviewed the full text of 274 manuscripts.  
203 Overall, 71 studies were included in the systematic review, comprising 119 reports on index  
204 test comparisons; 53 were included in meta-analyses. Full details of excluded studies and  
205 reasons for exclusion are in Supplemental Table S2.

206

207 **Figure 1: PRISMA 2020 Flow diagram for systematic review.**

208

209 From included manuscripts (Table 1; Supplementary Table S3 includes full methodological  
210 details and results for each study), we classified types of upper respiratory tract sampling into  
211 four groups: laryngeal swabs (32 studies); NPAs (ten studies); oral swabs (18 studies); and  
212 other (mouthwash: three studies; nasal swabs: one study; saliva: four studies; other  
213 mucosa/dental samples: three studies). Studies were published between 1933 and 2022 from  
214 South Africa (eleven studies), Norway (seven studies), UK (seven studies), Peru (four  
215 studies), Uganda (seven studies), Canada (three studies), India (three studies), USA (three  
216 studies), Australia (two studies), Germany (two studies), Kenya (two studies), and one study  
217 from each of Brazil, Chile, China, Czechoslovakia, Denmark, Finland, France, Hungary,  
218 Italy, Japan, Malawi, Moldova, Mozambique, Republic of Korea, Spain, South East Asia (not  
219 specified), Sweden, Taiwan, Turkey, and Yemen.

220

221 Overall, we included data on 24,899 index test samples from participants in hospitals (29  
222 studies); TB sanatoria (nine studies); Chest clinics (nine studies); TB hospitals (eight studies),  
223 hospital outpatients (seven studies); primary care clinics (three studies); mass

224 screening/asymptomatic/contact interventions (two studies); outpatient treatment centres (one  
225 study), prisons (one study) and studies where the setting was unknown (five studies). Eleven  
226 studies were in children aged 16 years or younger. In studies that reported demographic data,  
227 58.2% of participants were male (data from 24 studies) and 19.5% were HIV-positive (with  
228 22 out of 39 studies conducted after 1981 presenting data on HIV prevalence in study  
229 participants).

230 **Table 1: Study Characteristics**

Year	Author	Country	Study design	Setting	Technique and Device	Site of sampling	Participants	Index test analysis	Reference test	Included in analysis	Male	HIV positive (if study after 1981)
<b>Laryngeal swab</b>												
1933	Kereszturi (14)	USA	Diagnostics evaluation	Hospital	Throat swab		Children with TB	Culture	Gastric lavage culture	10	NR	
1937	Allodi (15)	Italy	Diagnostics evaluation	Clinic	Nichrome swab passed to larynx with 'fenestrated' cannula using a mirror.		Clinic patients	Culture	Gastric lavage culture	40	NR	
1941	Nassau (6)	UK	Diagnostics evaluation	Sanatorium	Sterilised angulated swab with cotton wool, passed to larynx and cough.		Discharged 1940 – unable to expectorate	Culture	Sputum culture culture	166	NR

232 **NR:** Not reported

## 233 **Laryngeal swabs**

234 Forty-one reports that evaluated the accuracy of laryngeal swabs were included, of which 23  
235 contributed data to the meta-analysis (Supplementary Table S4). Studies were published  
236 between 1941 and 1968, with sample sizes ranging from 10 to 2809. A variety of angulated  
237 metal swabs with cotton wool or other absorbent materials were used to sample from the  
238 larynx, and processed using acidic preparations (Table 1 and Supplemental Table S3).  
239 Samples (both index and reference) were then cultured using methodologies available at the  
240 time of the study including modified Petraghani's medium, Lowenstein-Jensen solid medium,  
241 liquid oleic acid albumin media and guinea pig inoculation. In all studies, the reference test  
242 used was culture of sputum or gastric lavage fluid (using either expectorated sputum [eight  
243 studies] or gastric lavage [15 studies]). Random-effects model estimated sensitivity was  
244 57.8% (95% CI: 50.5-65.0%), specificity 93.8% (95% CI: 88.4-96.8%), diagnostics odds  
245 ratio (DOR) 20.7 (95% CI: 11.1-38.8), positive likelihood ratio (PLR) 9.3 (95% CI: 5.1-  
246 17.0), and negative likelihood ratio 0.45 (95%CI 0.38-0.53) – Figure 2 (SROC  
247 Supplementary Figure S1).

248

## 249 **Figure 2: Sensitivity and specificity of laryngeal sampling for active pulmonary** 250 **tuberculosis, with random effects meta-analysis**

251

## 252 **Nasopharyngeal aspirates**

253 Nine studies that included data on the accuracy of NPA were included, providing 17 test  
254 comparisons, of which 10 were included in the meta-analysis. All studies were conducted  
255 among children and published between 1998 and 2021, with the number of sample sets  
256 ranging from 64 to 535. Multiple index testing methodologies (non-automated culture [four  
257 reports], MGIT [one report], Xpert MTB/RIF [three reports], Xpert Ultra [one report], PCR

258 [one report]) were carried out on samples and each was included as a separate comparison.  
259 For the microbiological reference test induced sputum culture (6 reports) or gastric aspirate  
260 culture (4 reports) were used – Supplementary Table S5. The proportion of children with a  
261 microbiologically confirmed diagnosis of PTB ranged from 3% (48) to 38% (43) within the  
262 included studies. Model-estimated sensitivity was 65.2% (95%CI 52.0-76.4%), specificity  
263 97.9% (95% CI 96.0-99.0%), DOR 91.0 (95%CI 37.8-218.8), PLR 32.2 (95% CI 15.8-66.1)  
264 and NLR 0.35 (95%CI 0.25-0.51) – Figure 3 (SROC, Supplementary Figure 2).

265

266 **Figure 3: Sensitivity and specificity of nasopharyngeal aspirate for active pulmonary**  
267 **tuberculosis with microbiological reference standard, with random effects meta-analysis**

268

269 A second model was calculated of reports that included study data of a composite reference  
270 standard (both microbiological and clinical diagnosis of PTB, see Supplementary Table 6 for  
271 inclusion criteria), with 12 comparisons included in the analysis (Supplementary Table S7).  
272 The random effects model gave an estimate of sensitivity 9.1% (95%CI 5.6-14.6%),  
273 specificity 99.9% (95% CI 93.6-99.9%), DOR 168.4 (95%CI 1.57-17959.1), PLR 153.1 (95%  
274 CI 1.43-16343.5) and NLR 0.91 (95%CI 0.87-0.95) – Figure 4 (SROC, Supplementary  
275 Figure 3).

276

277 **Figure 4: Sensitivity and specificity of nasopharyngeal aspirate for active pulmonary**  
278 **tuberculosis when clinical diagnosis used as a reference standard, with random effects**  
279 **meta-analysis.**

280 **Oral swab**

281 Eighteen studies, with 29 comparisons of oral swab samplings to microbiological reference  
282 standards were identified; of these twenty (2015-2022) were included in the meta-analysis.

283 Ten used PCR for analysis, three used Xpert Ultra, two used culture and one comparison each  
284 used Xpert MTB/RIF, TB-LAMP, spoligotyping, auramine smear and SLIM assay. Eight  
285 comparisons had sputum culture as reference standard, five used sputum culture and Xpert,  
286 two used sputum Xpert alone, four used gastric lavage culture and Xpert and one used  
287 sputum or bronchiolar lavage culture (Supplementary Table S8). Seven comparisons included  
288 children as participants and thirteen included adults. Pooled sensitivity of oral swab samples  
289 was 56.7% (95%CI 44.3-68.2%), specificity 91.3% (95% CI 81.0-96.3%), DOR 13.8 (95%CI  
290 5.6-34.0), PLR 6.54 (95% CI 3.0-14.5) and NLR 0.47 (95%CI 0.36-0.62) – Figure 5.

291

292 **Figure 5: Sensitivity and specificity of oral swab for active pulmonary tuberculosis, with**  
293 **random effects meta-analysis**

294

### 295 **Other sample types**

296 We identified only a small number of studies of alternative sample types, so meta-analysis  
297 was not undertaken. Of these three studies compared the accuracy of mouthwash samples,  
298 saliva (four studies), oral cavity samples (two studies) and nasopharyngeal swabs (one study)  
299 - Supplementary Table S9. A further study on nasal swabs and one on saliva did not contain  
300 sufficient information to permit summary of results.

301

### 302 **Risk of bias assessment**

303

304 The QUADAS-2 tool was used to assess the risk of bias for each study included (Figure 6,  
305 and for individual studies - Supplementary Figures S5 and S6). Overall, studies performed  
306 before the 1950s did not report on multiple domains, especially participant selection and use  
307 of index tests. In newer studies there was a high risk of bias in Domain 1 (participant

308 selection) due to case control designs and variability in reference standards used, with some  
309 reference standards less likely to correctly classify true TB status.

310

### 311 **Figure 6: Risk of bias assessment**

312

### 313 **Discussion**

314 Diagnosing PTB is challenging, and new, accurate sampling approaches that utilise easier-to-  
315 obtain specimens are urgently required. In this systematic review and meta-analysis, which  
316 included data on 24,899 sample comparisons from studies conducted over an 89-year period  
317 between 1933 and 2022, we found that three upper respiratory tract sample types show  
318 promise for accurately diagnosing PTB: laryngeal swabs with a pooled sensitivity of 57.8%  
319 and a specificity of 93.8%; NPA with a pooled sensitivity and specificity of 65.2% and  
320 97.9%; and oral swabs with 56.7% and 91.3% against microbiological reference standards.  
321 These accuracy estimates are similar to currently approved TB diagnostic tools on non-  
322 sputum samples such as urine lateral flow lipoarabinomannan assays in those who are HIV-  
323 positive (80) and stool in children (3).

324 Studies that used laryngeal swabs as a sample type were mostly from Europe in the early 20<sup>th</sup>  
325 century and gave a pooled sensitivity of 57.8% against microbiological reference standards  
326 (gastric lavage or sputum culture), here there was large variation in swabbing and culture  
327 methodologies used over time as new medias and techniques were invented, and all were  
328 conducted before the advent of molecular diagnostics. The studies were mostly carried out  
329 among outpatients being investigated for TB, who were unable to produce sputum, with the  
330 predominant reference standard being culture of gastric lavage. Use of laryngeal swab testing  
331 was discontinued with the advent of chemotherapy and the rapid decline of TB cases in  
332 Northern Europe and the closure of sanatoria (81,82), however the original rationale for

333 investigating this sample type, needing an outpatient test that was quick and well-tolerated,  
334 reflects similar diagnostic challenges still being faced in high burden countries and the  
335 requirements of the WHO TPP (4). Laryngeal swabs may hold promise as an alternative to  
336 expand access to TB diagnosis if re-evaluated in prospective studies using modern diagnostic  
337 platforms and culture.

338 The second sample type reviewed was NPA, which were mostly studied in children. NPAs  
339 had a sensitivity 65.5% compared to culture of gastric aspirate or induced sputum samples.  
340 However as microbiological tests of TB in children have a low sensitivity(83) we also  
341 compared NPA to a clinical reference standard for TB, where sensitivity fell to 9%. This  
342 reflects the very high proportion of children who were clinically diagnosed with TB in the  
343 absence of any positive microbiological test: a common occurrence in clinical practice which  
344 reflects the urgent need for improved diagnostic strategies in children. NPA and laryngeal  
345 swabs have the benefit of being able to be performed as an outpatient test rather than  
346 requiring admission, which could make them a viable alternative in settings where access to  
347 hospital services and admission are limited due to cost, distance, and availability. Further  
348 research is needed to investigate whether sensitivity can be improved by optimising sample  
349 preparation, collection or analysis, how NPA performs in adults, and how NPA could be used  
350 within diagnostic algorithms to increase microbiological diagnosis (50).

351 Oral swabs gave a pooled sensitivity of 56.7% against microbiological reference standards.  
352 However, many of the studies that evaluated oral swabs were case control studies with small  
353 numbers which have a high risk of bias and would be expected to over-estimate sensitivity.  
354 There was also a wide variability in the swab types, sampling methodologies, and specimen  
355 processing and analysis. Nevertheless, oral swabs do offer an easy option for sample  
356 collection and transport, potentially widening access to TB diagnosis. Further research is

357 needed including prospective diagnostic evaluations to find standardised methodologies and  
358 assess its accuracy in a wide range of populations, including children.

359 Limitations for this systematic review and meta-analysis include the variability of the  
360 methods of sample collection and analysis. We mitigated against this by stratifying studies  
361 into groups of sample types for meta-analysis; however, some within-group variability  
362 remains. For some studies from the early 20<sup>th</sup> century, we were unable to identify the full text  
363 despite extensive searches with librarians, and especially if they were published in a language  
364 other than English; this may have biased results to studies in more prominent journals that  
365 were more likely to be archived in libraries and those in English. Newer studies, particularly  
366 those that examined the accuracy of oral swabs, mainly used case control designs, and had  
367 small sample sizes.

368 Although upper respiratory tract sampling seems a promising avenue for improving access to  
369 TB diagnostic testing, further prospective studies are needed to optimise sampling and  
370 microbiological methodologies to maximise sensitivity. In children, where novel diagnostics  
371 are urgently needed NPA, potentially laryngeal swabs, and a combination of sample sites  
372 may offer an alternative sampling methodology that can be used in outpatient settings to  
373 widen access. Historical methods using laryngeal swabs showed similar sensitivity and  
374 higher specificity than modern studies using oral swabbing in much larger numbers of  
375 patients, some of whom were unable to expectorate. Updated evaluations of laryngeal  
376 swabbing is required to determine whether these findings are replicated in modern diagnostic  
377 accuracy evaluations and across a range of populations. Oral swabs are simple to collect and  
378 transport, however this review has shown that more prospective study data is needed to  
379 understand whether sensitivity is sufficient for use in clinical practice. If so, this may give a  
380 sample type that could be used in outpatient settings in children and adults who are unable to  
381 expectorate or in an inpatient setting in those too unwell to produce a sample. Overall upper

382 respiratory tract sampling may offer an alternative non-invasive sample type that can be used  
383 to increase access to microbiological diagnosis for Mtb.

384 **Contributors:** The study was conceived by HRS and LEC. The study design was developed  
385 by HRS, LEC and PMP. Data extraction was conducted by HRS, MLO, MS and BR. Data  
386 analysis and interpretation were conducted by HRS, PMP, HMR and RMB. The initial  
387 manuscript was prepared by HRS and PMP. All authors edited and approved the final  
388 manuscript (HRS, HMR, RMB, MLO, MS, BR, LEC and PMP).

389 **Declaration of interests:** We declare no competing interests.
