19 **ABSTRACT**

20 The majority of people with HIV live in sub-Saharan Africa, where HIV epidemics are generalized.
21 For these epidemics to develop, populations need to be mobile. However, population-level
22 mobility has not yet been studied in the context of the development of generalized HIV epidemics.
23 Here we do so by studying historical migration data from Botswana which has one of the most
24 severe generalized HIV epidemics worldwide; in 2021, HIV prevalence was 21%. The country
25 reported its first AIDS case in 1985 when it began to rapidly urbanize. We hypothesize that, during
26 the development of Botswana's epidemic, the population was highly mobile and there were
27 substantial urban-to-rural and rural-to-urban migratory flows. We test this hypothesis by
28 conducting a network analysis using a historical time series (1981 to 2011) of micro-census data
29 from Botswana. We found 10% of the population moved their residency annually, complex
30 migration networks connected urban with rural areas, and there were very high rates of rural-to-
31 urban migration. Notably, we also found mining towns were both important in-flow and out-flow
32 migration hubs; consequently, there was a very high turnover of residents in towns. Our results
33 support our hypothesis, and together, provide one explanation for the development of Botswana's
34 generalized epidemic.

35 INTRODUCTION:

36 Over 25 million people live with HIV infection in sub-Saharan Africa. All of the HIV epidemics in
37 this continent are generalized: in these type of epidemics, the epidemic is dispersed throughout
38 the country. Therefore, a population needs to be highly mobile in order for a generalized epidemic
39 to have developed. However, although the epidemiology of HIV in sub-Saharan Africa has been
40 widely studied (Farley et al., 2022; Read et al., 2022), the role of population-level mobility patterns
41 in the development of generalized HIV epidemics has not been assessed for any country on the
42 continent. Botswana has one of the most severe HIV epidemics worldwide, and reported its first
43 AIDS case in the early 1980s. Since then, the epidemic has become generalized and hyper-
44 endemic: in 2021, HIV prevalence in adults (15 to 64) was 21% (Mine et al., 2022). Simultaneous
45 to the development of its generalized HIV epidemic, Botswana has undergone rapid urbanization.
46 It was predominantly rural in 1981 (Tarver, 1984; Tarver & Miller, 1987), but had become
47 predominantly urban (Statistics Botswana, 2014) by 2011; by that time Botswana's HIV epidemic
48 had stabilized (CSO Botswana & NACA, 2009). We hypothesize that – during the development
49 of Botswana's epidemic – there was a high level of population mobility, and substantial urban-to-
50 rural migratory flows. We test this hypothesis by conducting a network analysis using a historical
51 time series of micro-census (i.e., individual-level) data collected in Botswana. These data contain
52 information both on migration and urbanization. The time series covers the time period from when
53 the epidemic was first apparent to when it stabilized in 2011. We use these data: (i) to estimate
54 the annual incidence (at the national level) of internal migration over three decades (1981 to
55 2011), (ii) to characterize migrants on the basis of gender and age, (iii) to reconstruct internal
56 migration networks (in order to identify large-scale population movements and connectivity
57 patterns), (iv) to identify migration hubs, and (v) to quantify urban-to-rural and rural-to-urban
58 migratory flows. The Government of Botswana defines internal migration as residents changing
59 their place of permanent residence within their home country. We discuss our results in the
60 context of understanding the development of the generalized hyper-endemic HIV epidemic in
61 Botswana.

62
63 Between 1981 and 2011, the population of Botswana increased from just under one million to
64 over two million (Statistics Botswana, 2014) and the country became progressively urbanized. In
65 1981, the vast majority of the population lived in small rural villages. Only ~18% of the population
66 were living in urban areas (Statistics Botswana, 2014): either in one of the two cities (Gaborone,
67 the capital, or Francistown) or one of the four towns (Lobatse, Selebi Phikwe, Orapa, and
68 Jwaneng). Lobatse is an administrative center, and the other three are mining towns. Selebi

69 Phikwe is based on copper and nickel mining, and was founded in the early 1970s. Orapa and
70 Jwaneng are based on mining diamonds, and were founded in the late 1960s and early 1980s,
71 respectively. By 2011, only ~36% of the population were living in rural areas (Statistics Botswana,
72 2014). The remaining population were living in one of the three types of urban centers: a city
73 (there were still only two cities), a town (there were now five towns following the 1991 addition of
74 Sowa, a mining town for soda ash) or an urban village. In Botswana, an urban village is defined
75 as a settlement with at least 5,000 individuals and 75% of the workforce engaged in non-
76 agricultural economic activities (Statistics Botswana, 2014). The urban villages developed by in
77 situ urbanization, which is defined as rural settlements transforming into urban areas by
78 expanding their non-agricultural activities and increasing economic linkages with neighboring
79 areas (Moriconi-Ebrard et al., 2020). Botswana consists of 28 administrative districts (Figure 2—
80 figure supplement 1) (Okano et al., 2021). Each city and town are separate administrative districts,
81 and the remaining 21 districts contain at least one urban village and many rural villages.

82
83 A great deal is known about the epidemiology of HIV in Botswana in terms of the increase in
84 prevalence and geographic variation in prevalence (Magosi et al., 2022; Novitsky et al., 2015;
85 Novitsky et al., 2020; Okano et al., 2021). The first case of AIDS was reported in 1985 from the
86 nickel mining town of Selebi Phikwe (African Natural Resources Center, 2016); in the late 1980s,
87 additional cases were reported from two diamond mining towns (Jwaneng and Orapa) and the
88 city, Francistown. In 1990, the first HIV Sentinel Surveillance Survey of antenatal clinic (ANC)
89 attendees (15 to 49 years old) was conducted in Gaborone and in one rural district (Boteti): HIV
90 prevalence was found to be 6% and 4%, respectively (UNAIDS & World Health Organization,
91 2004). In 1992, a national sentinel surveillance survey began and was conducted annually to
92 2011. National prevalence in pregnant women was found to have already reached a very high
93 level (18%) by 1992, and continued to increase for the next eight years: 23% by 1993, 32% by
94 1995, and 39% by 2000 (UNAIDS & World Health Organization, 2004). Based on the ANC data
95 (UNAIDS & World Health Organization, 2004), HIV prevalence in the cities and the mines was
96 the highest. In Francistown, prevalence was 8% in 1991, 24% by 1992, and 44% by 2000. In
97 Gaborone, prevalence rose from 15% in 1992 to 36% by 2000. In the mining town of Selebi
98 Phikwe, prevalence rose from 27% in 1994 to 50% by 2000. By the late 1990s, a high AIDS
99 morbidity and mortality rate in miners led the diamond mining company Debswana to conduct an
100 HIV prevalence survey of its (male) employees. The survey took place in 1999: 29% of miners
101 were found to be infected with HIV (Barnett et al., 2002). The first population-level survey in
102 Botswana to test participants for HIV (BAIS II, the Botswana AIDS Impact Survey) was conducted

103 in 2004 (NACA & CSO Botswana, 2005). It found that, at that time, prevalence in the general
104 population was ~29% in women and ~20% in men aged 15 to 49 years old. Notably, phylogenetic
105 studies have shown that viral lineages have dispersed widely throughout Botswana suggesting
106 large-scale population-level movements have occurred (Magosi et al., 2022; Novitsky et al., 2015;
107 Novitsky et al., 2020).

108

109 **RESULTS:**

110 **Estimated incidence of internal migration:**

111 We estimated the Crude Migration Intensity (CMI) (Bell et al., 2002) for Botswana in the 12 months
112 before each census was conducted (i.e., between 1980 and 1981, 1990 and 1991, 2000 and
113 2001, and 2010 and 2011). The CMI represents the overall incidence, or level of internal
114 migration, per hundred residents over a specified time interval (Bell et al., 2002); it is an indicator
115 of the propensity of the population to move, and is a measure of migration both between districts
116 and within districts. The CMI remained markedly high and constant: 9.05 per hundred persons
117 between 1980 and 1981, 10.45 per hundred persons between 1990 and 1991, 10.73 per hundred
118 persons between 2000 and 2001, and 10.33 per hundred persons between 2010 and 2011. We
119 found that migrants were more likely to move between districts than to move within districts; this
120 propensity, calculated as a ratio (the number of migrants moving between districts relative to the
121 number of migrants moving within districts), increased over time from 1.25 (1981) to 2.40 (2001
122 and 2011).

123

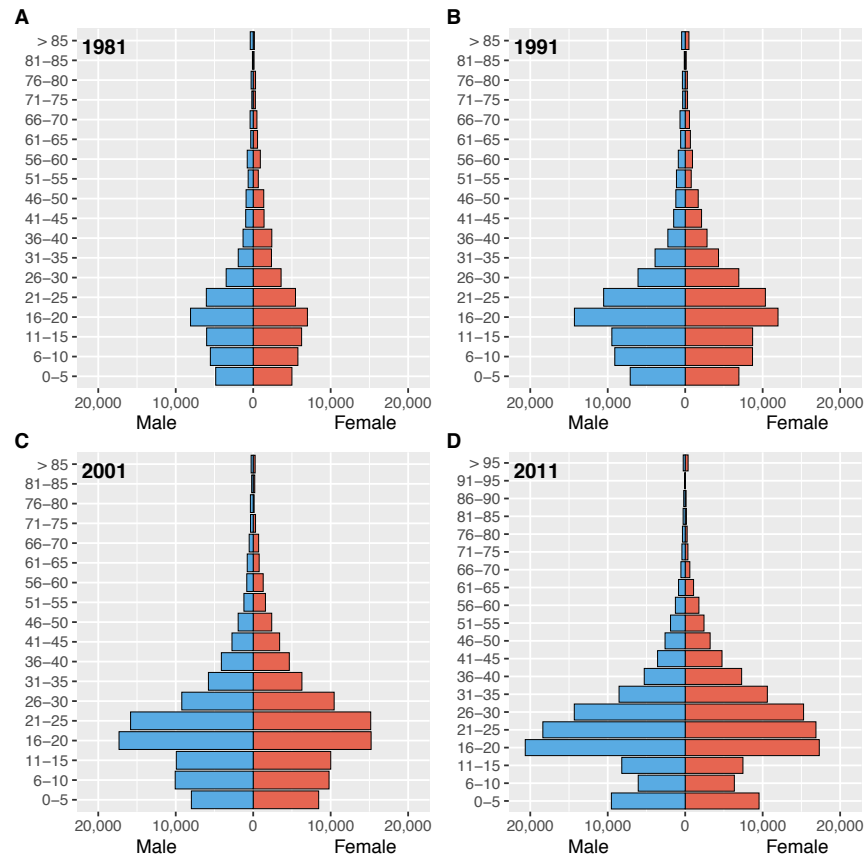

124 **Age profiles of migrants:**

125 Gender-stratified age profiles of migrants are presented in Figure 1. These results show that the
126 type of individual who migrated within Botswana at the time of each census was markedly similar,
127 with respect to gender and age. Approximately 50% of migrants were women, and the most
128 common age to migrate (for both women and men) was between 16 and 20 years old.

129

130 **Migratory flows:**

131 To reconstruct the internal migration networks, we first calculated migratory flows between
132 districts. We define a district-level migratory flow as the number of migrants who changed their
133 residency from one district to another during the 12 months prior to the census. The migratory
134 flows for each district (within district, in-flow, and out-flow) are listed in Table 1 (1980-1981), Table
135 2 (1990-1991), Table 3 (2000-2001), and Table 4 (2010-2011). Over three decades (between
136 1981 and 2011), the number of migrants more than doubled (as did the population of Botswana).

137

138 **Figure 1: Gender-stratified age profiles of internal migrants by census year. (A) 1981, (B)**
139 **1991, (C) 2001, and (D) 2011.**

140

141 In 1981, the two cities and four towns were fairly small. The capital, Gaborone, had a population
142 of 56,860 and Francistown had a population of only 31,120. The populations of the four towns
143 ranged in size from 5,200 to 27,430. The number of individuals who lived in the other districts
144 ranged in size from 1,050 in the Okavango Delta to 111,820 in Kweneng. All of these districts had
145 an in-flow, and/or out-flow, of migrants (Table 1). More than half also had a fairly high within district
146 migration intensity (WDMI): for example, in Central Bobonong, ~7% of residents moved from one
147 rural village to another between 1980 and 1981. Migratory flows continued to increase over the
148 next three decades (Tables 2-4), as the population size increased and the country became
149 progressively urbanized.

150

151 We also estimated the annual turnover rate in each district in the year before each census (Tables
152 1-4). This rate is defined as the net change in the district's annual migration rate per hundred
153 residents. A negative rate signifies that the district's population size decreased, a positive rate

154 signifies that it increased. By far, the highest turnover rates were in 1981 (Table 1). In that year,
 155 the highest turnover rate was in the mining town, Jwaneng.
 156

184

185 **Table 4: Migration metrics by district, 2010-11.** The table presents each district's urban/rural
186 classification, population size, total number of migrants (both within and between districts), within
187 district migration intensity per 100 residents (WDMI), and population turnover. The urban/rural
188 classes were: city (C), town (T), predominantly urban (U), partially urban (PU) and predominantly
189 rural (R). Population sizes are tabulated for residents for whom there was one-year migration
190 data. Turnover was calculated as the net change in the annual migration rate per 100 residents.
191 The Central Kgalagadi Game Reserve district is denoted CKGR.

192 **Reconstructed internal migration networks:**

193 The chord diagrams (Figure 2) show the reconstructed internal migration networks, based on the
194 micro-census data, between: 1980-81 (Figure 2A), 1990-91 (Figure 2B), 2000-01 (Figure 2C),
195 and 2010-11 (Figure 2D). Each district is a node in the network. Networks are shown in terms of
196 the magnitude of the migratory in-flows and out-flows between districts, and the effect of these
197 flows on connecting different districts throughout the country: two districts are connected if they

198
199 **Figure 2: Chord diagrams by census year. (A) 1981, (B) 1991, (C) 2001, and (D) 2011.** Each
200 diagram shows the internal migration network of the general population in the 12 months prior to
201 the census. Each color represents a different administrative district. The thickness of each line is
202 proportional to the number of migrants that moved between the two connected districts. The
203 angular width of each district is proportional to the total number of migrants who moved into, or
204 out of, that district. For clarity, in (A)-(C) only connections with greater than 200 migrants are
205 shown, and in (D) only connections with greater than 400 migrants are shown. Consequently,
206 some districts are not shown in the chord diagram. The total number of migrants (in and out) of
207 every district is listed in Tables 1-4.

208 have a migratory flow between them. Even the earliest migration network in 1981 – when
209 Botswana was predominantly rural – can be seen to be fairly complex and shows a high degree
210 of connectivity amongst the districts, although the migratory flows and counter-flows are fairly
211 small. Notably, in all four networks, many of the flows and counter-flows are similar in magnitude.
212 Both the magnitude of the migratory flows, and counter-flows, increased with time (between 1981
213 and 2011) as the population increased in size.

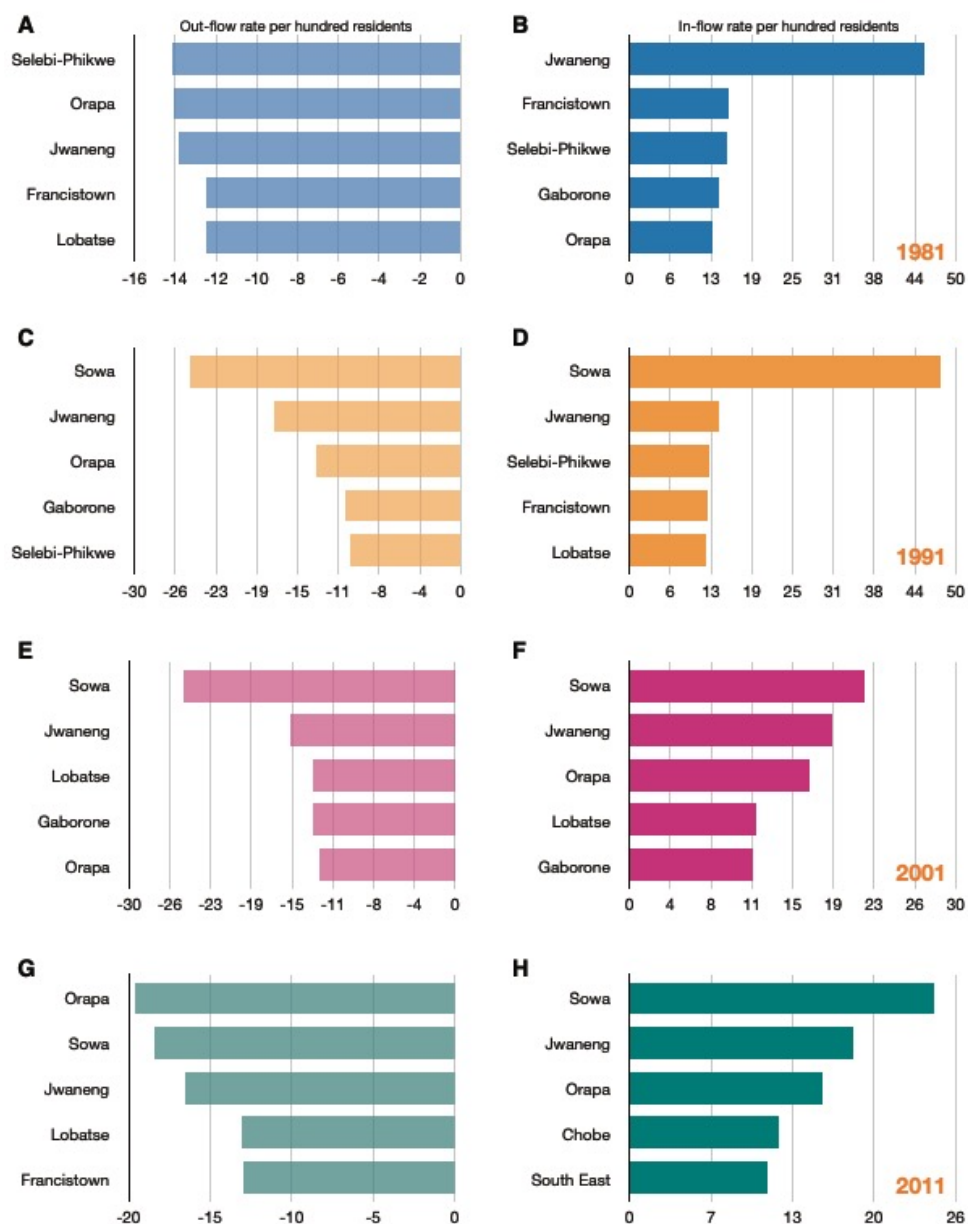

214
215 **Figure 2**—supplement 1: Map of Botswana with current district names, colored by class.
216

217 **In-flow and out-flow migration hubs:**

218 Out-flow and in-flow migration hubs are shown in Figure 3. Notably, the towns (Jwaneng, Selebi
219 Phikwe, Sowa, Lobatse, and Orapa) were amongst the top five out-flow and in-flow migration
220 hubs at every census period.

221
222 In 1981, the top in-flow hub was the diamond mining town, Jwaneng: 45% of the town's population
223 consisted of migrants who had moved to the town between 1980 and 1981 (Figure 3B). At that
224 time, Jwaneng was also an important out-flow hub: 14% of the town's population moved to another
225 district between 1980 and 1981 (Figure 3A). The ego networks for Jwaneng show the districts
226 that migrants returned to (Figure 4A), and the districts that they came from (Figure 4B). It can be

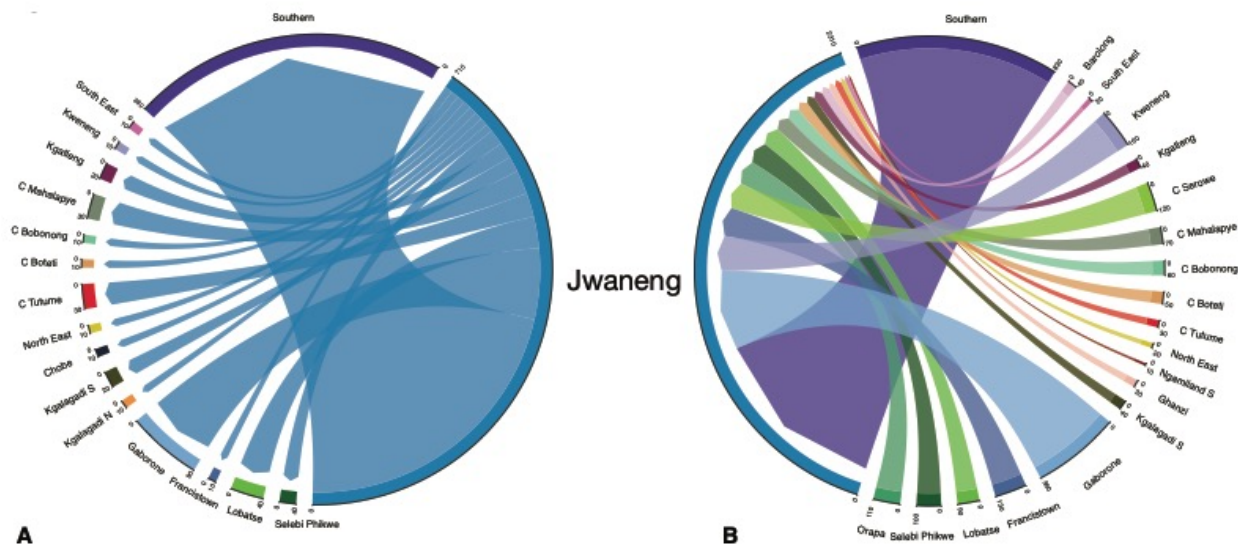

227

228

229 **Figure 3: The top five out-flow and in-flow migration hubs by census year. (A)** Top out-flow
 230 hubs in 1981, **(B)** Top in-flow hubs in 1981, **(C)** Top out-flow hubs in 1991, **(D)** Top in-flow hubs
 231 in 1991, **(E)** Top out-flow hubs in 2001, **(F)** Top in-flow hubs in 2001, **(G)** Top out-flow hubs in
 232 2011, **(H)** Top in-flow hubs in 2011. Out-flow hubs are sorted by the rate per hundred residents
 233 of a district's population that moves out to another district; in-flow hubs are sorted by the rate per
 234 hundred residents of a district's population that moves in from another district.
 235

236 seen that migrants moved between the other mining towns, the two cities, and many of the rural
 237 districts, with the majority of migrants moving between Jwaneng and Southern, a district abutting
 238 the town (Figure 2—figure supplement 1).

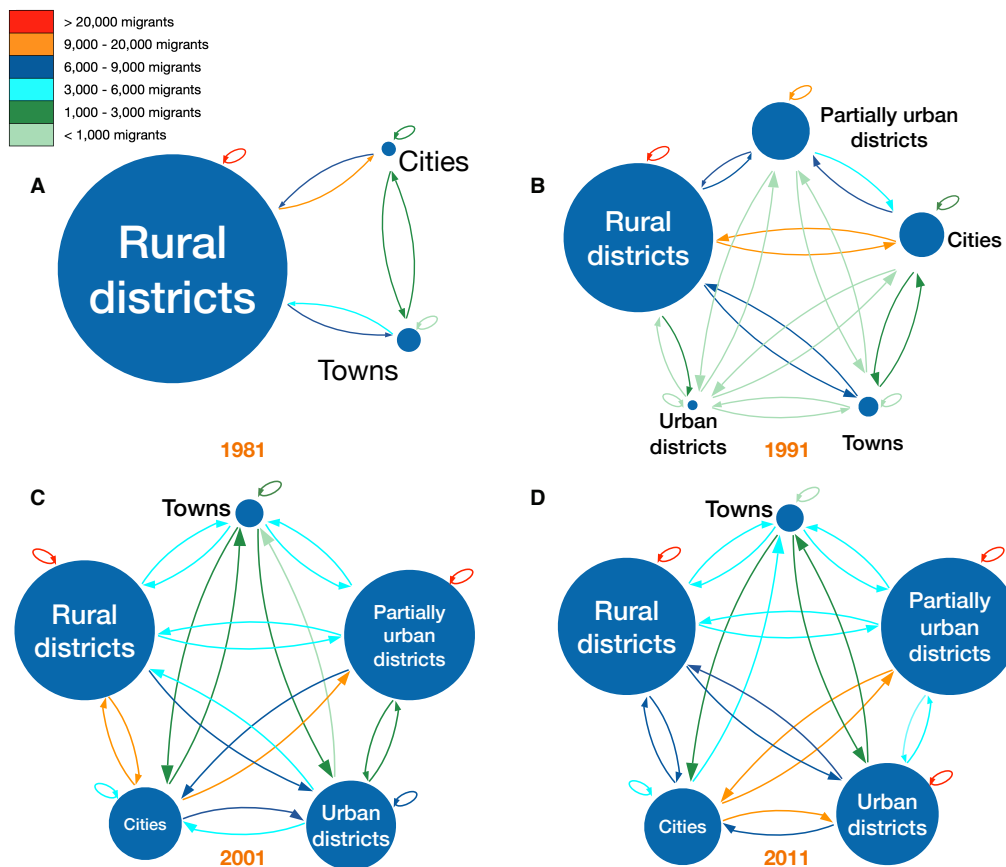

239 **A**
240 **Figure 4: Ego network of Jwaneng.** The chord diagrams show migrants flowing **(A)** out of, and
241 **(B)** into, the diamond mining town in 1981.

242
243 In 1991 and 2001, the top out-flow (and in-flow) hub was the mining town, Sowa. In 1991, 48% of
244 the population consisted of migrants who had moved to the town in the previous 12 months
245 (Figure 3D); 25% of the town's population moved to another district between 1990 and 1991
246 (Figure 3C). In 2001, 22% of the population consisted of migrants who had moved to the town in
247 the previous 12 months (Figure 3F); 25% of the town's population moved to another district in
248 2000-2001 (Figure 3E).

249
250 Francistown was an important in-flow and out-flow hub between 1980 and 1981. In 1981, 15% of
251 the population consisted of migrants who had moved to the town in the previous 12 months
252 (Figure 3B); 13% of the town's population moved to another district between 1980 and 1981
253 (Figure 3A). The city was also an important in-flow hub in 1991 (Figure 3D) and out-flow hub in
254 2011 (Figure 3G). Gaborone was only an important out-flow hub in 1991 and 2001 (Figure 3C
255 and Figure 3E); it was also an important in-flow hub in 1981 and 2001 (Figure 3B and Figure 3F).

256
257 **Quantifying urban-to-rural and rural-to-urban migratory flows:**
258 The internal migration networks for each of the four time periods (1981, 1991, 2001, and 2011)
259 are presented in terms of our urban/rural classification framework, both as schemata (Figure 5)
260 and as Sankey diagrams (Figure 6). Both the schemata and the Sankey diagrams show the
261 magnitude of the migratory flows amongst the five classes in the 12 months before each census.
262 Between 1981 and 2011 the overall percentage of the population living in urban areas increased

263 more than 3.5 fold (from ~18% to ~64%) (Statistics Botswana, 2014), and the internal migration
 264 networks changed substantially over that period.

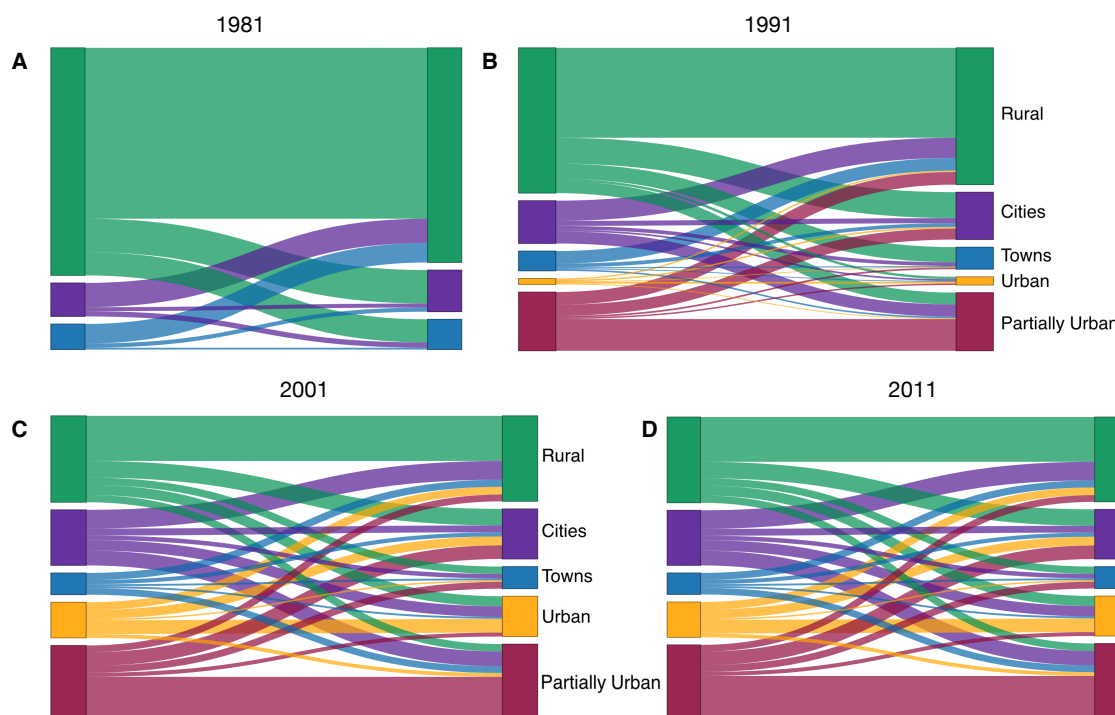

265
 266 **Figure 5: Schemata of urban/rural classification framework by census year. (A)** 1981, **(B)**
 267 1991, **(C)** 2001, and **(D)** 2011. Circles represent the five classes based on an urban/rural
 268 classification (see Methods). The radius of each circle is proportional to the number of residents
 269 living in the districts in that specific class. The color of each arrow indicates the size of the net
 270 migration between classes. The class designation (city, town, predominantly urban, partially
 271 urban, predominantly rural) of each district over time is provided in Tables 1-4.
 272

273 In 1981, there were only six districts (the two cities and four towns) that were urban areas (Table
 274 1, Figure 5A, and Figure 6A). The other districts contained several hundred small rural villages
 275 and no urbanized areas. Almost all districts had an in-flow and out-flow of migrants: notably, rural-
 276 to-urban, and counter flows (urban-to-rural) are apparent. Taken together the results show that in
 277 1981 the population was very mobile, the majority of migratory flows were within and amongst
 278 rural districts, and rural-to-urban migrations were greater than urban-to-rural counter-flows.
 279

280 By 1991, due to in situ urbanization, one previously rural district (South East) had become
 281 predominantly urban, and four districts (Kweneng East, Kgatleng, Ngamiland South, and Chobe)

282 had become partially urban (Table 2). Migratory flows appear to be fairly symmetrical (in terms of
283 the number of migrants who moved between pairs of districts) throughout the country (Figure 5B
284 and Figure 6B). The towns had increased ~1.5 fold since 1981, and the cities had more than
285 doubled in size. As at the time of the previous census, there were considerable rural-to-urban and
286 urban-to-rural migratory flows.

287
288 **Figure 6: Sankey diagrams showing urban/rural classification framework by census year.**
289 **(A)** 1981, **(B)** 1991, **(C)** 2001, and **(D)** 2011. The diagrams show the relative magnitude of
290 migratory flows between the different classes over time. Cities are shown in purple, towns in blue,
291 predominantly urban districts in gold, partially urban districts in magenta, and predominantly rural
292 districts in green. The class designation (city, town, predominantly urban, partially urban,
293 predominantly rural) of each district over time is provided in Tables 1-4.

294
295 By 2001, considerably more in situ urbanization had occurred: since 1981, four districts had
296 become predominantly urban, six districts partially urban, and only nine districts remained
297 predominantly rural (Table 3). Notably, some of the migratory flows were now asymmetric: the
298 number of migrants moving from the cities to the predominantly urban and partially urban districts
299 were greater than the counter-flows (Figure 5C and Figure 6C). The growth rate of towns
300 remained approximately the same as in the previous decade, but the growth rate of the cities had
301 decreased to ~1.4 fold; these rates depended upon the number of migrants, births, and deaths.

302

303 By 2011, twelve districts had become predominantly or partially urbanized (Table 4). The growth
304 rate of cities had decreased to ~1.2 fold, and the towns had not increased substantially in size. At
305 this time, while most flows were symmetric, migrants were disproportionately leaving the cities in
306 favor of towns and urban villages (Figure 5D and Figure 6D). Approximately 42% of the population
307 were living in these urban villages; there was at least one urban village in every district.

308

309 **DISCUSSION:**

310

311 Our results support our hypothesis that – during the development of Botswana’s generalized HIV
312 epidemic (i.e., between 1981 and 2011) – there was a high level of population mobility, and
313 substantial urban-to-rural migratory flows. Using our time series of historical data, we found ~10%
314 of the population moved their residency in the 12 months before each census in 1981, 1991,
315 2001, and 2011. The constancy of this value at each census suggests that the annual migration
316 rate in Botswana was stable at ~10% for each year between 1981 and 2011. Notably, the type of
317 migrants also remained constant over this time period: evenly split by gender, with younger people
318 more likely to migrate. We found that migration occurred within districts, as well as between
319 districts, but that migration between districts was more common. Even in 1981, at the beginning
320 of the period of rapid urbanization, the migration network was highly connected and therefore
321 large-scale population movements linked almost all of the districts in the country. Notably, we
322 found at each census, that although the number of urbanized districts increased (as did their
323 population size) the vast majority of migratory flows between the rural and developing urban
324 districts were balanced by counter-flows.

325

326 Our results provide insights into how HIV could have diffused through the population of Botswana
327 as the epidemic became generalized. The first cases of AIDS in Botswana were reported in the
328 1980s (African Natural Resources Center, 2016); this suggests that HIV may have been
329 circulating in Botswana in the 1970s, as HIV has an incubation period of 10 to 12 years (Hendriks
330 et al., 1993; Muñoz et al., 1989). One phylogenetic study indicates that HIV was introduced into
331 Botswana in the 1960s, but exponential growth did not begin until the 1980s (Wilkinson et al.,
332 2015). Another study suggests that HIV spread southwards from Kinshasa (the epicenter of the
333 HIV epidemic) in the Democratic Republic of the Congo via travelers on the railroad that was built
334 in the 1800s (Faria et al., 2014); notably, this railroad goes through Francistown. It is possible that
335 HIV was introduced into the mining towns of Botswana from overseas or South Africa. In the
336 1970s and 1980s many young men from Botswana went to work in the mines in South Africa,

337 returning as the mining industry became established in their home country. Our results show that,
338 by 1981, the migration networks (for women and men) linked almost every district in Botswana;
339 this indicates that residents from Francistown (UNAIDS & World Health Organization, 2004) and
340 the mining towns (Barnett et al., 2002) could have seeded sub-epidemics in multiple rural districts
341 throughout the country. HIV could then have spread widely within these districts due to the high
342 rates of within-district migration. Due to the high migration rates, the sub-epidemics in rural
343 districts were likely to have been seeded numerous times. When HIV was first introduced into
344 rural districts, the sub-epidemics in these districts may have been maintained by source-sink
345 dynamics (Okano et al., 2020): districts where transmission was high enough to be self-sustaining
346 (e.g., mining towns) could have maintained sub-epidemics in rural districts where transmission
347 was too low to be self-sustaining. Our results suggest that migratory flows between high and low
348 prevalence areas are likely to have existed, at least from the early 1980s onwards. These flows
349 would have functioned as “transmission corridors” (Okano et al., 2021), and created high risk
350 flows (Valdano et al., 2021). Taken together, our quantitative results show that the highly-
351 connected migration networks, with high migratory flows and increasing urbanization, could have
352 contributed to the development of Botswana’s generalized epidemic.

353
354 Our results also provide insights into how the Botswana epidemic could have become hyper-
355 endemic. Migrants have been shown to be at high risk of acquiring HIV infection (Camlin &
356 Charlebois, 2019; Dobra et al., 2017; Olawore et al., 2018); our results suggest that, due to
357 migration alone, each year ~10% of the population of Botswana was at high risk. The migrants in
358 Botswana were young women and men, a group generally at the highest risk of infection through
359 sexual transmission. Mining towns and cities would have been transmission hot-spots (for both
360 women and men) due to high levels of risky sexual behavior (as evidenced by high prevalence
361 (Barnett et al., 2002)) and a high probability of encountering an HIV-infected individual as a sex
362 partner. Due to the high prevalence (Barnett et al., 2002; UNAIDS & World Health Organization,
363 2004), high turnover rates, and a high level of connectivity to other districts, the mining towns and
364 cities could have functioned as geographically-defined core groups for sexual transmission (for
365 both women and men). Some individuals could have been part of a high-risk core group when
366 they were living in the cities and mining towns, and decreased their risky behavior when they
367 returned to the rural districts. For example, FSWs in Botswana can have an extremely high
368 number of sex partners in mining towns and urban areas (~7 per week) and remain as FSWs for
369 ~4 years (Ministry of Health Botswana, 2013). Notably we found that the mining towns and cities
370 were both migration in-flow hubs and migration out-flow hubs. The fact that they were migration

371 in-flow hubs would have led to a high in-flow of uninfected individuals from rural districts; the fact
372 that they were migration out-flow hubs would have led to a high out-flow of HIV-infected individuals
373 to rural districts. Therefore, rural-to-urban migration coupled with urban-to-rural migration could
374 have been a very important driver in the Botswana epidemic becoming hyper-endemic. Without
375 this driver, prevalence could have reached very high levels in the mining towns and cities, but
376 remained fairly low in rural districts.

377
378 Our study has several limitations. First, we have examined only internal migration (i.e., migration
379 that takes place within a country), and have not included international migration. However, for the
380 three-decade time period that we have investigated, the number of international migrants to
381 Botswana was much smaller than the number of internal migrants (Statistics Botswana, 2014;
382 Statistics Botswana, 2015). Second, all of our analyses are focused on Botswana in order to
383 analyze the impact of migration networks on a hyper-endemic epidemic; we have not evaluated
384 migration networks in other African countries. We recommend that studies, such as we have
385 conducted here, are conducted in these other countries by analyzing a time series of historical
386 micro-census data, especially in the only other two countries in sub-Saharan Africa that have
387 generalized hyper-endemic HIV epidemics: Eswatini and Lesotho. Third, a potential limitation is
388 that the IPUMS data are samples rather than the complete censuses; we used this approach as
389 it is generally not possible to obtain complete census data due to privacy reasons. Fourth, while
390 we have gained insights into understanding the development of the generalized hyper-endemic
391 HIV epidemic in Botswana, we have not conducted an analysis of the transmission dynamics of
392 the epidemic in order to explore these insights. This is the focus of current research in which we
393 are analyzing a geospatial mathematical model of the epidemiological evolution of the HIV
394 epidemic in Botswana. Fifth, we have examined only two processes that affected the evolution of
395 Botswana's epidemic, other factors could also have been important.

396
397 All HIV epidemics in SSA are generalized; HIV can only diffuse through a population by the
398 movement of people. To our knowledge, our study is the first to study population-level mobility
399 patterns and rates in any country in sub-Saharan Africa. Taken together, our results identify
400 particular characteristics of migration in Botswana that could explain why HIV prevalence rose to
401 very high levels in many districts throughout the country. Migratory behavior in other countries
402 with generalized epidemics may be very different. For example, migrants in other African
403 countries tend to have a very male-biased sex ratio; consequently, women are unlikely to have
404 seeded multiple sub-epidemics throughout these countries. If mining towns and cities in these

405 countries were not migratory in-flow and out-flow hubs with high turnover of their populations, as
406 in Botswana, they would not have served as major sources of infection. Botswana has recently
407 achieved the 95-95-95 targets that UNAIDS specified needed to be reached by 2030 in order to
408 eliminate HIV: 95% of people living with HIV to be diagnosed, 95% of the diagnosed to be on
409 treatment, and 95% of those on treatment to be virally suppressed (Mine et al., 2022). However,
410 transmission is continuing (Magosi et al., 2022), as is urbanization and large-scale population
411 movements (Okano et al., 2021). The same processes that we have identified that may have
412 contributed to the development of the generalized hyper-endemic HIV epidemic in Botswana may
413 prevent the elimination of HIV.

414

415 **MATERIALS AND METHODS:**

416 **Data:**

417 To conduct our analyses, we used representative samples of micro-census data extracted from
418 the IPUMS-International (Integrated Public Use Microdata Series-International) database
419 (Minnesota Population Center, 2020): micro-census data are anonymized individual-level data
420 (Ruggles et al., 2015). IPUMS-International currently disseminates data from 547 censuses and
421 surveys in 103 countries worldwide (Minnesota Population Center, 2020). The Botswana dataset
422 consists of representative 10% samples from the original censuses, and includes anonymized
423 individual-level data on age, gender, and residence (current, as well as 12 months prior). The
424 data also includes individual survey weights that allow for population-level estimation (Ruggles et
425 al., 2015).

426

427 To examine historical trends in internal migration networks and urbanization, we analyzed data
428 collected in the 1981, 1991, 2001, and 2011 censuses. We used data on internal migration that
429 had occurred in the 12 months prior to each census: an individual was classified as a migrant if
430 they had changed their permanent residency within that 1-year interval.

431

432 **Estimating the incidence of internal migration:**

433 We estimated the incidence of internal migration by calculating the CMI. This statistic represents
434 the overall incidence, or level of internal migration (between district plus within district), per
435 hundred residents over a year. The mathematical definition of the CMI is given in Equation 1:

$$CMI = 100 \cdot \frac{M}{P} \quad (1)$$

436 where M is the total number of internal migrants and P is the population size of Botswana in a
437 given year. M is calculated as $M = \sum_i D_i = \sum_i O_i$ where D_i represents the in-flows to each district
438 i , and O_i represents the out-flows to each district i .

439

440 **Constructing gender-stratified age structure pyramids:**

441 We aggregated the migration data from each census by gender and age (using 5-year age
442 groupings) to construct population pyramids; these pyramids show the age-gender demographics
443 of all individuals internally migrating in the 12 months prior to each census.

444

445 **Calculating migratory flows:**

446 We define a district-level migratory flow as the number of migrants who change their residency
447 from one district to another during the 12 months prior to the census. We calculated migratory
448 flows between each pair of districts. The country consists of 28 administrative districts (Okano et
449 al., 2021). Each city and town are separate administrative districts.

450

451 **Calculating annual turn-over rates:**

452 We defined the annual turn-over rate for a district as the net change in its annual migration rate
453 per hundred residents.

$$TO_i = 100 \cdot \frac{[D_i - O_i]}{P_i} \quad (2)$$

454 Here the turn-over rate TO_i for district i is a function of the number of in-migrants D_i and out-
455 migrants O_i within the past year, and its population P_i at the beginning of the year.

456

457 **Reconstructing migration networks:**

458 We used the micro-census data to construct Origin-Destination (OD) matrices: the origin was the
459 district that an individual lived in 12 months prior to the census, the destination was the district
460 they lived in at the time of the census. Coefficients of these matrices specify the number of
461 migrants who moved between each pair of districts in the 12 months prior to each census.

462

463 **Identifying in-flow and out-flow migration hubs:**

464 Migration hubs are those districts where recent migration has a sizeable impact on the size of the
465 resident population, by either bringing it down (out-flow hubs) or increasing it (in-flow hubs) above
466 the average. In-flow migration hubs were identified by calculating the total number of in-migrants
467 to a node/district and dividing by the district's population that year. Out-flow migration hubs were

468 identified by calculating the total number of out-migrants to a node/district and dividing by the
469 district's population that year. We list the top five in-flow and out-flow hubs each census year.

470

471 **Quantifying urban-to-rural and rural-to-urban migratory flows:**

472 To measure and visualize migratory flows during urbanization, we developed a classification
473 framework. This framework enables us to measure the magnitude of migratory flows and counter-
474 flows between districts (based upon their degree of urbanization), and distinguishes between
475 urban-to-rural and rural-to-urban flows.

476

477 The framework consists of five classes. The classes (at any point in time) are defined based on
478 the degree of urbanization of the districts at the time of the most recent census: (i) predominantly
479 rural (< 40% of the population living in urban areas), (ii) partially urban (40%-60% of the population
480 living in urban areas), (iii) predominantly urban (> 60% of the population living in urban areas),
481 (iv) town (100% of the population living in urban areas), or (v) city (100% of the population living
482 in urban areas). Classes (i), (ii), and (iii) only include urban areas that develop by in situ
483 urbanization, i.e., rural villages transforming into urban villages. There are migratory flows and
484 counter-flows between the five classes, and flows within each of the five classes: therefore, 25
485 migratory flows/counter-flows are possible.

486

487 The classification framework can be visualized in two formats: (i) a schematic figure showing the
488 five classes, the number of residents in each class, and migratory flows (and counter-flows)
489 amongst and within the classes, and (ii) Sankey diagrams showing the number of migrants who
490 move within, and between, the five classes.

491

492 We used the micro-census data to parameterize the framework for Botswana. Specifically, we
493 estimated – at the time of each census – the population size of each district, and determined how
494 many individuals lived in rural and urban areas. We used these estimates to classify all districts
495 into one of the five classes. We then calculated the migratory flows and counter-flows between,
496 and within, districts in the 12 months prior to each survey. These parameter estimates are given
497 for 1981 census (Table 1), the 1991 census (Table 2), the 2001 census (Table 3), and the 2011
498 census (Table 4). Between each census, districts change in size due to births, deaths and
499 migration. Also, between each census, districts can be reclassified based upon their increase in
500 urbanization.
