70 **Clinical validation of novel second-trimester preterm preeclampsia risk predictors combining clinical**
71 **variables and serum protein biomarkers**

72

73 **Précis**

74 Combining novel serum protein biomarkers and selected clinical variables for preterm preeclampsia
75 prediction outperforms widely used clinical risk assessment algorithms currently recommended by
76 practice guidelines.

77

78 **Abstract**

79 *Objective*

80 To develop and validate mid-trimester preterm preeclampsia (PE) risk predictors combining clinical
81 factors and serum protein analytes, and to compare their performance with those of widely used clinical
82 and risk assessment algorithms endorsed by professional societies.

83

84 *Methods*

85 This was a secondary analysis of data from two large, multicenter studies in pregnant individuals (PAPR,
86 NCT01371019; TREETOP, NCT02787213), originally conducted to discover, verify, and validate a serum
87 proteomic predictor of preterm birth risk. Serum protein abundances were determined by mass
88 spectrometry. Classifier models combined one or two novel protein ratio(s) with a composite clinical
89 variable, denoted as ClinRisk3, which included prior PE, pre-existing hypertension, or pregestational
90 diabetes. Predictive performance was assessed for the full validation cohort and for a subset that had
91 early gestational age (GA) dating via ultrasound. Classifier performance was compared directly to the
92 U.S. Preventive Services Task Force (USPSTF) algorithm for identification of pregnancies that should
93 receive low-dose aspirin (LDASA) for PE prevention.

94

95 *Results*

96 Nine of nine prespecified classifier models were validated for risk of preterm PE with delivery <37
97 weeks' gestation. Areas under the receiver operating characteristic curve ranged from 0.72-0.78 in the
98 full validation cohort, compared to 0.68 for both ClinRisk3 alone and for the USPSTF algorithm. In the
99 early GA dating subcohort, an exemplar predictor, ClinRisk3 + inhibin subunit beta C chain/sex hormone
100 binding globulin (ClinRisk3+INHBC/SHBG) showed a markedly lower screen positive rate (11.1% vs
101 43.3%) and higher positive predictive value (13.0% vs 5.0%) and odds ratio (9.93 vs 5.24) than USPSTF.
102 Its performance was similar in nulliparas and all parities.

103

104 *Conclusion*

105 Nine preterm PE risk predictors were identified, validated in an independent cohort, and shown to be
106 more predictive than the USPSTF-endorsed algorithm. Our results indicate that a single blood test
107 performed in the first half of pregnancy can be used for personalized PE risk assessment, particularly for
108 pregnancies with minimal or no identified clinical risk factors, including nulliparas. Results can be used to
109 guide personalized pregnancy management, including but not restricted to LDASA for PE prophylaxis,
110 and serve as a basis for developing new prevention strategies.

114 **Introduction**

115 Preeclampsia (PE) occurs in ~5-7% of pregnancies¹ and is implicated in 14% of maternal² and 10-25% of
116 perinatal³ deaths. It is associated with approximately one-quarter of all preterm births (PTBs) and 50%
117 of medically indicated PTBs.⁴ The only cure for PE is delivery, with other therapies focused on preventing
118 or delaying onset (low-dose aspirin [LDASA]),⁵ preventing end-organ damage (antihypertensive
119 medications to prevent strokes⁶ and magnesium sulfate to prevent seizures),⁷ and reducing neonatal
120 complications of prematurity (antenatal steroids).⁷ Because PE-associated perinatal morbidity and
121 mortality and healthcare costs correlate with prematurity,^{8,9} accurate prediction of preterm PE
122 (gestational age [GA] at delivery [GAD] <37 weeks) is of greater clinical and economic value than
123 prediction of term PE.

124 Until recently, PE prediction relied largely on clinical risk factors, including: PE in a previous
125 pregnancy; high body mass index (BMI); maternal chronic hypertension, diabetes, renal disease, and
126 autoimmune conditions; and obstetric characteristics such as multiple gestation and use of assisted
127 reproductive technologies.⁷ PE and gestational hypertension in a previous pregnancy are among the
128 most predictive and commonly used risk factors but are irrelevant in nulliparous pregnancies.

129 Numerous PE-associated molecular biomarkers have been reported,¹⁰⁻¹³ including soluble fms-
130 like tyrosine kinase 1 (sFlt-1) and placental growth factor (PlGF). In patients with clinically suspected PE,
131 sFlt-1 and PlGF measurement enables earlier diagnosis and/or modestly decreases adverse maternal
132 outcomes.^{14,15} but do not adequately predict PE risk in asymptomatic pregnancies. Strategies
133 incorporating combinations of serum analytes, patient history, blood pressure, and uterine artery
134 pulsatility index accurately predict PE risk in asymptomatic pregnancies but are not widely used, as they
135 require sophisticated equipment with trained sonographers along with molecular analyses.^{16,17} Also,
136 sFlt-1 and PlGF clinical studies have focused on late-onset PE; included only cases conforming to classical
137 definitions; or grouped PE cases across all GAs and/or severities together. Since PE is highly

138 heterogeneous,^{18,19} biomarker studies should at minimum assess performance for early-onset and late-
139 onset cases separately.^{8,20,21}

140 There is an urgent need for an accurate, safe, and practical predictor for preterm PE, particularly
141 for nulliparas. A predictor with good AUC (>0.70), sensitivity (>50%), and PPV (>5%) at a reasonably low
142 screen positive rate (SPR) (<15%) would markedly improve identification of high-risk pregnancies for
143 LDASA prophylaxis, increased surveillance, and research studies compared to current clinical paradigms,
144 while a high negative predictive value (NPV; >99%) would enable low-risk patients to safely forgo or
145 discontinue unnecessary interventions. This study aimed to develop and validate a mid-trimester
146 predictor comprising molecular biomarkers and relevant clinical factors across demographically,
147 geographically, and temporally diverse populations, comparing predictive performance to that of
148 currently used risk assessment paradigms.

149

150 **Methods**

151 Biomarker development was based on U.S. National Academy of Medicine guidelines.²² This was a
152 secondary analysis, using data from two large, multicenter U.S. cohort studies, conducted to discover,
153 verify, and validate risk predictors for preterm PE. The Proteomic Assessment of Preterm Risk (PAPR,
154 NCT01371019)²³ and the Multicenter Assessment of a Spontaneous Preterm Birth Risk Predictor
155 (TREETOP, NCT02787213)²⁴ studies were prospective, observational studies conducted to develop a
156 maternal serum-based proteomic biomarker for PTB risk stratification. Study approvals were provided
157 by site IRBs, and participants provided written informed consent.

158 PAPR and TREETOP enrolled gravidas ≥ 18 years of age with singleton pregnancies from 17^{0/7}-
159 28^{6/7} or 17^{0/7}-21^{6/7} weeks' gestation, respectively, and excluded pregnancies with planned delivery <37^{0/7}-
160 weeks' gestation, major anomalies or chromosomal disorders, or planned cervical cerclage. GA was
161 determined according to ACOG criteria^{25,26}. In TREETOP, progesterone use after 13^{6/7} weeks' gestation

162 was an exclusion criterion. Demographic, medical and pregnancy history, medication, and post-delivery
163 maternal and infant outcome information was collected. No attempt was made to control for LDASA use
164 in these studies. Adjudication of PE and PTB cases was blinded, occurring prior to database lockdown
165 and analyses.

166 Discovery was performed in a PAPR-derived cohort that was distinct from the TREETOP-derived
167 verification and validation cohorts (**Fig. 1**). The discovery and verification/validation cohorts included
168 blood samples drawn 18^{0/7}-22^{6/7} and 18^{0/7}-20^{6/7} weeks' gestation, respectively. The discovery cohort
169 used a broader GA at blood draw (GABD) window to increase sample size. TREETOP subjects enrolled
170 before April 18, 2018 were randomly assigned by an independent third-party statistician to blinded
171 verification (one-third) or validation (two-thirds) cohorts.²⁴ The validation cohort also included six
172 months of later enrollment at four additional sites not represented in the verification cohort. Cases were
173 defined as subjects with PE who delivered <37 weeks' gestation, and controls were defined as noncases,
174 inclusive of term PE and sPTB.

175 Maternal blood was collected, processed and stored as described previously.^{23,24} Serum samples
176 were depleted of abundant proteins, reduced, alkylated, and digested with trypsin. Stable isotope
177 standard (SIS) peptides were added post-digest, and peptides were analyzed by a liquid
178 chromatography-multiple reaction monitoring mass spectrometry assay.^{23,27} Quantification was based
179 on peptide response ratios, wherein the area of each endogenous peptide was divided by that of its
180 corresponding SIS. Sample batches were required to meet quality control metrics.

181 Biomarker measurements were made for 77 proteins, comprising those enriched for pathways
182 relevant to pregnancy conditions and quality control proteins. Proteins for building classifier models
183 were prefiltered using analytical performance criteria, including mass spectrometry peak area cutoffs,
184 coefficients of variance from replicate quality control samples, and preanalytic stability. Simple models
185 were then constructed to avoid overfitting and to leverage protein ratios for normalizing and amplifying

186 predictive signals²³. Models included one novel two-protein ratio and a composite clinical variable.
187 Based on strong predictive performance in nulliparous individuals, the log ratio of insulin-like growth
188 factor-binding protein 4 (IBP4) to sex hormone-binding globulin (SHBG) was included in models as a
189 second two-protein ratio unless SHBG was part of the novel ratio. Among many clinical factors specified
190 in current practice guidelines,^{7,28-32} three (PE in a previous pregnancy, pre-existing hypertension, and
191 pregestational diabetes) were selected and combined into one variable (ClinRisk3), which was deemed
192 positive if any was true for the subject. This simple, fixed approach reduced overfitting, leveraged prior
193 biomarker knowledge, and produced classifiers that followed two model structures:

- 194 1. $A_1 \cdot \log(\text{IBP4}/\text{SHBG}) + A_2 \cdot \text{ClinRisk3} + A_3 \cdot \log(X/Y)$ or
- 195 2. $A_1 \cdot \text{ClinRisk3} + A_2 \cdot \log(X/\text{SHBG})$

196 where X and Y are protein analytes, identified herein by Uniprot name without species identifier. Model
197 coefficients A_i were fit using logistic regression.

198 In discovery, models were ranked by a combination of area under the receiver operating
199 characteristic curve (AUC) and correlation with GAD amongst preeclamptic subjects. Candidate models
200 ascertained in discovery were confirmed and tuned in verification to account for temporal changes in
201 care and population, then validated by an independent third-party statistician. Each classifier was
202 initially validated using AUC, then *P*-value, for three score thresholds distinguishing higher from lower
203 risk. Thresholds were predefined based on discovery performance to allow for sensitivity and specificity
204 tradeoffs and to enable use in varied clinical settings.

205 Previously we showed that for prediction of spontaneous PTB using protein biomarkers, better
206 estimation of test performance is obtained in more precisely GA-dated individuals.³³ Since crown-rump
207 length is more precise when determined prior to 9^{0/7} weeks' gestation,²⁶ post-validation performance
208 metrics were calculated on a sub-cohort comprised of subjects dated by ultrasound prior to 9^{0/7}-weeks'
209 gestation (early GA dating). Performance metrics were calculated for GA cutoffs of <37 and <34 weeks in

210 all subjects and in nulliparous individuals. PE prevalence was calculated on the TREETOP validation
211 cohort and was consistent with the broader U.S. population, as represented by National Vital Statistics
212 System (NVSS) reporting³⁴ and Lisonkova et al. (2013)⁸ (e.g., for PE <34 weeks: TREETOP, 1.13%;
213 Lisonkova, 1.24%; $P=0.78$).

214 Guidelines³⁵ set by the U.S. Preventive Services Task Force (USPSTF) for PE clinical risk factor
215 assessment were compared to the biomarker-driven model. The TREETOP validation dataset contained
216 most USPSTF-prescribed clinical risk factors, including prior history of preeclampsia, chronic
217 hypertension, type 1 or type 2 diabetes, kidney disease, multi-gestational birth, elevated pre-pregnancy
218 body mass index, instances of nulliparous births, and maternal African American heritage (attributed to
219 socioeconomic factors). Using these variables, a classifier was developed to approximate the USPSTF risk
220 assessment and compare its performance with biomarker-driven models using the same predefined
221 benchmarks.

222 Analyses were conducted according to prespecified protocols. Laboratory personnel and
223 statisticians were blinded to clinical data. Data linked to classifier scores were analyzed by an
224 independent third-party statistician. Type I error was controlled by fixed sequence hypothesis
225 testing.^{36,37} The sample size of the validation sub-cohort was shown to have 84% power at 5% alpha to
226 detect by Fisher's exact test an enrichment of spontaneous PTB cases above a predictor score threshold
227 associated with two-fold increased risk.³⁸ For the purpose of validating preterm PE classifiers, this sub-
228 cohort was estimated to show >90% power at 5% alpha to detect by regression test a significant
229 enrichment above a 75% sensitivity threshold. At such a threshold, the sub-cohort sample size was
230 estimated to produce a 95% CI width for sensitivity of <25% and for specificity of <5%.

231 Unless otherwise specified, all statistical tests were 2-tailed at significance <0.05 and performed
232 in R v3.5.1 or higher.³⁹ Count differences in categorical variables were assessed using the chi-squared
233 test, and median differences in continuous variables were assessed with the Wilcoxon test.⁴⁰

234 Comparison across cohorts was performed using the Kruskal-Wallis test. Overall predictive performance
235 was assessed via AUC with direction of effect prespecified, significance assessed with a 1-sided Wilcoxon
236 test, and confidence intervals (CI) calculated using DeLong's method.⁴¹ Clinical validity was assessed
237 using predictive performance and statistically significant stratification of preterm PE subjects above vs
238 below threshold scores. Following validation, sensitivity, specificity, PPV, NPV, SPR, likelihood ratios
239 (LR+/-), and odds ratios (OR) were calculated for preterm PE (GAD <37 weeks), and early preterm PE
240 (GAD <34 weeks) for the entire validation cohort (all parities) and for nulliparas only. Calculation of
241 prevalence-dependent predictor performance used the prevalence of the analysed outcome in the
242 entire TREETOP-based validation cohort, as well as the early GA dating subset.

243

244 **Results**

245 Characteristics of the discovery, verification, and validation cohorts are summarized in **Table 1** and **Fig.**
246 **1**. Subjects delivering with preterm PE were more likely than controls to have higher BMI, prior PE,
247 chronic hypertension, pregestational diabetes, and longer neonatal hospital stays. GABD showed no
248 significant difference between cases and controls in any cohort.

249 No significant differences were seen across cohorts for chronic hypertension and pregestational
250 diabetes, but prior PE was increased among validation cohort controls (**Appendix 1**). There were also
251 significant differences between cohorts in race, ethnicity, parity, educational attainment, maternal age,
252 BMI, and GAD. Despite both case/control and cohort differences, regression analysis showed that
253 maternal age and BMI did not contribute independently to preterm PE risk. The significant difference in
254 GABD reflected the broader collection window in the discovery cohort.

255 Nine of nine classifiers ascertained in discovery showed acceptable predictive performance in
256 verification for risk of preterm PE with GAD <37 weeks. In validation, all nine exhibited significant AUCs
257 (0.72-0.78) for preterm PE risk prediction, significant risk stratification at three threshold scores, and

258 significant Pearson correlations between predictor score and GAD among individuals with PE (**Appendix**
259 **2**). ClinRisk3 alone exhibited an AUC of 0.68 for preterm PE, falling below the lower 95% CI of most of
260 the validated combined classifiers. **Fig. 2** shows ROC curves for the predictor with the largest AUC (0.78),
261 ClinRisk3 + inhibin beta c chain/SHBG (ClinRisk3+INHBC/SHBG), in the full validation cohort for (A) all
262 parity and (B) nulliparas.

263 For prediction of preterm PE <37 weeks' gestation in gravidas with any parity or nulliparas,
264 **Table 2** details ClinRisk3+INHBC/SHBG performance for validation cohort subjects with early GA dating,
265 and **Appendix 3** shows its performance in the full validation cohort. In the early GA dating sub-cohort,
266 setting the ClinRisk3+INHBC/SHBG cutoff to achieve a specificity of at least 90%, the sensitivity for
267 prediction of preterm PE with GAD <37 weeks for all parities was 51.7%, with a SPR 11.1%, PPV 13.0%,
268 NPV 98.5%, and OR 9.93; the performance for nulliparas was extremely similar, with the exception of a
269 lower PPV (6.9%) and higher NPV (99.8%). We also applied USPSTF clinical practice guidelines³⁵ to our
270 validation cohort – either the entire validation cohort (**Appendix 3**) or the sub-cohort with early GA
271 dating (**Table 2**). In these comparisons, predictive performance for the combination of ClinRisk3 and
272 INHBC/SHBG was superior to that of USPSTF guidelines.

273

274 **Discussion**

275 Nine classifier models predictive of preterm PE risk were validated, with ClinRisk3+INHBC/SHBG showing
276 the best overall performance. Requiring simplicity (one or two bivariate protein biomarkers and a
277 composite clinical variable) and using large, diverse, and temporally divergent cohorts mitigated
278 overfitting and enabled validation in an independent population. Three clinical features that differed
279 significantly between cases and controls in the discovery cohort (prior PE, pre-existing hypertension, and
280 pregestational diabetes) comprised the composite clinical variable. A fourth, BMI, was excluded as it did
281 not contribute independently to preterm PE risk, perhaps due to strong associations between BMI and

282 both diabetes and SHBG.^{42,43} Emphasizing strong predictive performance in both nulliparous and
283 multiparous pregnancies during discovery ensures broad applicability. In the two source cohorts, Black
284 (17.8-19.0%) and Hispanic (37.3-41.2%) subjects were represented at proportions higher than those in
285 the general U.S. birthing population (14.1-15.2% Black; 23.7-24.2% Hispanic),^{44,45} ensuring
286 generalizability.

287 Inhibin and activin, members of the transforming growth factor beta (TGF β) family, are
288 dysregulated in pregnancy disorders. Elevated maternal serum Inhibin A was first reported as a
289 biomarker of fetal aneuploidy⁴⁶ but is also associated with PE,^{47,48} including preclinical PE.⁴⁹ However,
290 Inhibin A, alone or in combination with other aneuploidy and fetal anomaly biomarkers, demonstrates
291 insufficient predictive performance for clinical use.^{50,51} INHBC, a less well-characterized inhibin family
292 member comprised of activin C homodimers, was recently reported to function through activin
293 receptor-like kinase 7 (ALK7), which participates in angiogenesis, cytokine activity, hormone signaling,
294 and embryonic development.⁵² Expressed in villous and extravillous trophoblasts, ALK7 is dysregulated
295 in placentas from individuals with PE⁵³ and is a mediator of hypoxia-induced impairment trophoblast
296 invasion.⁵⁴ A potential role for INHBC in extravillous trophoblast development and function may help
297 explain its predictive value for preterm PE (**Fig. 3**).

298 SHBG regulates biologically active free steroid hormone levels,⁵⁵ increases up to 10-fold in the
299 maternal circulation during pregnancy, and is expressed by placental trophoblasts.^{55,56} SHBG
300 transcription is suppressed by pro-inflammatory cytokines, such as tumor necrosis factor-alpha (TNF-
301 α),⁵⁷ which is relevant because inflammation, along with increased placental⁵⁸ and circulating⁵⁹ TNF- α , is
302 associated with PE (**Fig. 3**). Dysregulation of maternal circulating SHBG in PE has been reported by
303 some⁶⁰ and disputed by others⁶¹⁻⁶⁵, perhaps due to variability in PE phenotype and GABD among studies.
304 Even in studies associating SHBG with PE, its predictive performance is poor.⁶⁰ In non-pregnant adults,
305 low serum SHBG has been associated with insulin resistance,⁶⁶ Type 2 diabetes,⁶⁷ and endothelial

306 dysfunction.⁶⁸ In one study, gravidas with low first-trimester SHBG and PIGF were at highest risk of
307 developing PE, leading authors to conclude that dysregulated angiogenesis and insulin resistance
308 exerted additive effects on PE risk.⁶⁶ Similarly, these results suggest that SHBG is an independent PE risk
309 predictor due to potential effects on insulin resistance and endothelial function, and predictive
310 performance improves markedly when combined with an angiogenic factor such as INHBC.

311 Since the validated ClinRisk3+INHBC/SHBG predictor makes early risk assessment possible for
312 preterm PE (<37 weeks) in a given pregnancy for any parity, it can enable individualized clinical
313 management. Individuals at higher risk can be assigned to increased surveillance (e.g., more frequent
314 antenatal visits, home blood pressure monitoring) for early detection of PE and associated
315 complications, along with nutritional modification, exercise coaching, and other interventions,⁶⁹ while
316 those at lower risk can safely avoid unnecessary interventions. Determining whether our predictors will
317 be useful for decision-making regarding LDASA prophylaxis requires more study, to establish LDASA
318 efficacy among patients for whom guideline criteria and the predictors produce discordant risk
319 assessments.

320 ClinRisk3+INHBC/SHBG provided excellent stratification of subjects at elevated risk for early-
321 onset preterm PE (diagnosis <34 weeks' GA), an outcome with a large clinical burden and unmet need.
322 ACOG recommends delivery for PE diagnosed \geq 34 weeks' GA and expectant management with close
323 observation for those diagnosed earlier.⁷ Clark et al. (2023)⁷⁰ recently recommended changes to
324 classification of different PE subtypes to better reflect the type and degree of associated organ
325 dysfunction. We acknowledge that, if adopted, such recommendations may alter clinical decision-
326 making relevant to timing of delivery for PE. In addition, new prevention or treatment strategies may be
327 developed. Any of these developments may require us to reassess predictor performance in the
328 appropriate contexts.

329 Clinical practice guidelines include expectations for test performance, including high PPV, to
330 limit overtreatment.⁷ However, PPV is impacted by a condition's prevalence. This study validated
331 predictive algorithms for preterm PE, a clinically important yet low-prevalence PE phenotype, in a cohort
332 with a PE rate similar to the overall U.S. prevalence (2.7% preterm PE, 7.7% all PE). This contrasts with a
333 recent RNA biomarker study⁷¹ that interrogated PE at any GA in a high-risk population (PE rate of
334 13.6%), which reported a sensitivity of 75.0% and a PPV of 32.3%. We chose to establish a threshold at
335 approximately a 10% false positive rate (FPR), as this is a common practice that helps to avoid
336 overtreatment. It is also common to establish a threshold that results in 10% of a population being
337 screen positive. As our 10% thresholds result in approximately an 11-12% SPR, the performance
338 estimates provided here apply generally for both approaches.

339 Importantly, according to the current standard of care, PE risk is assessed using a range of
340 clinical algorithms. Specifically, in a large Danish mixed parity cohort, National Institute of Health and
341 Care Excellence (NICE) guidelines²⁸ had a sensitivity of 47%, PPV of 5.4%, and NPV of 99.6% at a SPR of
342 8.1%, while American College of Obstetrics and Gynecology (ACOG) guidelines⁷ had a sensitivity of
343 60.5%, PPV of 5.6%, and NPV of 99.7% at a SPR of 18.2% for preterm preeclampsia <37 weeks' GA.⁷² In
344 our validation cohort, we applied USPSTF clinical practice guidelines, which yielded a sensitivity of
345 79.3%, PPV of 5.0%, and NPV of 99.0% at a SPR of 43.4% for preterm preeclampsia <37 weeks' GA. The
346 Fetal Medicine Foundation's (FMF) recommended a more involved screening algorithm⁷³, including
347 maternal risk factors, maternal mean arterial pressure, the uterine artery pulsatility index, and serum
348 PLGF, which has a reported 79.9% sensitivity, 4.4% PPV, and 99.8% NPV at a SPR of 14.7% for all parities,
349 and 79.0% sensitivity, 3.8% PPV, and 99.8% NPV at a SPR of 19.2% for nulliparas, for preterm PE.⁷⁴

350 Consisting of straightforward measurement of 2 proteins in a single blood sample combined
351 with easily ascertained clinical factors, the performance of ClinRisk3+INHBC/SHBG in the total validation
352 cohort (sensitivity 51.7%, PPV of 13.0%, and NPV of 98.5% at a SPR of 11.1%) and specifically in

353 nulliparas (sensitivity 53.3%, PPV of 6.9%, and NPV of 99.8% at a SPR of 11.7%) is superior to standard-
354 of-care clinical risk assessment approaches endorsed by NICE, ACOG, and USPSTF, and also compares
355 favorably with the more burdensome approach endorsed by the FMF, which is comprised of not only
356 clinical factors and a protein biomarker, but also uterine artery Doppler measurement, which is
357 unfeasible for universal screening. ClinRisk3+INHBC/SHBG and the other predictors validated in this
358 study can be used to select high-risk pregnancies for interventional studies of prophylactic or
359 therapeutic agents. Determining whether preventive or therapeutic interventions alter biomarker levels
360 in maternal serum is also of interest. Clinical application of a screening test is a two-step process: The
361 first step, reported here, is validation of the biomarkers' predictive abilities. The second, demonstrating
362 clinical utility – i.e., improved outcomes, cost effectiveness, and ease of implementation – requires
363 additional work.

364 Strengths of the study include the large, diverse, and temporally distinct datasets used for
365 discovery, verification, and validation. The composite clinical variable uses readily ascertained factors,
366 and the biomarkers were prefiltered for excellent performance in ambient temperature sample
367 transport conditions. These properties support practicality for clinical use. Limitations include the
368 modest number of early preterm PE cases due to the low prevalence of the condition and a mid-
369 trimester blood draw window (18^{0/7}-22^{6/7} weeks' GA) that falls within the guideline-recommended
370 timeframe for LDASA initiation (12-28 week's GA, optimally <16 weeks' GA).⁷

371 In summary, nine mid-trimester preterm PE risk predictors, designed to assess both proteomic
372 biomarkers and clinical risk factors from 18-20 weeks' gestation, demonstrated predictive ability
373 superior to that of clinical factors alone. ClinRisk3+INHBC/SHBG includes biomarkers with functional
374 relevance to pregnancy. All show promise for detecting risk of PE <34 weeks' GA and identifying pre-
375 symptomatic individuals who can benefit from increased surveillance, LDASA prophylaxis, and future
376 therapies.

Categorical variables are shown with counts and percentages, and continuous variables are shown with medians and interquartile ranges. Comparisons between cases (PE <37 weeks' gestation) and noncases (no PE or PE ≥37 weeks' gestation) were performed using Wilcoxon or chi squared tests as appropriate. Collection of neonatal hospital stay was capped at 28 days according to the PAPR²³ and TREETOP²⁴ study protocols. BMI, body mass index; IQR, interquartile range; GED, general education diploma; NA, not applicable; PE, preeclampsia; PTB, preterm birth.

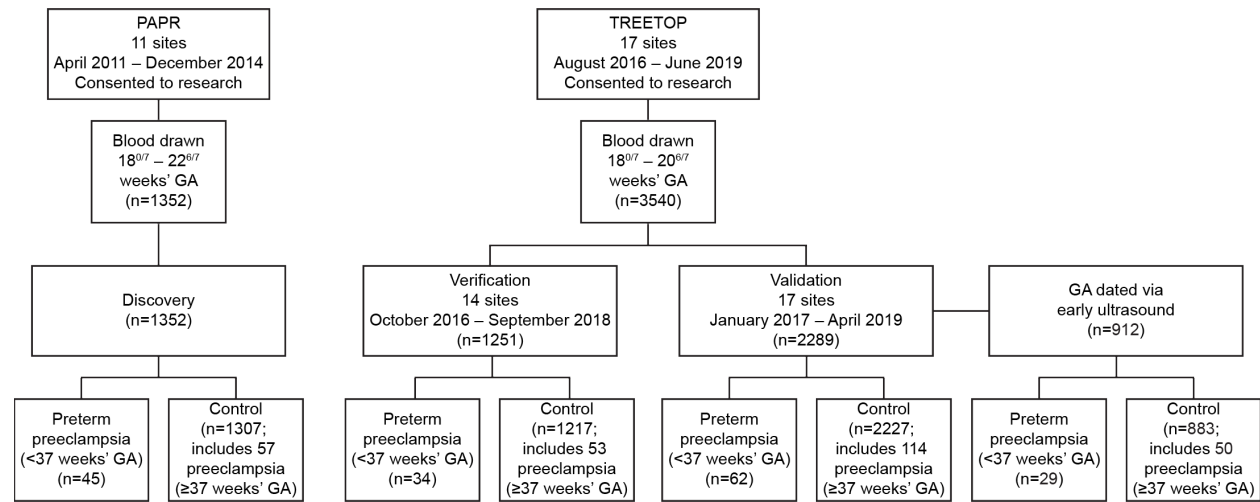

Table 2. Predictive performance of ClinRisk3+INHBC/SHBG and a U.S. Preventive Services Task Force clinical risk factor-based classifier (representing standard care) for risk of preeclampsia with delivery <37 weeks' gestation in the early gestational age dating-restricted population.

Tested population	PE <37 weeks' GA cases/ total subjects (%)	Predictor	AUC (95% CI)	Sensitivity	Specificity	SPR	PPV	NPV	LR+	LR-	OR
Early GA dating All parity	29/912 (3.2%)	ClinRisk3 + INHBC/SHBG	0.82 (0.75 – 0.89)	51.7%	90.3%	11.1%	13.0%	98.5%	5.31	0.53	9.93
		USPSTF guidelines (standard of care)	0.69 (0.61 – 0.76)	79.3%	57.8%	43.4%	5.0%	99.0%	1.88	0.36	5.24
Early GA dating Nulliparas	15/376 (4.0%)	ClinRisk3 + INHBC/SHBG	0.81 (0.71 – 0.92)	53.3%	90.0%	11.7%	6.9%	99.8%	5.35	0.52	10.32
		USPSTF guidelines (standard of care)	0.70 (0.61 – 0.80)	86.7%	54.3%	47.3%	2.6%	99.1%	1.90	0.25	7.72

AUC, area under the receiver operating characteristic curve; CI, confidence interval; ClinRisk3, composite clinical risk variable including preeclampsia in a previous pregnancy, pregestational hypertension, and pregestational diabetes; GA, gestational age; INHBC, inhibin subunit beta C chain; NPV, negative predictive value; LR+/-, positive and negative likelihood ratios; OR, odds ratio; PPV, positive predictive value; SHBG, sex hormone-binding globulin; SPR, screen positive rate; USPSTF, U.S. Preventive Services Task Force.

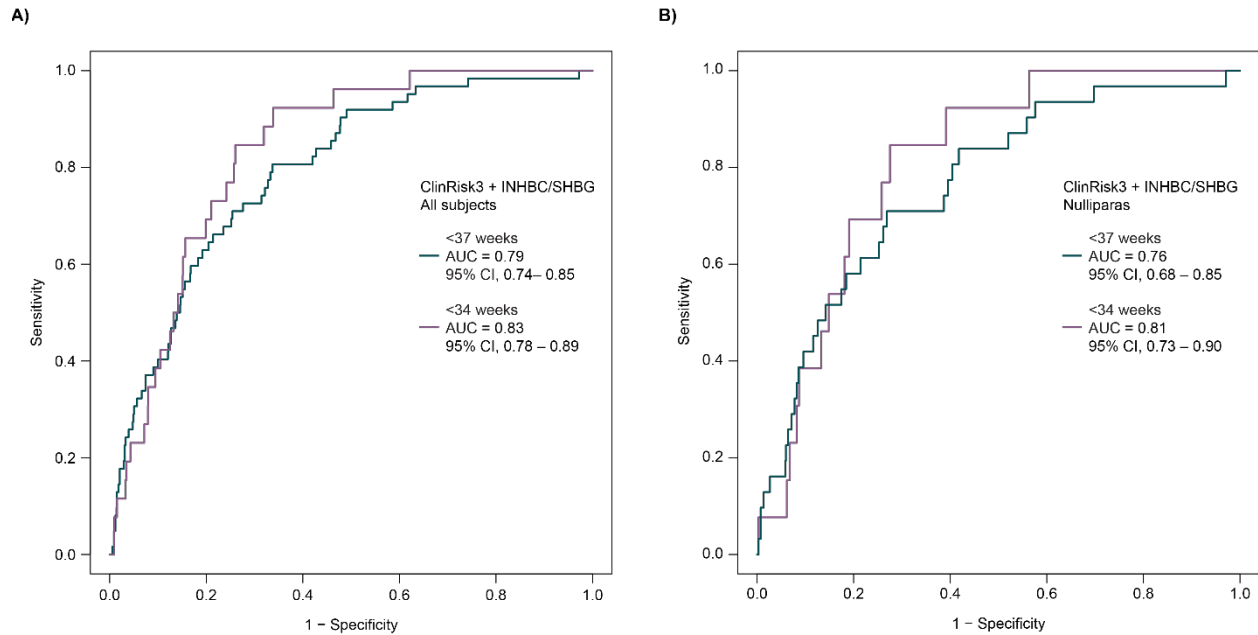

Figure Legends

Fig. 1. Distribution of subjects in the discovery, verification, and validation cohorts.

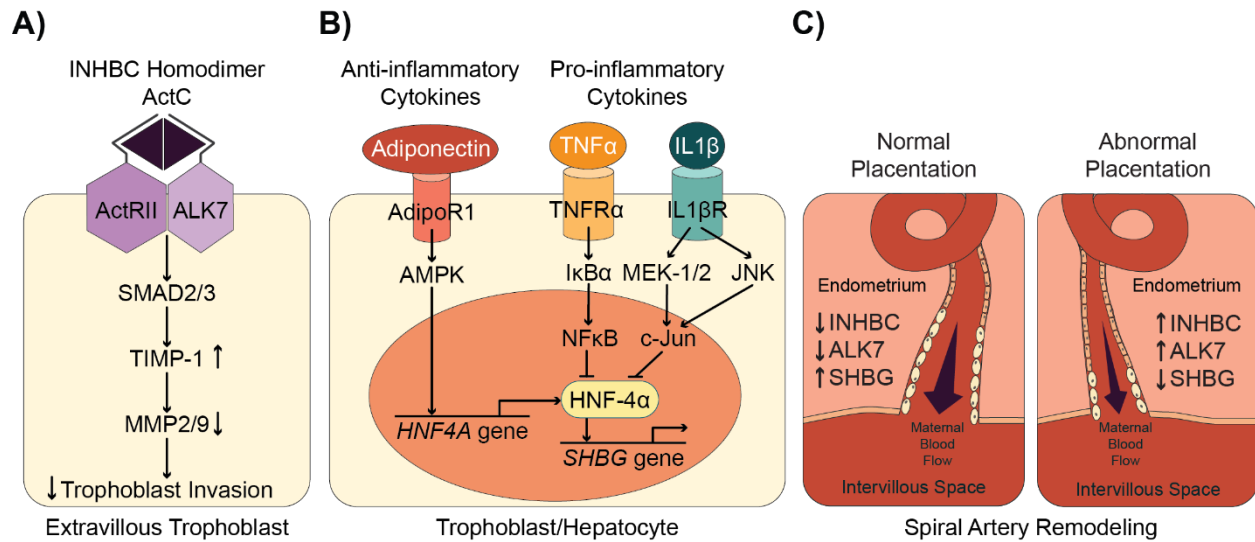

GA, gestational age.

Fig. 2. Receiver operating characteristic performance for the preterm preeclampsia (PE) classifier ClinRisk3+INHBC/SHBG in the full validation cohort. The plots graph sensitivity (true positive rate) vs 1-specificity (false positive rate) for preterm PE cases with gestational age at delivery <37 and <34 weeks among (A) all subjects and (B) nulliparous subjects only.

AUC, area under the receiver operating characteristic curve; CI, confidence interval; ClinRisk3, composite clinical variable including preeclampsia in a previous pregnancy, pregestational hypertension, and pregestational diabetes; INHBC, inhibin subunit beta c; SHBG, sex hormone binding globulin.

Fig. 3. Potential roles of INHBC and SHBG in placentation. (A) Activin C, a homodimer of INHBC, signals through the ALK7 receptor, which is itself dysregulated in preeclampsia. (B) SHBG expression has been demonstrated to be downregulated by pro-inflammatory cytokines in hepatocytes, and its extra-hepatic expression has been shown to include trophoblasts. (C) A model illustrating the association of INHBC, ALK7 and SHBG with abnormal placentation and aberrant spiral artery remodeling.

ActC, activin C, an INHBC homodimer; ACTRII, activin receptor type 2A; ALK7, activin A receptor type 1C; AMPK, AMP-activated protein kinase; c-Jun, Jun proto-oncogene, AP-1 transcription factor subunit; HNF-4 α , hepatocyte nuclear factor 4 alpha; I κ B α , NF κ B inhibitor alpha; IL1 β , interleukin 1 beta; IL1 β R, interleukin 1 beta receptor; INHBC, inhibin subunit beta c; JNK, mitogen-activated protein kinase 8; MEK1/2, mitogen-activated protein kinase kinases 1 and 2; MMP2/9, matrix metalloproteinases 2 and 9; NF κ B, nuclear factor kappa B; SHBG, sex hormone binding globulin; SMAD2/3, SMAD family members 2 and 3; TIMP-1, TIMP metalloproteinase inhibitor 1; TNF α , tumor necrosis factor alpha; TNFR α , tumor necrosis factor alpha receptor.

Categorical variables are shown with counts and percentages, and continuous variables are shown with medians and interquartile ranges. Comparison among the three cohorts was performed using Kruskal-Wallis or chi squared tests as appropriate. Collection of neonatal hospital stay was capped at 28 days according to the PAPR²³ and TREETOP²⁴ study protocols.

BMI, body mass index; IQR, interquartile range; GED, general education diploma; NA, not applicable; PE, preeclampsia; PTB, preterm birth.

Appendix 2. Validation performance of nine candidate preeclampsia classifier models. Score thresholds are specific to each classifier and differentiate subjects predicted to be at higher risk for preterm preeclampsia, defined as preeclampsia <37 weeks' gestation, from those predicted to be at lower risk. Three score thresholds distinguishing higher from lower risk were validated for each classifier. The linear relationship between the gestational age at delivery and classifier prediction was assessed by the Pearson correlation coefficient. Validation performance is reported across the nine classifiers without protein specific batch calibration.

Classifier	AUC [95% CI]	1° threshold P value	2° threshold P value	3° threshold P value	Pearson correlation coefficient <i>r</i>	Pearson correlation coefficient P value
ClinRisk3 + INHBC/SHBG	0.78 [0.73-0.84]	7.26×10^{-13}	2.69×10^{-12}	3.64×10^{-11}	-0.275	2.20×10^{-04}
ClinRisk3 + IBP4/SHBG + AFAM/PRG2	0.77 [0.71-0.83]	4.13×10^{-12}	1.30×10^{-11}	2.26×10^{-11}	-0.29	1.19×10^{-04}
ClinRisk3 + AFAM/SHBG	0.76 [0.69-0.82]	7.36×10^{-11}	7.46×10^{-11}	4.22×10^{-13}	-0.24	1.25×10^{-03}
ClinRisk3 + CD14/SHBG	0.76 [0.70-0.82]	5.27×10^{-12}	1.24×10^{-10}	3.03×10^{-10}	-0.26	4.44×10^{-04}
