Trajectories of COVID-19: a longitudinal analysis of many nations and 1 subnational regions. 2 David Burg^{1,2,*}, Jesse H. Ausubel² 3 ¹) Tel Hai Academic College, Israel. 4 ²) Program for the Human Environment, The Rockefeller University, New York, USA 5 *) email: davidb@telhai.ac.il 6 7 Abstract 8 The COVID-19 pandemic is the first to be rapidly and sequentially measured by nation-wide PCR community 9 testing for the presence of the viral RNA at a global scale. We take advantage of the novel "natural experiment" 10 where diverse nations and major subnational regions implemented various policies including social distancing 11 and vaccination at different times with different levels of stringency and adherence. Initially, case numbers 12 expanding exponentially with doubling times of \sim 1-2 weeks. In the nations where lockdowns were not 13 implemented or ineffectual, case numbers increased exponentially but then stabilized around 10^2 -to- 10^3 new 14 infections (per km² built-up area per day). Dynamics under strict lockdowns were perturbed and infections 15

decayed to low levels. They rebounded following the lifting of the policies but converged on an equilibrium 16 setpoint. Here we deploy a mathematical model which captures this behavior, incorporates a direct measure of 17 lockdown efficacies, and allows derivation of a maximal estimate for the basic reproductive number R_0 (mean 18 19 1.6-1.8). We were able to test this approach by comparing the approximated "herd immunity" to the vaccination coverage observed that corresponded to rapid declines in community infections during 2021. The estimates 20 reported here agree with the observed phenomena. Moreover, the decay rates d (0.4-0.5) and rebound rates r_0 (0.2-21 0.3) were similar throughout the pandemic and among all the nations and regions studied. Finally, a longitudinal 22 analysis comparing multiple national and regional results provides insights on the underlying epidemiology of 23 SARS-CoV-2 and lockdown and vaccine efficacy, as well as evidence for the existence of an endemic steady state 24 of COVID-19. 25

Introduction

Quantitative studies of viral infection in human severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)30infected subjects have been enabled by the massive global deployment of sensitive and rapid PCR testing for31detecting viral RNA in infected persons. Data obtained with these procedures have allowed for extensive32mathematical modeling of infection expansion dynamics [1]. Indeed, epidemiological modeling of this pandemic33has exploded, though results have been mixed and proved how difficult it can be to provide accurate information34and predictions, especially in the early stages of the pandemic [2].35

COVID-19 cases initially grew exponentially in every nation. Reduction of community infection was initially 36 achieved by non-pharmaceutical and social distancing interventions [3,4]. The drastic social distancing measures 37 undoubtedly curbed viral expansion [5]. However, the underlying biological, environmental and social dynamics 38 were not fundamentally modified, and viral circulation was only temporarily inhibited. National vaccination 39 programs deployed during 2021 were also aimed to block person-to-person infection. These interventions were 40 enacted at different times, with different levels of enforcement, compliance and extent among nations and in major 41 regions within nations. This global "natural experiment" makes the COVID-19 pandemic a unique opportunity to 42 43 longitudinally model epidemiological dynamics.

COVID-19 modeling is primarily based on the standard SIR model as the foundational tool of mathematical 44 epidemiology and attempts to capture the main characteristics of the complex interplay among the virus, its host 45 and the environment [6]. The theoretical SIR model's solution converges on a logistic-like s-curve trajectory with 46 rapid expansion reaching a peak and declining in one wave [7]. Many much more elaborate models were deployed 47 to study COVID-19 dynamics [8,9]; however, complexity invokes problems such as overfitting, global 48 optimization, and interpretability. An important feature not reproduced in these models is the existence of a non-49 trivial equilibrium setpoint. 50

A key criterion of epidemic expansion is the basic reproductive number (R_0) which represents a disease's 51 transmissibility. Specifically, it is the average number of productive secondary infections arising from one active 52 infectious individual [10]. It is derived from the ratio between the infection and removal rate constants in the SIR 53 or similar models [11]. A bifurcation threshold condition for the occurrence of a sustained epidemic is $R_0 \ge 1$, 54 meaning that as $R_0 < 1$ the infection will converge on the disease-free state. This is also an indication for "herd 55

immunity" [12,13]. In contrast to the outcome of a disease-free state, most models in the context of COVID-19 56 have lacked capacity to depict sustained endemic levels of infection. 57

Estimation of the value of R_0 is commonly based on the initial exponential growth rate [14] and the median 58 infectious period [15,16]. This is clearly an overestimate as it disregards the removal rate of cases [17]. Another 59 problem is it ignores the distinctive infection peak and inherent inevitable negative second derivative predicted 60 by SIR models. Other approximations treat reproductive rates as a function of time during the epidemic. Wallinga 61 & Lipsitch [18] summarize the main methods to calculate this time-dependent "effective" $R(R_e)$. A recent review 62 demonstrated that Cori et al. [19] derived an accurate estimate for this parameter [20]. It has also been suggested 63 that a simple Dirac delta distribution can be used as a proxy for R_e [21]. These are important though R_e will 64 fluctuate as a function of the changes in infection rates as the epidemic develops [22], but further discussion is 65 beyond the scope of this paper. While these measure changes in infection rates change over time (e.g., the first 66 derivative) they do not capture the underlying fundamental biological and social interactions. 67

This paper highlights applicability of mathematical models based on the viral dynamics paradigm [23–25]. A 68 notable characteristic of these models is a non-trivial non-zero infection dynamical steady state equilibrium 69 setpoint. Further, they represent effects of interventions to block transmission of the pathogen throughout the 70 population. The major advantage of this methodology is the ability to derive estimations for the values of model 71 parameters directly from the data [26].

We refrain from exploring the dynamics of the COVID-19 virus itself. SARS-CoV-2, the virus that causes 73 COVID-19, keeps changing and accumulating mutations in its genetic code. Some variants emerge and disappear, 74 while others emerge, spread, and replace previous variants. For the USA, for example, variant proportions are 75 tracked at https://covid.cdc.gov/covid-data-tracker/#variant-proportions. Obviously, the strategies for suppression 76 can interact with the evolution of the virus. We simply assume a virus able to evolve so that it can reinfect 77 previously infected individuals. 78

Publicly available data for COVID-19 were used to characterize the epidemiological dynamics of community 79 infection. The implementation of efficacious social distancing and lockdown interventions instituted across many 80 nations allows the modeling of the dynamics of infection decay and subsequent rebound as interventions were 81 lifted or lose effectiveness. A longitudinal comparison among nations and major subnational regions provides 82 insights into pathogenesis that would be difficult or impossible to obtain in past pandemics. 83

Materials and Methods

Epidemiological data

Data for confirmed active infected cases, COVID-19-associated mortality and PCR tests were retrieved [27]. For 86 most purposes we stop in September 2021 when the widespread availability of self-testing reduces the reliability 87 of some of the relevant time series. Preliminary review shows that the data exhibit two artifacts. First, a weekly 88 cycle is clearly observed with a tendency for more reporting in the middle of the week and less during weekends. 89 90 sometimes with orders-of-magnitude differences. Second, large inter-day fluctuations are reported, sometimes with differences spanning multiple orders-of-magnitude. While it is common to smooth the data with a moving 91 average, the resulting estimates are highly sensitive to the fitting window, especially with small numbers and the 92 extremely noisy data (up to an order-of-magnitude between days). Therefore, weekly averages were adopted here 93 94 and calculated from the geometric mean of the daily measurements to stabilize the variance in the data [28]. There is clearly a delay between time of infection and reporting. Incubation times for COVID-19 are 6.2 days and 95 the mean generation interval is 6.7 days, with a concurrent latent period of 3.3 days [29]. Further, there is a lag 96 between infection and detection by lab test with a skewed distribution [30,31]. While the exact value is unknown, 97 it will only offset the data in time and does not affect the shape of the infection trajectories. Therefore, a ten-day 98 99 delay is applied here to all confirmed case numbers, only shifting them left in time and not affecting the shape of the data. 100

Inclusion criteria

Analyses were performed for nations and major subnational regions with 10-fold mean difference between PCR 102 tests and positive confirmed cases, high GDP (PPP) per capita [32] indicating the ability to perform an extensive 103 testing program, and approximately one log decrease in infections from peak to minimum rates during lockdowns. 104 The forty-five units qualifying are 24 European nations, Australia and New Zealand, the UK and the four nations 105 constituting the UK, 10 USA states, and four Asian nations. 106

Lockdown interventions, mobility and vaccination coverage

Dates for national policy lockdown initiation and termination are available and collated from numerous sources 108 and the COVID-19 stringency index was accessed [33]. Even so, compliance was imperfect, and mobility was 109 used as a minimal estimate for the efficacy of the intervention to block infection [34,35]. The number of doses of 110

84

85

101

vaccines were retrieved from Mathei et al. [36] and population data from the World Bank [37]; these enable 111 calculation of the percent of the populace vaccinated. To compare countries and regions, data are commonly 112 normalized to population size, such as "per million." However, COVID-19 is strongly dependent on population 113 density [38]. Therefore, to alleviate the population density bias, the data were normalized to the built-up area 114 [39,40].

116

Mathematical modeling of COVID-19

The epidemiology of COVID-19 was analyzed using a mathematical model of viral dynamics. The three model 117 compartments include susceptibles (*S*), COVID-19-confirmed individuals (*I*), and free virus particles (*V*). The 118 model assumes that uninfected people are being made available at a constant rate (σ) and the virus productively 119 infects them with probability βVS . Detected individuals are removed by quarantine at rate δI . Deaths can be 120 thought of as a subset of these and are neglected for the purposes of this study. Viral particles are released from 121 infected individuals at rate pI and are inactivated at rate cV. These assumptions lead to the coupled nonlinear 122 ordinary differential equations: 123

$$\frac{dS}{dt} = \sigma - (1 - \eta(t))\beta VS$$
$$\frac{dI}{dt} = (1 - \eta(t))\beta VS - \delta I \tag{1}$$
$$\frac{dV}{dt} = pI - cV$$

Intervention efficacy to block infection, via lockdowns or vaccination, is parameterized here by $\eta(t)$. Assuming 127 partial and incomplete effectiveness, e.g. $0 < \eta < 1$, the system will converge on a new lower steady state. The mean 128 infectious time is $1/\delta$. The average number of virus particles produced during the infectious interval of a single 129 infected person (the burst size) is given by p/c. While asymptomatic carriers are thought to be efficient spreaders, 130 they are neglected here, and we assume as a first approximation that their dynamics are similar with *I* and change 131 in tandem with the confirmed cases. 132

Sustained viral propagation ensues if, and only if, the average number of secondary infections that arise from one 133 productively infected person is larger than one (1). This is the basic reproductive number and for Eq. (1) it is 134 defined by $R_0 = \beta \sigma p/(\delta c)$. The intrinsic growth rate constant, *r*, is solved for by the dominant root of the equation 135 $r^2 + (\delta + c)r + \delta c(1 - R_0)$. However, if $c >> \delta$ and *r*, then it can be simplified to: $r = \delta (R_0 - 1)$. When $R_0 > 1$, then infection 136 rates will initially experience an exponential increase [41]. 137

The model predicts that as the infection grows it decelerates. The infection will converge in damped oscillations 138 to the non-trivial equilibrium: $S = \delta c / \beta p$, $\bar{I} = (R_0 - 1) \delta c / (\beta p)$, $V = (R_0 - 1) (\beta)$. This dynamical steady state is obtained 139 when the number of new infections equals the number of recovering individuals, where every productive infection 140 generates, on average, only one more new secondary infection. A global stability analysis can be found here [42]. 141 As far as we know, this is the simplest dynamical model which affords a non-trivial non-zero infection steady 142 state. 143

Assuming a quasi-steady state, e.g., the viral dynamics are much more rapid than the epidemiological phenomenon 144 (p >> c), then Eq. (1) can be reduced to: 145

$$\frac{dS}{dt} = \sigma - (1 - \eta)\beta' IS$$

$$\frac{dI}{dt} = (1 - \eta)\beta' IS - \delta I \qquad (2)$$

$$\beta' = \beta p/c$$

with no loss of generality for the major trajectories of infection dynamics [43]. The model dynamics are shown 149 in Figure 1. This functional form has the advantage to decrease model complexity, especially because the viral 150 compartment is less relevant at the community-scale. Exponential decay under interventions to block infection is 151 given by $r_0 = \delta - (1 - \eta)\beta' S_0$, where S_0 are the number of susceptibles at t_0 . Under highly efficient interventions, i.e., 152 153 $\eta \rightarrow 1$, then a minimal estimate for δ can be derived directly from the observed decay half-life of t₂=ln(2)/ δ [44,45]. When social interventions are withdrawn or vaccines become ineffectual at time t_1 , infections rebound at an 154 exponential rate given by $r = \beta' S_1 - \delta$, where S_1 is the level of available susceptibles at t_1 . Crucially, r can be obtained 155 directly from the observed slope on the semi-log graph, and its doubling-time is $t_2 = \ln(2)/r$. This expansion in 156 infections will continue in damped oscillations returning to the steady-state. 157

158

Figure 1. Epidemiological dynamics under interventions to block infection. Initially, infections rise exponentially 159 (though national COVID-19 testing programs were also ramping up). During stringent lockdown and effective 160 cessation of viral transmission, between t_0 and t_1 , infection decays exponentially with a half-life of $t_{\frac{1}{2}}=\ln(2)/r_0$, 161 where r_0 is derived from the slope of the ln-transformed infection data. This provides a minimal estimate for the 162 value of parameter δ , assuming partial intervention efficacy ($0 < \eta < 1$). This decay will decelerate reaching a lower 163 steady state. Infections will naturally rebound upon lifting of interventions and/or loss of vaccine efficacy with a 164

doubling time of $t_2=ln(2)/r$ and r also calculated from the exponential up-slope. The system will converge with 165 damped oscillations to an elevated infection steady state. This basic pattern will recur as interventions are 166 deployed at different times. 167

168

169

170

176

177

Estimation of the basic reproductive ratio

The basic reproductive number is based on a ratio among all five model parameters. However, the paucity of 171 independent knowledge and accurate values for them precludes adequate approximations of R_0 . To alleviate this, 172 the relationship between the basic reproductive ratio (R_0) and the exponential growth rate (r) can be recovered 173 such that $R_0=1+r(r+\delta+c)/\delta c$. If $r+\delta$ is small compared to c, then this approaches: 174

$$R_{\rm o} = 1 + r/\delta \tag{3}$$

which can be calculated directly from the exponential slopes, r_0 and r, as described above.

Parameter values and statistical analysis

To determine the initial values for model parameters, half-life decay during lockdowns and rebound doublingtimes were calculated from the log_n-transformed data of confirmed cases (weekly geometric means). Optimized values were generated by nonlinear fitting (Berkeley Madonna v8), minimizing the objective function $J = \sum_{i=1}^{n} \log(O_i / P_i)$ where O_i and P_i are the observed and expected values, for *n* datapoints, with the advantage of 181

stabilizing the variance during the fit [28]. Many functional forms for intervention efficacy (η) can be used but 182 for simplicity, generalizability and as a first approximation: 183

$$\eta(t) = \begin{cases} \eta , t_0 < t < t_1 \\ 0 , \text{ otherwise} \end{cases}$$

for each intervention wave. The observed decrease in mobility is used here be used as a proxy to estimate its value 185 for each country [46]. Trivially, the proportion of the population needed to be vaccinated in order to block 186 community spread, known as "herd immunity" threshold is [47,48]: 187

$$H=1-1/R_{\rm o}$$
 (4)

Longitudinal comparisons on the parameter values is performed using the Mann-Whitney u test. 95% confidence 189 intervals, along with their statistical significance, are calculated as appropriate. Model errors (RMS) are reported. 190 Data, simulations and results are available online at: https://github.com/davidville/COVID-19. 191

Results

192

Dynamics of COVID-19 epidemiology

193

A preliminary analysis of confirmed COVID-19 cases from 15 nations which did not implement stringent 194 lockdown policies, or were unsuccessful at their implementation, indicates widely varying rates and infection 195 levels (Fig. 2). By the end of Feb 2020 these nations had initial infection levels of $\sim 10^{\circ}$ cases per km² with 196 sustained infection doubling times of 1.2-1.7 weeks. Levels increased exponentially for 20±8 weeks and stabilized 197 198 around a dynamical steady state with fluctuations no more than 0.5log. Setpoints among these countries were 100-400 cases per km² built-up area per day. Interestingly, South Africa and Armenia exhibited spontaneously 199 oscillating kinetics with an amplitude one order-of-magnitude, perhaps alluding to the existence of a 'limit cycle'. 200 India exhibited one of the largest differences in infection over time, increasing to 10^{2.5}, declining to 10^{1.5} then 201 peaking at 10³ before declining spontaneously again to 10² cases per km² built-up area per day. Because there 202 were no effective measures to block COVID-19 spread, the number of confirmed cases attained a dynamical 203 204 equilibrium around which case numbers fluctuated.

Dynamics during effective lockdowns

212 213

211

COVID-19 positive case turnover allows analysis of effective social distancing through population-level 214 lockdowns. Non-pharmaceutical means to block new rounds of infections were initially rapid and effectively 215 implemented. Infections begin to decay exponentially 7-10 days after the lockdown policies are implemented, 216 with down slopes of 0.5 ± 0.3 per week and corresponding to half-life values of 2.0 ± 1.1 weeks. Infection rates 217 attained nadir within 4-6 weeks with average efficacy of 68% (range: 46-93%), declining 1-2log lower than pre-218 lockdown case numbers. Confirmed cases rebounded exponentially with doubling times of 2.3-2.6 weeks 219 following the end of severe lockdowns. The trajectory then converged on an empirical equilibrium steady state of 220 approximately 10^2 - 10^3 cases per km² built area and with fluctuations less than 0.5log. 221

The USA is composed of distinct political entities, with large inter-state variation. SARS-CoV-2 surged and 222 waned differently, peaking and ebbing at different times among the various states. Therefore, analyses of COVID-223 19 for the USA have been done at the state level. Ten states conformed to the inclusion criteria. The US state 224 COVID-19 dynamics were less extreme with lockdown declines of less than 2log in some states, albeit the up-225 and down slopes during lockdowns were comparable with European nations. Four states suffered elevated steady-226 states approximately one order-of-magnitude higher $(10^{3.2}-10^{3.5} \text{ cases per built-up area per day})$. 227

The UK as a whole had, on average, similar dynamical characteristics as its neighbors. However, the observed 228 decay rates during lockdowns were significantly less rapid, leading to differences that will be expanded upon 229 later. Asian nations, generally, had somewhat different COVID-19 trajectories. While the initial doubling times 230 before lockdowns were similar to other nations and regions, half-lives during lockdowns were nearly twice as 231 rapid, 1.3 ± 0.5 vs. 2.0 ± 1.1 weeks. The Asian rebound rates differed less relative to other countries, though they 232 were more prolonged with some clear oscillatory effects. Additionally, the setpoint infection rates in Japan and233South Korea were an order-of-magnitude lower than in Europe.234

The earliest, most stringent and prolonged restrictions were implemented in Australia and New Zealand (Fig. 5). 235 Confirmed case rates were perturbed to low levels for 35 months. They were kept 0.5log below the lowest rates 236 achieved in Europe until July 2021. Even so, these strict "Zero COVID" policies were insufficient to snuff out 237 community spread entirely. As limits were relaxed, infections surged exponentially with doubling times and 238 equilibrium states comparable to elsewhere, even in the milieu of high vaccination coverage. 239

240

Figure 3. COVID-19 positive confirmed cases between February 2020 and September 2021. Data are normalized241to built-up area to account for density effects in infection rates. On this scale the recurring patterns become242apparent. The exponential decay during lockdowns and following vaccination is clear, as are the geometric243rebound trajectories. On this scale the recurring patterns in COVID-19 community diffusion kinetics are244undoubtedly evident.245

246

247

Figure 4. COVID-19 positive confirmed cases ten US states conforming to inclusion criteria from February 2020248to September 2021. More rural and less dense populations have lower COVID-19 infection rates, in general. Data249are normalized to built-up area to account for density effects in infection rates.250

251

Figure 5. COVID-19 positive confirmed cases for Australia and New Zealand from February 2020 to September2522021. The strict "Zero COVID" policies implemented for 35 months kept infection levels but they rebounded253when restriction were lifted and achieved levels similar to those in Europe. Data are normalized to built-up to254account for density effects in infection rates.255

258

Modeling of early COVID-19 infection dynamics

The frequent and robust PCR testing for COVID-19 deployed in nations and regions included here allow for the	259
mathematical analyses of infectious persons. Results of the modeling and the parameter values obtained are found	260
in Table 2. The infection dynamics parameter values were obtained from the exponential slopes directly from the	261
data. Initial infection expansion rate constants were 0.5-0.7 per week during February-March 2020, with	262
corresponding doubling times of 1.2-1.6 weeks. Social distancing and lockdowns resulted in exponential decay	263
of infection rates from the pre-lockdown peak values of 0.4-0.5 per week with half-life values of 1.7-2.3 weeks.	264
This provides a maximal estimate for the case recovery rate constant parameter (δ).	265

*) No rapid decreases in cases observed following vaccination.

268 269

270

Infection rates rebounded with doubling times of 2.6-3.7 weeks (range:0.6-4.4 weeks) upon lifting of the extreme 271 social distancing measures. These represent a minimal estimate for r_0 . This is four-fold less rapid than the initial 272 pre-lockdown exponential growth rates. Finally, after 4-12 weeks infections reached a relatively stable setpoint 273 level with values ranging among countries ranging between $10^{1.3}$ - $10^{3.4}$ (CI_{95%}: $10^{2.3}$ - $10^{2.6}$) cases per km² built-up 274 area per day. Notably, initial pre-lockdown infection rates are significantly correlated with steady state infection 275 levels (PPMCC=0.41, P=0.037) alluding to the importance of the intrinsic infection rate and extent of very early 276 viral expansion in the infective dynamical and endemic steady state. 277

Similar patterns were observed for ten states in the USA and five nations in Asian regions. Israel implemented a 278 second lockdown in 2020 leading to infections decaying with a half-life of 1.5 weeks and subsequent rebound 279 with a doubling time of 2.0 weeks; values which are only 15 and 43% more rapid than those during the primary 280 lockdown, respectively. Markedly, not only were decay and rebound slopes among countries of similar magnitude, 281 but they were also similar among infection waves within countries. 282

Basic reproductive number (R_o)

283

The analytical approach here contributes insight on the basic reproductive ratio for the community spread of 284 SARS-CoV-2. In the literature reporting on COVID-19, and other epidemics, this is approximated from the initial 285 exponential growth phase [14] and represents an overestimation because it ignores the β/δ ratio. Here the "natural 286 experiment" of the efficient impedance of viral community spread during the initial phase of the SARS-CoV-2 287 pandemic allows the use of the empirical rebound up-slope (r) and values for the recovery/removal rate constant 288 (δ) . The estimates for the basic reproductive number are provided in Table 2. Using experimentally established 289 values for δ (0.4-0.5) from the decay slope during interventions to block viral expansion and ranges for r (0.2-290 0.3) leads to basic reproductive numbers ranging between 1.4-2.3, narrowing for a CI_{95%} to 1.6-1.8. From this 291 perspective, active COVID-19 infected individuals would generate approximately 1.7 new secondary infections, 292 on average. 293

Herd immunity and inhibition of infection by vaccination

Herd immunity is a threshold value at which new infections cannot perpetuate within the community and is 295 derived from the basic reproductive number. Indeed, nearly all countries experienced a rapid exponential decline 296 297 in case numbers with efficacies of 44-99% (CI_{95%}: 64-72) and half-life values similar to those during lockdowns (CI_{95%}: 1.3-1.7. Table A1) following the distribution of SARS-CoV-2 vaccinations. The observed percent of the 298 population vaccinated which coincides with decay in confirmed cases is between 44-55%, based on the nations 299 and regions included here (Table 2). First, empirically, the values for R_0 in other studies seem extremely high. 300 Second, now it is possible to test the previous calculation of R_0 , which should be smaller than the observed values. 301 Indeed, the observed "herd immunity" was slightly above the values derived mathematically, as expected from 302 303 Eq. (4).

Delta variant wave rebound

In June 2021, after the large decrease in COVID-19 following national vaccination programs, COVID-19 cases 305 rebounded spontaneously. The wave was driven by the Delta variant, which became dominant. This rebound was 306 characterized by doubling times of 1.1-1.3 (Table A1). It finally reasserted levels similar to those observed prior 307 to vaccination deployment. The decay due to vaccinations and this resurgence both correspond to the trajectories 308 observed in 2020. 309

Discussion

310

304

Infection doubling times (t_2) and half-life $(t_{1/2})$ values reveal consistent rates with extremely small variance and 311 narrow range, longitudinally, among all countries analyzed here (Table 1). Mean doubling times for infection 312 levels during the initial exponential phase of the pandemic were 1.0 weeks (CI_{95%}: 0.5-2.0). These were quite 313 robust with a caveat about the rate of deployment of testing regimes (see shorturl.at/hmuFN for analysis). 314 Lockdowns were extremely effective by inhibiting physical contact and blocking the virus from circulating. 315 Countries with no effective social distancing measures rapidly reached a setpoint equilibrium state. Limiting 316 movement of the population was related to lockdown efficacy. Restrictions to travel of 45-93% decreased 317 infection rates by 10-fold or more, leading to an exponential decay of >90% in confirmed cases. Importantly, this 318 was uncorrelated with the minimal infection numbers. More stringent lockdowns do not appear to confer further 319 inhibition to stop viral diffusion and may signify the existence of an optimum in interventions to block COVID-320 19. The mean associated half-life value during lockdowns was 2.0 (CI_{95%}: 1.7-2.39) with no statistically significant 321

difference among the nations and regions studied here. The epidemiological interpretation of this measure is the322maximal value for the recovery rate of infected individuals.323

As distancing policies were lifted, infections rebounded exponentially as viral diffusion over the social network 324 is no longer perturbed. Intrinsic doubling times can therefore be determined empirically by the up-slope on a semilog graph. The observed doubling time was consistent with 2.5 ± 0.7 weeks in European countries. Asian nations 326 included here had values of 3.5 ± 2.1 , perhaps owing to their stricter regulations. In the states of the United States 327 the value was even higher at 5.1 ± 2.6 weeks. 328

Taken together, the rebound and decay rates were harnessed to provide a maximal estimate for the basic329reproductive number. R_0 is consistent with a mean value of 1.7 (CI_{95%}: 1-6-1.8), due to the invariance of the model330parameters. Spain, Greece, and Britain (*i.e.*, England and Wales) were areas with elevated infectivity with values331of 2.3, 2.0 and 2.1, respectively. An important outcome of this calculation is the elucidation of the epidemiological332"herd immunity" threshold.333

During emergent pandemics, estimates of the basic reproductive number tend to be overestimated. EarlyCOVID- 334 19 studies reported very high values [49,50]. Our estimates for SARS-CoV-2's R_0 vary only slightly during waves 335 of COVID-19, which would make sense if the dynamical properties of the infection did not appreciably change, 336 and they are comparable to historical influenza pandemics [51] and commensurate with seasonal influenza 337 outbreaks [52]. Although these estimates are substantially lower than those reported elsewhere for COVID-19, 338 they agree with some studies [53]. 339

Vaccination deployment against SARS-CoV-2 had a dramatic effect on infection rates. Confirmed cases decayed 340 exponentially with a mean half-life value with similar rates as during the social distancing lockdowns, after 341 achieving the herd immunity threshold. For example, Israel with its early and rapid program experienced a half-1ife of 1.03 weeks in confirmed cases once 45% of the population was immunized. This agrees with the prediction 343 given by the approximations for R_0 based on Eq. (3). 344

Following the achievement of herd immunity, after approximately 30 weeks, infections spontaneously rebounded 345 again as the delta-variant emerged. The observed escape trajectory was empirically equivalent to the rebound 346 trajectories following the lockdowns and with doubling times approximately every 1.2 ± 0.3 weeks, similar to the 347 post-lockdown rebounds doubling times. Interestingly, the Delta variant emerged in every nation included here 348

within 4 weeks, surprising due to the low volume of international travel. Finally, infection rates returned to similar 349 levels as the pre-vaccination setpoint and invariant among the sampled countries. 350

Although infection rates tended to initially increase exponentially when numbers were low, they quickly saturated 351 to a level of 10^2 - 10^3 confirmed cases per km² built-up area per day. This was reached in nearly all nations and 352 regions within 4-6 weeks, even in absence of interventions. Even New Zealand and Australia with strict and highly 353 effective lockdowns rapidly reached this level of infections with the lifting of social distancing measures). Such 354 observations, seen everywhere, suggest a basic, perhaps fundamental, shared epidemiological dynamic and the 355 importance of population density for the spread of SARS-CoV-2 [38,54,55]. 356

As we have shown, waves of both infection and suppression can define COVID-19. Our concluding perspective 357 views the infection data decomposed into their wavelet phases and modeled with the generalized multi-logistic 358 model [56]. This approach allows derivation of the saturation level of cases as well as the "characteristic time" 359 (Δt) denoting how long the infection takes to increase from 10% to 90% of its extent. While data for many nations 360 and regions resolve neatly into a succession of waves. Israel is unusual in having excellent data for (so far) seven 361 waves of infection as well as companion data about societal responses and suppression for the first five waves. 362 Figure 6 shows the first five infection waves and their durations ranging from 4.4 to 10.6 weeks. The sequence of 363 waves suggests the extremely dynamic interaction of COVID-19, generating new variants, with the social and 364 medical context, including lockdowns, distancing, and vaccines. Predicting new waves remains an unsolved 365 366 challenge.

Figure 6. Logistic curves for first five waves of COVID-19 in Israel and the number of weeks each waves took 367 368

to run its course.

369

370

To conclude, the dynamical properties of COVID-19 epidemiology are conserved with consistent kinetic patterns 371 with little variation during multiple waves of infection and globally among nations and subnational regions. 372 Nations and regions which implemented lockdowns sufficient to block community spread effectively experienced 373 a rapid decline in confirmed cases. However, with lifting of interventions, rates rebounded to the previous high 374 infection rates and attained a relatively stable empirical steady state. For COVID-19 societies so far appear to face 375

a choice between relatively high oscillations involving waves of suppression and infection and lesser oscillations	376
around an endemic setpoint. The approach presented here based on the viral dynamics paradigm allows derivation	377
of fundamental measures vital to policy such as the basic reproductive number and lockdown efficacies. Values	378
for R_0 derived here of 1.6-1.8 are maximal estimates and lower than other reports. Information on variables of	379
interest for policy normally difficult to obtain is available through this approach and may suggest monitoring	380
strategies efficient for accurate determination of the dynamical properties of future pandemics.	381
