9	
10	
11	Background
12	The time-varying reproduction number (Rt) is an important measure of epidemic transmissibility; it can directly
13	inform policy decisions and the optimisation of control measures. EpiEstim is a widely used software tool that
14	uses case incidence and the serial interval (SI, time between symptoms in a case and their infector) to estimate
15	$R_{t}\ in\ real-time.$ The incidence and the SI distribution must be provided at the same temporal resolution, which
16	limits the applicability of EpiEstim and other similar methods, e.g. for pathogens with a mean SI shorter than
17	the frequency of incidence reporting.
18	Methods
19	We use an expectation-maximisation algorithm to reconstruct daily incidence from temporally aggregated
20	data, from which $R_t\ \text{can}$ then be estimated using EpiEstim. We assess the validity of our method using an
21	extensive simulation study and apply it to COVID-19 and influenza data. The method is implemented in the
22	opensource R package EpiEstim.
23	Findings
24	For all datasets, the influence of intra-weekly variability in reported data was mitigated by using aggregated
25	weekly data. Rt estimated on weekly sliding windows using incidence reconstructed from weekly data was
26	strongly correlated with estimates from the original daily data. The simulation study revealed that Rt was well
27	estimated in all scenarios and regardless of the temporal aggregation of the data. In the presence of weekend
28	effects, Rt estimates from reconstructed data were more successful at recovering the true value of Rt than
29	those obtained from reported daily data.
30	Interpretation
31	R <sub>t</sub> can be successfully recovered from aggregated data, and estimation accuracy can even be improved by
32	smoothing out administrative noise in the reported data.
33	Funding
34 25	MRC doctoral training partnership, MRC centre for global infectious disease analysis, the NIHR HPRU in
35	Modelling and Health Economics, and the Academy of Medical Sciences Springboard, funded by the AMS,

3/ 20	
38 20	Introduction
39 40	
40	As infectious disease outbreaks become more common, it is increasingly important to rapidly characterise the
41 42	unear or emerging and re-emerging parrogens. <sup>-</sup> transmissibility, i.e. a pathogen's ability to spread through a
+2 13	population, can be quantified using the time-varying reproduction number, $R_t$ , defined as the average number of infactions that are caused by a primary case at time t of an authreak. Business whether an authreak is
тэ ДД	or mections that are caused by a primary case at time t or an outbreak. Rt signals whether an outbreak is growing ( $R_1 > 1$ ) or declining ( $R_2 < 1$ ) and whether current interventions are sufficient to control the spread of
45	the disease.

#### 46

47 One of the most popular tools for real-time Rt estimation, the R package EpiEstim, relies on observing the 48 incidence data and supplying an estimated serial interval (SI) distribution – the time between symptom onset 49 in a case and their infector. EpiEstim requires that the SI distribution and incidence data are supplied using 50 the same time units. This can be problematic when daily incidence data is not reported, which is common for 51 many diseases, such as influenza, Zika virus disease, and most notifiable diseases in countries such as the UK 52 and the US.<sup>2-5</sup> Additionally, several studies intentionally aggregate data to reduce the impact of daily reporting 53 variability; administrative noise, such as "weekend effects", are characterised by a drop in reported cases over 54 weekends, due to reduced care seeking and longer delays in reporting, followed by a peak on Mondays.<sup>6,7</sup> A 55 commonly used workaround is to aggregate the SI distribution to match the frequency of incidence 56 reporting,<sup>8,9</sup> however this is not possible if the SI is shorter than the aggregation of data. For example, 57 influenza-like illness is typically reported on a weekly basis, but influenza has an estimated mean SI of 2-4 58 days.<sup>10,11</sup> Similarly, reporting of COVID-19, which has an estimated SI of 3-7 days, has typically moved from daily to weekly.<sup>12,13</sup> Therefore, enabling estimation of Rt from temporally aggregated data is critical to ensure 59 60 methods such as EpiEstim are widely applicable.<sup>14</sup>

61

In this study, we combine an expectation-maximisation (EM) algorithm with the renewal equation approach
implemented in EpiEstim to reconstruct daily incidence from aggregated data and estimate R<sub>t</sub>. We assess the
performance of the method using influenza and COVID-19 data, in addition to an extensive simulation study.

#### 66 Methods

67

65

68 EpiEstim 69

EpiEstim uses the renewal equation (eq.1), a form of branching process model.<sup>15</sup> In this formulation, the incidence of new symptomatic cases at time t ( $I_t$ ) is approximated by a Poisson process, where  $I_{t-s}$  is the past incidence, and  $g_s$  is the probability mass function of the serial interval.

73

$$I_t \sim Pois\left(R_t \sum_{s=1}^t I_{t-s} g_s\right) \tag{1}$$

74

With EpiEstim, Rt can be assumed to remain constant within user defined time windows, which smooth out
estimates.

77

## 78 Extending EpiEstim for coarsely aggregated data

79

We extended EpiEstim to estimate  $R_t$  from aggregated incidence data  $(I_w)$ , where each aggregation window (w) is >1 day, whilst still conditioning on an assumed serial interval distribution  $(g_s)$ . We use an EM algorithm to iteratively reconstruct daily incidence  $(I_t)$  from  $I_w$ , and in turn estimate  $R_t$ . We present the method with weekly data in mind, but the method and software can be applied to any temporal aggregation (Figure 1 & appendix pp22-24). The algorithm involves three steps: initialisation, expectation, and maximisation. medRxiv preprint doi: https://doi.org/10.1101/2022.12.08.22283241; this version posted December 13, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY 4.0 International license .

86

87 Figure 1. Schematic of the EM algorithm approach used to reconstruct daily incidence (It) from weekly 88 aggregated incidence data (I<sub>w</sub>). The algorithm is initialised with a naive disaggregation of the weekly incidence 89 (assuming constant daily incidence throughout the aggregation window). The resulting daily incidence is then 90 used to estimate the reproduction number for each aggregation window, in this case for each week, R<sub>w</sub>. R<sub>w</sub> is 91 converted into a growth rate (see eq. 2), which is in turn used to reconstruct daily incidence data, whilst 92 ensuring that if It were to be reaggregated it would still sum to the original weekly totals. The process cycles 93 between the expectation and maximisation steps until convergence.

#### 94 95 Initialisation

96 The algorithm is initialised with naively disaggregated incidence data. For weekly data, the total incidence for 97 each week is split evenly over 7 days (allowing for non-integers).

### 98 99

102

#### Expectation

100 The current reconstructed I<sub>t</sub> is used to estimate the expected reproduction number for each aggregation 101 window, R<sub>w</sub>, obtained as the posterior mean from EpiEstim.<sup>16</sup>

#### 103 Maximisation

104 Conditional on R<sub>w</sub>, we reconstruct the most likely It. First, R<sub>w</sub> is translated into a daily growth rate for that week 105 (r<sub>w</sub>), using Wallinga and Lipsitch's method:<sup>17</sup>

106

$$R_{w} = \frac{1}{\sum_{s=0}^{+\infty} e^{-r_{w}s}g(s)}$$
(2)

107

108 It for that week is then computed assuming exponential growth, with a multiplying constant kw ensuring that 109 when reaggregated, the reconstructed  $I_t$  matches the original  $I_w$ :

110

$$I_t = k_w \exp\left(r_w a_t\right) \tag{3}$$

$$k_{w} = \frac{I_{w}}{\sum_{n=1}^{7} \exp(r_{w}n)}$$
(4)

111

112 where t is time (in days) and at is an index representing the day of the aggregation window, e.g. taking values 113 1 to 7.

114

115 The process is repeated iteratively until convergence, at which point It can be used to estimate the full 116 posterior distribution of Rt using EpiEstim. For this final step, Rt can be estimated on any time window.

#### 117

#### 118 Case studies

119

120 We chose datasets where incidence data was available daily, and then artificially aggregated them to weekly 121 counts. Rt was estimated from daily incidence that was reconstructed from weekly aggregated data using our 122 new approach, and compared to Rt estimates obtained from the reported daily incidence using the original 123 EpiEstim R package. All Rt estimates were made using both daily and weekly sliding time windows, and we 124 refer to those estimates as daily Rt estimates and weekly Rt estimates respectively.

125

126 We considered three characteristics: 1) mean  $R_t$  estimates, 2) uncertainty in the  $R_t$  estimates, and 3) the 127 classification of Rt as increasing, uncertain or declining (appendix pp8-9). To compare the performance of this 128 approach to the original method, we assessed the correlations between each of the three characteristics when 129 using the reported and reconstructed incidence.

## 130

132

131 The priors for  $R_w$  and  $R_t$  were set to a mean and standard deviation of 5.

#### 133 Influenza

134 We obtained a five-week subset of a dataset (11<sup>th</sup> December 2009 – 14<sup>th</sup> January 2010) on US active 135 component military personnel (employed by the military as their full-time occupation) that made an 136 outpatient visit to a permanent military treatment facility describing a respiratory-related illness. This daily 137 incidence by date of presentation at a clinic was originally obtained by Riley et al. from the Armed Forces 138 Health Surveillance Center and were digitally extracted for use here.<sup>18</sup> We used a mean SI of 3.6 days and SD 139 of 1.6 days.<sup>10</sup>

140 141

## COVID-19

142 Incidence of UK COVID-19 cases and deaths were taken from the UK government website.<sup>19</sup> For COVID-19 cases, we obtained ninety-seven weeks of data (21<sup>st</sup> February 2020 to 30<sup>th</sup> December 2021) for incidence by 143 date of specimen, which is the date that a sample was taken from an individual which later tested positive. 144 For COVID-19 deaths, we used ninety-six weeks of data (2<sup>nd</sup> March 2020 to 2<sup>nd</sup> January 2022) for incidence by 145 146 date of death within twenty-eight days of a positive test. We assumed a mean SI of 6.1 days and SD of 4.2 147 days.12

- 148
- 149 Simulation study
- 150

151 We considered scenarios where Rt either remained constant or varied over time, with a stepwise or gradual 152 change. For each scenario, one hundred seventy-day epidemic trajectories were simulated using a Poisson 153 branching process as implemented in the R package projections.<sup>20</sup> Daily datasets were aggregated weekly and 154 used to estimate Rt using the proposed method; these values were compared to Rt estimates obtained from 155 simulated daily data using the original EpiEstim R package. We explored the impact of weekend effects on Rt 156 estimates, the ability to supply alternative temporal aggregations of data e.g., three-day, ten-day, or two-157 weekly aggregations, and finally, the number of iterations required to reach convergence when reconstructing 158 daily incidence data. The full simulation study description and details can be found in the appendix.

- 165 Results
- 166

Hereafter, we refer to reported and reconstructed incidence data, these are the reported daily incidenceand the daily incidence that has been reconstructed from weekly aggregated data, respectively.

- 169
- 170 Influenza
- 171

177

172The reconstructed incidence of influenza was much smoother than the reported incidence, which showed173clear weekend effects and lower reported cases on two public holidays, both occurring on Fridays (Figure 2A174& appendix p8). Considering weekly sliding Rt first, there was a high correlation in both the mean Rt estimates175derived from each dataset ( $R^2 = 0.91$ , Figure 2C & appendix p2) and their associated uncertainty ( $R^2 = 0.93$  &176Figure 2C). The overall agreement in the classification of Rt reached 81.8% (see methods & appendix p9).

In contrast, mean daily Rt estimates differed markedly depending on whether the reported or reconstructed data were used, with an R<sup>2</sup> of 0.13 and much higher mean Rt and uncertainty in estimates obtained from reported data (Figure 2E-F). Higher mean Rt estimates coincided with large peaks in the reported daily incidence (typically on Mondays), as daily Rt estimates were not smoothed and therefore more affected by intra-weekly variability (appendix p2). The overall agreement in the classification of daily Rt estimates was much lower, with only 44.4% agreement (appendix p9).

184

In this case study, the greatest differences in R<sub>t</sub> estimates tended to correspond to time periods when the reported and reconstructed incidence data were most dissimilar (Figure 2B & appendix p3). There was no apparent pattern in the estimates with regard to the outbreak phase, i.e. early, mid or late-phase, but this is

188 likely due to this dataset being a snapshot of incidence taken from within an established epidemic (Figure 2).

## 210 COVID-19 cases

211

The reconstructed incidence of COVID-19 smoothed out intra-weekly variability, caused by factors such as weekend effects (Figure 3A & appendix pp7-8). Weekly sliding  $R_t$  estimates obtained from reconstructed and reported incidence were similar, both in their means ( $R^2 = 0.98$ ) and their level of uncertainty ( $R^2 = 0.99$ , Figure 3C-D & appendix p4). Mean daily  $R_t$  estimates were less well correlated ( $R^2 = 0.67$ ), although the difference is medRxiv preprint doi: https://doi.org/10.1101/2022.12.08.22283241; this version posted December 13, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in

perpetuity. It is made available under a CC-BY 4.0 International license .

216 less marked than in the influenza case study (Figure 3E), and the uncertainty in the estimates was similar 217 across both approaches ( $R^2$  = 0.97, Figure 3F). Most of the discrepant  $R_t$  estimates and higher levels of 218 uncertainty coincide with the early phase of the outbreak when incidence was lower (Figure 3E-F). Outside of 219 periods of low incidence, the largest differences in Rt estimates tended to correspond to time periods with 220 greater disparities between the reported and reconstructed incidence data (Figure 3B & appendix p5). The 221 overall agreement in the classification of Rt estimates was higher than for influenza, with 74.4% and 94.9% 222 agreement for daily and weekly sliding Rt estimates respectively (appendix p9).

225 226

227 Figure 3. Rt estimates from daily incidence that was either reported or reconstructed from weekly aggregated 228 COVID-19 case data. A) The reported (grey) and reconstructed (green) daily incidence of COVID-19 by date of 229 specimen. B) Squared error of the daily (orange) and weekly sliding (pink) Rt estimates made from 230 reconstructed data compared to those obtained from the reported daily data. Rt estimation starts on the first 231 day of the second aggregation window (day 8 – 28<sup>th</sup> February 2020) and is plotted on the last day of the time 232 window used for estimation (i.e., starting on day 9 (29<sup>th</sup> February) for daily estimates and day 14 (5<sup>th</sup> March) 233 for weekly estimates). Note: the x-axis is shared with the incidence plot above and the y-axis has been limited 234 to 0.5 for clarity. C & E) Correlation between the weekly sliding (C) and daily (E) mean Rt estimates using 235 reconstructed (y-axis) and reported (x-axis) daily data, excluding the first 30 days due to low incidence. Vertical 236 and horizontal lines depict the 95% credible intervals and dotted lines show the threshold of  $R_t = 1$ . ### 244 COVID-19 deaths

245

256

243

246 The reported incidence of COVID-19 deaths was much less influenced by day-to-day variation. The 247 reconstructed daily incidence was more similar to the observed daily data than in the previous case studies 248 (Figure 4A). Both weekly and daily Rt estimates obtained from weekly data were highly consistent with those 249 obtained from daily observations ( $R^2 = 0.98$  and  $R^2 = 0.80$  respectively, Figure 4C & 4E). The overall agreement 250 in Rt classifications for daily estimates was the highest of all case studies at 85.8%, and 93.3% for weekly Rt 251 estimates (appendix p9). Discrepancies between the two mostly coincide with periods of particularly low 252 incidence of deaths (Figure 4B & appendix p7). The overall lower incidence of COVID-19 deaths compared to 253 COVID-19 cases means there is greater uncertainty in Rt estimates in this case study (Figure 4D, 4F & appendix 254 p6). However, there was minimal difference in the uncertainty of estimates obtained from daily and weekly 255 data (Figure 4D & 4F).

257 258

259 Figure 4. Rt estimates from daily incidence that was either reported or reconstructed from weekly aggregated 260 COVID-19 death data. A) The reported (grey) and reconstructed (green) daily incidence of COVID-19 by date 261 of death within 28 days of a positive test. B) Squared error of the daily (orange) and weekly sliding (pink) Rt 262 estimates that were made from reconstructed data compared to those obtained from the reported daily data. 263 Rt estimation starts on the first day of the second aggregation window (day 8 – 9<sup>th</sup> March 2020) and is plotted 264 on the last day of the time window used for estimation (i.e., starting on day 9 (10<sup>th</sup> March) for daily estimates 265 and day 14 (15<sup>th</sup> March) for weekly estimates). Note: the x-axis is shared with the incidence plot above and 266 the y-axis has been limited to 0.5 for clarity. C & E) Correlation between the weekly sliding (C) and daily (E) 267 mean Rt estimates using reconstructed (y-axis) and reported daily data (x-axis), excluding the first 30 days due 268 to low incidence. Vertical and horizontal lines depict the 95% credible intervals and dotted lines show the medRxiv preprint doi: https://doi.org/10.1101/2022.12.08.22283241; this version posted December 13, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity.

perpetuity. It is made available under a CC-BY 4.0 International license .

threshold of  $R_t = 1$ . D & F) Correlation between the uncertainty in the weekly sliding (D) and daily (F)  $R_t$ estimates, defined as the width of the 95% credible intervals, using the reconstructed (y-axis) and reported daily (x-axis) data. The colour of the points in panels C-F correspond to the epidemic phase, i.e. the early (31<sup>st</sup> March - 20<sup>th</sup> October 2020), middle (21<sup>st</sup> October 2020 – 28<sup>th</sup> May 2021) or late (29<sup>th</sup> May 2021 – 2<sup>nd</sup> January 2022) phase of the data, shown by the strip in panel A. Solid lines show the linear model fit with 95% confidence intervals (grey shading). Dashed lines represent the x = y line.

275

In all case-studies, incidence reconstructions converged within 10 iterations of the EM algorithm. The overall process of Rt estimation from weekly aggregated data took three seconds or less to run on MacOS (2 GHz Quad-Core Intel Core i5) 16GB RAM (appendix p10); the influenza scenario, with over 57,000 cases, took two seconds to run, whilst the COVID-19 cases and deaths scenarios, with an overall incidence over 149,000 and 13 million cases respectively, took three seconds to run.

- 281282 Simulation study
- 283

287

The method performed well across all scenarios, successfully estimating R<sub>t</sub> from the aggregated simulated data (appendix pp10-20). Convergence of the EM algorithm was quick, with negligible differences in the reconstructed incidence beyond 5 iterations (appendix p22).

When introducing weekend effects into simulated data, Rt estimates from reconstructed incidence were more successful at recovering the true value of Rt than when using reported incidence (appendix p21). The method can also be successfully applied to other temporal aggregations of data, e.g. three-, ten- or fourteen-day windows (appendix pp22-24).

- 292
- 293 Discussion
- 294

295 Estimates of the time-varying reproduction number  $(R_t)$  have frequently been used to inform and guide 296 policymaking during outbreaks, and a commonly used approach to estimate Rt is EpiEstim, which relies on 297 daily incidence data. However, maintaining daily incidence databases requires substantial time and 298 investment in resources, which is not always feasible, particularly for less acute or routinely reported diseases. 299 Therefore, in practice, many diseases are not reported on a daily basis, including influenza and other notifiable diseases in the UK and US.<sup>2-5</sup> As the COVID-19 pandemic persists, daily reporting is also becoming less 300 301 common.<sup>21</sup> Coarsely aggregated data can be challenging to deal with in the context of Rt estimation methods, 302 restricting their applications in certain contexts. In this study, we develop a statistical framework and tool that 303 allows Rt estimation from aggregated incidence without introducing bias. Using influenza and COVID-19 data, 304 alongside a simulation study, we demonstrate how a simple expectation-maximisation algorithm approach 305 can rapidly reconstruct daily incidence data and accurately estimate R<sub>t</sub>.

306

In all case studies, direct comparisons between weekly sliding R<sub>t</sub> estimates show that very similar estimates can be made from the reported daily incidence and the reconstructed daily incidence from weekly aggregated data. However, daily R<sub>t</sub> estimates are more influenced by noise, such as intra-weekly variability, leading to greater disparities in estimates between datasets. There are clear weekend effects exhibited in the influenza and COVID-19 case data (appendix p8), leading to peaks and troughs in the reported incidence and the resulting daily R<sub>t</sub> estimates (Figures 2 & 3, appendix pp2&4). Using reconstructed incidence considerably smoothed the daily R<sub>t</sub> estimates, removing the impact of weekend-effects. The overall agreement in the medRxiv preprint doi: https://doi.org/10.1101/2022.12.08.22283241; this version posted December 13, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY 4.0 International license .

314 classification of Rt as increasing, uncertain, or declining between estimates made from each dataset rose 315 substantially when some of the variability in the reported data was smoothed by estimating  $R_t$  using weekly 316 sliding windows (appendix pp8-9).

317

318 Despite both being affected by weekly periodicity in reporting, concordance of Rt estimates obtained from 319 COVID-19 case data is considerably better than for influenza, perhaps due to the greater quantity of data, with 320 a very strong positive correlation between daily and weekly Rt estimates (Figure 3). This is reflected in the high 321 overall agreement in the classification of Rt estimates obtained from the reported and reconstructed datasets. 322 It is important to note that outlying and much larger Rt estimates obtained from both datasets coincide with 323 the early phase of the epidemic, when incidence was lower and the prior for R<sub>t</sub> ( $\mu$ =5,  $\sigma$ =5) had more weight 324 on estimates.

325

326 During the early stages of epidemics, despite there being far fewer deaths than cases, death data can sometimes be considered more reliable.<sup>22,23</sup> For example, case reporting is affected by surveillance system 327 328 quality and the robustness of testing practices, which can vary considerably over the course of an epidemic, 329 especially early on. COVID-19 incidence by date of death is much less influenced by administrative noise in the 330 data (appendix p8), and the reconstructed incidence is most similar to the reported daily incidence of any case 331 study. Therefore, the greatest differences in Rt estimates from death data coincide with periods of low 332 incidence (appendix p7) when uncertainty increases. Weekly sliding Rt estimates are equally as correlated as 333 those from COVID-19 case data, but daily Rt estimates are the most strongly correlated of any dataset (Figure 334 4). Additionally, there is very high overall agreement in the classification of daily and weekly Rt (appendix p9). 335 This provides further support that differences between daily R<sub>t</sub> estimates for influenza and COVID-19 cases is 336 likely due to the reconstructed incidence smoothing out weekly periodicity in reporting.

338 To investigate further, weekend effects were artificially introduced to data in the simulation study (appendix 339 p21). We have shown that, when using reported incidence, Rt estimates are all strongly influenced by weekend 340 effects (regardless of the smoothing time-window). Reconstructing daily incidence from weekly data 341 completely removes the effect of noise from resulting Rt values, greatly improving the accuracy of estimates. 342 This demonstrates that it may be beneficial to artificially aggregate daily data, as has been done in previous 343 studies.<sup>6,7</sup> However, we did assume quite an extreme level of administrative noise, so in instances where the 344 pattern is less prominent, it may have less of an impact on estimates. Disentangling important temporal trends 345 in Rt from noise in the data can be difficult, and if aggregated data is used it will be at the cost of reduced 346 temporal resolution in R<sub>t</sub> estimates.

347

337

348 This can be seen when the method is applied to data aggregated over longer timescales, such as ten- to 349 fourteen-days (appendix pp22-24). This approach requires two layers of smoothing: 1) the incidence is 350 smoothed over each aggregation window during the reconstruction process and 2) Rt estimates are smoothed 351 by the sliding window chosen by the user. If a change in Rt occurs at the end of an aggregation window (i.e. on 352 the last day), such as a sudden decrease in  $R_t$  due to a strict lockdown, that change is detected with a lag, 353 corresponding to the length of the sliding window used for Rt estimation (appendix p23). However, if the event 354 occurs mid-aggregation window, then in addition to the usual lag caused by the sliding window, estimates will 355 be affected by the smoothing of the incidence within the aggregation window during reconstruction (appendix 356 p24). The change in  $R_t$  will seem more gradual over the period that data are aggregated over and will appear 357 to start earlier than in reality (corresponding to the first day of the aggregation window). It is important for 358 users to keep this in mind, particularly when using longer aggregations of data.

### 359

360 Another consideration is that the reconstructed incidence can have discontinuities in the borders between 361 aggregation windows (appendix pp11-12). This occurs because in reconstructing daily incidence we impose 362 that, if it were to be re-aggregated, it would match the original data. Methods that simply fit smoothing splines 363 to weekly data, inferring daily case counts from the daily difference in cumulative counts, are not affected by 364 this.<sup>24,25</sup> To circumvent this problem, we recommend that sliding windows used to estimate Rt are at least 365 equal to or longer than the length of aggregation windows to reduce the impact of discontinuities on estimates 366 (appendix pp22-24).

367

368 Alternative approaches include modelling frameworks implemented in the Epidemia and EpiNow2 R 369 packages.<sup>6,22,26</sup> Daily infections are modelled as a latent process, back-calculated from observed data on cases 370 or deaths, depending on an appropriate infection to observation distribution. In addition, Epidemia integrates 371 further information, such as the infection ascertainment rate (for cases) or the infection fatality rate (for deaths).<sup>22</sup> This facilitates a 'nowcasting' approach, allowing users to estimate Rt directly from the unobserved 372 373 infections, but they typically require more data (e.g. incidence of deaths and cases), more assumptions (e.g. 374 delay distributions and ascertainment rates), and are much more computationally intensive, which can be a 375 barrier to the adoption of such methods by users.<sup>14</sup>

376

377 Here, Rt estimates are based on a single daily incidence reconstruction, meaning Rt can be estimated very 378 rapidly from aggregated data, which is particularly desirable during real-time outbreak analysis.<sup>14</sup> A potential 379 downside is that uncertainty in Rt estimates could be underestimated. However, the simulation study showed 380 that the 95% credible interval of estimates encompassed the correct value of Rt the majority of the time, and 381 we found no substantial indication that this approach detrimentally affected our characterisation of the 382 uncertainty.

383

384 Given that this method is directly derived from EpiEstim, it relies on similar assumptions and caveats.<sup>15,27</sup> As 385 time of infection is more difficult to observe than symptom onset, the SI is typically used as an approximation of the generation time in the renewal equation, which may introduce bias.<sup>28</sup> The SI, the level of undetected 386 387 cases, and the reporting rate are assumed to remain constant, which is often not the case in practice. Factors 388 such as changes in population immunity, and the introduction of interventions, can alter the SI throughout an 389 epidemic.<sup>29</sup> Whilst changing case definitions, new testing practices, and increased healthcare-seeking 390 behaviour, can all affect case ascertainment.<sup>15</sup> Parameters chosen by users can also influence estimation 391 accuracy, for instance, the time window length for temporal smoothing and the prior for Rt.<sup>27</sup>

392

393 To make the method simple to implement for current and future users of EpiEstim, this extension has been 394 fully integrated with the 'estimate R()' function in the original R package on github.<sup>30</sup> Just one additional 395 parameter is required – the number of days data are aggregated over (with some other optional parameters). 396 More details regarding the applications of this method can be found in the package vignette and associated 397 examples.<sup>30</sup>

- 398
- 399 Conclusion
- 400

401 We extended the widely used Rt estimation approach proposed by Cori et al.,<sup>15</sup> and implemented in the R 402 package EpiEstim, to incorporate a new feature which allows Rt to be easily estimated from any temporal 403 aggregation of incidence data. We have demonstrated that the method performs well using both simulated medRxiv preprint doi: https://doi.org/10.1101/2022.12.08.22283241; this version posted December 13, 2022. 404 and real-world data, recovering or even improving upon the estimates that would have been made from 405 reported daily data. This extension is easy to use and computationally efficient, which will enable 406 epidemiologists and other public health professionals to apply EpiEstim to a wider range of diseases and 407 epidemic contexts.
