38 **Abstract:**

39 The functional domain of the cerebellum has expanded beyond motor control to also include
40 cognitive and affective functions. In line with this notion, cerebellar volume has increased over recent
41 primate evolution, and cerebellar alterations have been linked to heritable mental disorders. To map
42 the genetic architecture of human cerebellar morphology, we here studied a large imaging genetics
43 sample from the UK Biobank (n discovery = 27,302; n replication: 11,264) with state-of-the art
44 neuroimaging and biostatistics tools. Multivariate GWAS on regional cerebellar MRI features yielded
45 351 significant genetic loci (228 novel, 94% replicated). Lead SNPs showed positive enrichment for
46 relatively recent genetic mutations over the last 20-40k years (i.e., overlapping the Upper Paleolithic,
47 a period characterized by rapid cultural evolution), while gene level analyses revealed enrichment
48 for human-specific evolution over the last ~6-8 million years. Finally, we observed genetic overlap
49 with major mental disorders, supporting cerebellar involvement in psychopathology.

74 **Introduction**

75 The cerebellum contains ~80% of all neurons in the human brain¹ and has rapidly expanded in
76 volume over recent primate evolution². Indeed, the surface area of the cerebellar cortex extends to
77 almost 80% of the surface area of the cerebral cortex³. Comparative genetic analyses suggest that
78 protein coding genes with known roles in cerebellar development have been subject to a similar, or
79 even greater, rate of hominid evolution as compared to cerebro-cortical developmental genes⁴. Thus,
80 the evolution of the cerebellum may have played a key role in the emergence of human cognition,
81 including language⁵.

82 A growing number of neuroimaging and clinical studies in humans also link cerebellar
83 structure and function to a wide range of cognitive and affective functions⁶⁻⁸, as well as to a number
84 of heritable developmental⁹ and psychiatric¹⁰ disorders where these abilities either fail to develop
85 properly or are compromised later in life. However, compared to supra-tentorial brain structures such
86 as the cerebral cortex¹¹ and the hippocampus¹², few studies have mapped the genetic architecture
87 of the cerebellum.

88 Of note, the few existing cerebellar genome-wide association studies (GWAS) have mostly
89 been restricted to total cerebellar volume^{13,14}, thus largely ignoring regional variation in cerebellar
90 morphology. Importantly, such variation in the relative volumes of cerebellar subregions (i.e.,
91 variation in cerebellar shape independent of total cerebellar volume) has been associated with
92 variation in behavioral repertoires in several species^{15,16}, including domain-general cognition in
93 primates¹⁶.

94 We here performed a multivariate GWAS of MRI-derived regional cerebellar morphological
95 features in a large population-based sample from the UK biobank (n discovery = 27,302; n replication
96 = 11,264), functionally characterized the genetic signal, tested for enrichment of SNPs and genes
97 linked to human evolution, and assessed genetic overlap with major mental disorders.

98

99 **Results**

100

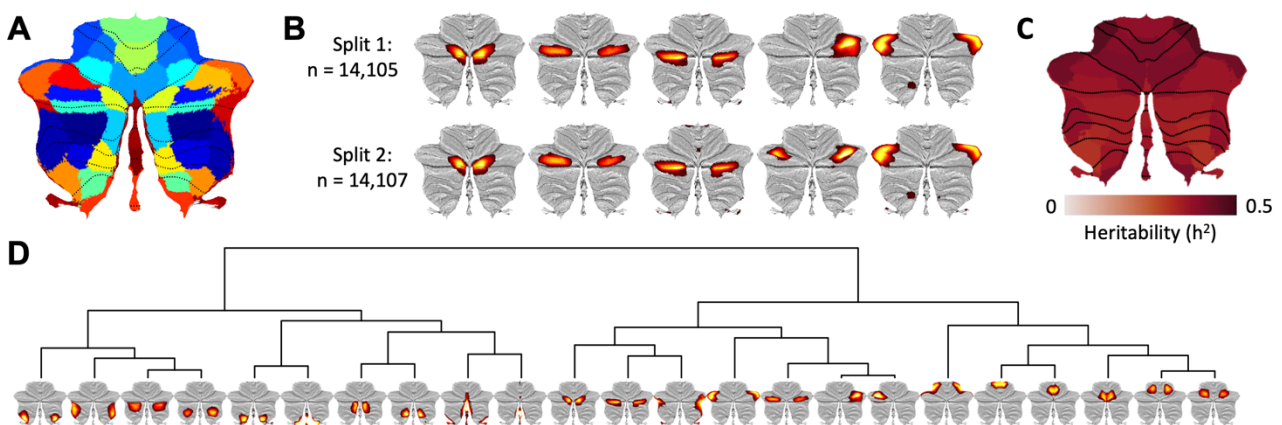

101 **Data-driven decomposition of cerebellar grey matter maps reveals highly reproducible** 102 **structural covariance patterns.**

103 Since traditional atlases of the cerebellar cortex based on gross anatomical landmarks (i.e., lobules)
104 only partially overlap with more recent functional parcellations of the cerebellum¹⁷⁻²⁵, we first used a
105 data-driven approach (non-negative matrix factorization, NNMF²⁶⁻²⁸) to parcellate voxel-based
106 morphometry (VBM) based maps of cerebellar grey matter volume (containing 147,121 1*1*1 mm
107 voxels) from 28,212 participants into a smaller number of structural covariance patterns (SCPs), i.e.,
108 cerebellar sub-regions where voxel-volumes co-vary consistently across individuals (see Online
109 Methods for details about the study sample, MRI processing and quality control procedures). Like
110 other dimensionality reduction methods, such as principal component analysis (PCA) or independent
111 component analysis (ICA), NNMF decomposes the input matrix (here 147k voxels * 28k participants)

112 into two lower rank matrices (voxel weights: W , and participant weights: H), so that the product of W
113 and H approximates the original input data. The defining feature of NNMF is that it requires these
114 lower rank matrices to be non-negative, which has previously been shown to result in sparse,
115 reproducible and easily interpretable parcellations of high-dimensional brain imaging data²⁶⁻³⁰. In
116 essence, when applied to voxel-wise indices of grey matter volume, NNMF yields distinct maps of
117 voxels that show similar patterns of volume-variation across individuals, commonly referred to as
118 “structural covariance patterns”^{26,27,29}. For each structural covariance pattern (common across all
119 participants), NNMF also provides individual subject weights expressing the degree to which these
120 patterns are expressed, i.e., reflecting individual variation in regional cerebellar volumes.

121 In the current study NNMF yielded highly reproducible cerebellar structural covariance
122 patterns (across split-half datasets) for model orders (i.e., number of components/patterns specified)
123 ranging from 2 to 100 (see Supplementary Figures 2 for summary maps of all tested model orders).
124 After observing that the improved fit to the original data seen with higher model orders tended to
125 level off between 15 and 30 components (indicating that the intrinsic dimensionality of the data might
126 have been reached (see Supplementary Figure 3), we decided on a model order of 23 based on its
127 good split-half reproducibility (see Fig. 1B, and Online Online Methods for details regarding model
128 order selection). Importantly, when subject weights were summed across the 23 structural
129 covariance maps, the resulting values correlated tightly ($r = 0.9995$) with estimates of total cerebellar
130 grey matter volume (see also Supplementary Figure 4), demonstrating that our data-driven
131 decomposition preserved inter-individual variation in cerebellar volume.

132

133

134 **Figure 1: Data driven decomposition of cerebellar grey matter maps yields highly reproducible and**
135 **moderately heritable structural covariance patterns (SCPs).** **A:** Binarized winner-takes-all map for the 23-
136 component solution based on data-driven decomposition of cerebellar grey matter maps from 28,212
137 participants. Note that empirically derived boundaries between cerebellar regions only partially follow
138 traditional lobular borders (marked with dotted black lines); **B:** Five distinct components overlapping cerebellar
139 Crus I derived from the split-half reliability analyses. While one of these SCPs emerged as bilateral in Split 2,
140 the remaining four SCPs were almost identical, despite being derived from two independent samples; **C:**
141 Narrow sense (SNP-based) heritability of the 23 SCPs (see Supplementary Data 5 for numerical values). **D:**
142 Hierarchical clustering of the 23 SCPs (derived from the full sample decomposition) based on their pairwise

143 *genetic correlations revealed a primary division between the anterior and posterior cerebellum, with additional*
144 *separations between medial and lateral regions. The full genetic correlation matrix can be found in*
145 *Supplementary Data 6.*

146

147 Of note, our data-driven decomposition differed markedly from the standard cerebellar atlas based
148 on gross anatomical features, shown as dotted lines in Fig 1A (see Supplementary Figure 3 for all
149 23 components and Supplementary Data 1 for quantification of overlap between NNMF-derived
150 structural covariance patterns (SCPs) and standard cerebellar anatomical regions, i.e. lobules). For
151 instance, five distinct SCPs overlapped Crus I of cerebellar lobule VII (shown in Fig 1B), an
152 anatomical region which already started to split into separate components at a model order of three.
153 We further observed only partial overlap with task-based functional parcellations of the cerebellar
154 cortex (Supplementary Data 2). While some SCPs clearly overlapped cerebellar regions previously
155 associated with hand movements, eye-movements/saccades or autobiographical recall, other data-
156 driven SCPs overlapped multiple functionally defined cerebellar regions (Supplementary Data 2).

157

158 **Cerebellar structural covariance patterns are heritable and reveals a distinct anterior-**
159 **posterior pattern based on their bivariate genetic correlations.**

160 After removal of one of each genetically related pair of individuals ($n = 910$), 27,302 participants
161 remained for the genetic analyses. In addition to the 23 regional cerebellar structural covariance
162 patterns of primary interest, we also included total cerebellar volume, estimated total intracranial
163 volume and 9 cerebral brain phenotypes to serve as covariates and/or comparison phenotypes. Prior
164 to all genetic analyses, morphological features were adjusted for effects of scanner site, sex, age,
165 estimated total intracranial volume, 40 genetic population components, genetic analysis batch and
166 a quantitative structural MRI quality index (the Euler number³¹) using general additive models, before
167 finally being rank-order normalized (see Online Methods for details).

168 To validate our analysis approach, we computed genetic correlations (using LD-score
169 regression, LDSC³²) between univariate GWAS results on the comparison features (see Manhattan-
170 and QQ-plots in Supplementary Figure 5) and previously published neuroimaging GWAS studies on
171 these brain phenotypes. Results showed a mean r_g of .90 (range: .80-.99, see Supplementary Data
172 3). For the 23 cerebellar morphological features, we used the univariate GWAS summary statistics
173 (see Supplementary Figures 6-7 for Manhattan- and QQ-plots) to compute genetic correlations
174 between discovery ($n = 27,302$) and replication ($n = 11,264$) samples using LDSC³². These genetic
175 correlations were high (mean r_G : .92; range: .83-1), indicating reliable genetic signals (see
176 Supplementary Data 4).

177 Genetic complex trait analysis (GCTA³³) revealed SNP-based heritability estimates (h^2)
178 ranging from .33 to .44 (Figure 1C and Supplementary Data 5). Analyses of total cerebellar volume
179 ($h^2 = .35$), estimated total intracranial volume ($h^2 = .41$) and the 9 cerebral comparison phenotypes
180 (h^2 range: .26 to .45) gave a similar range of heritability estimates (Supplementary Data 5).

181 Hierarchical clustering of cerebellar features based on their bivariate genetic correlation
182 matrix (GCTA-based rG ranging from 0.35 to 0.98, Supplementary Data 8) revealed a primary
183 anterior-posterior division running along the horizontal fissure separating Crus I and Crus II, with
184 secondary divisions grouping features into more lateral or medial, as well as more anterior and
185 posterior features within the major anterior and posterior regions (Fig 1D). Of note, the primary
186 division along the horizontal fissure was also evident from the (genetically naïve) two-component
187 NNMF decomposition, while medial-to-lateral divisions already began to emerge with a model order
188 of three (see Supplementary Figure 1).

189 In order to examine whether this phenotypic and genetic correlation structure was also
190 reflected in regional cerebellar gene expression patterns, we used the abagen toolbox³⁴ to extract
191 Allen Human Brain Atlas³⁵ gene expression profiles for 22 of the 23 morphological features and
192 computed their bivariate Pearson correlations (across 15,631 genes; Supplementary Data 7) and
193 hierarchical clustering solution (Supplementary Figure 8). The anterior-posterior boundary across
194 the horizontal fissure was also evident in the gene expression data, which in addition highlighted
195 distinct gene expression patterns for the posterior midline (grouped together with the horizontal
196 fissure), as well as for the most lateral regions of the cerebellar cortex.

197

198 **Multivariate GWAS reveals 351 genetic loci associated with cerebellar morphology.**

199 Figure 2A shows the main results for the multivariate GWAS across the 23 cerebellar structural
200 covariance patterns applying MOSTest³⁶. We observed 35,098 genome-wide significant (GWS)
201 SNPs, which were mapped by FUMA³⁷ to a total of 51,803 candidate SNPs by adding reference
202 panel SNPs in high LD ($r > .6$) with GWS SNPs. The 51,803 candidate SNPs (see Supplementary
203 Data 8) were represented by 1,936 independent significant SNPs and 560 lead SNPs in 351 genomic
204 loci (see Supplementary Data 10). The LDSC intercept of the MOSTest summary statistics was
205 1.0352 (i.e., indicative of no or minimal genetic inflation), while the QQ-plot of results based on
206 permuted data (under the null hypothesis) confirmed the validity of the MOSTest analytical approach
207 (Supplementary Figure 9).

225

Figure 2: Multivariate GWAS analysis of the 23 cerebellar structural covariance patterns revealed 351 independent genome-wide significant (GWS) loci. **A:** The upper half of the Miami plot shows the main results from the multivariate analysis. The lower half displays results from a series of 23 univariate analyses (corrected for multiple comparisons using the standard min-P approach), as well as results from a univariate analysis of total cerebellar grey matter (marked in orange). **B-D:** Euler diagrams showing the relative numbers of - and overlaps between - candidate SNPs (in thousands) mapped by the three analysis approaches employed in the current study (**B**), the current and four recent studies reporting genetic associations with cerebellar morphology (**C**), as well as results from multivariate GWASs on hippocampal and cerebrocortical morphology (**D**). For full results on overlap between all cerebellar candidate SNPs and other brain phenotypes, see Supplementary Data 8.

Annotation of all candidate SNPs using ANNOVAR³⁸ as implemented in FUMA³⁵ revealed that the majority of candidate SNPs were intronic (57.8%) or intergenic (38.3%). While only 0.7% were exonic, about 81% of the candidate SNPs were assigned minimal chromatin states between 1 and 7 (i.e., open chromatin states), implying effects on active transcription³⁷ (see Supplementary Data 8-9).

226 We evaluated the robustness of these multivariate results using a multivariate replication
227 procedure established in Loughnan et al³⁹, which computes a composite score from the mass-
228 univariate z-statistics (i.e., applying multivariate weights from the discovery sample to the replication
229 sample input data) and then tests for associations between this composite score and genotypes in
230 the replication sample (for mathematical formulation see Loughnan et al³⁹). Results showed that
231 97% of the 339 loci lead SNPs present in both samples (i.e., 94% of the 351 reported loci lead SNPs
232 from the discovery sample) replicated at a nominal significance threshold of $p < .05$ (Supplementary
233 Figure 10 and Supplementary Data 10), and that 74% remained significant after Bonferroni
234 correction (Supplementary Data 10). Moreover, 99% of loci lead SNPs showed the same effect
235 direction across discovery and replication samples (Supplementary Figure 9 and Supplementary
236 Data 10).

237 In addition, we assessed the robustness of the multivariate patterns by computing bivariate
238 correlations between feature z-score vectors assigned to the discovery sample lead SNPs in an
239 independent multivariate GWAS (MOSTest) performed on the replication sample. These correlations
240 (restricted to the 339 loci lead SNPs present in both samples) were relatively high (mean r : .70, see
241 Supplementary Data 10 and Supplementary Figure 11). Figure 3 and Supplementary Figure 11 also
242 give some examples of discovery and replication sample multivariate patterns projected back onto
243 the cerebellar cortex.

244 To compare our main multivariate MOSTest results to univariate approaches, the lower part
245 of the Miami plot in Figure 2A, and Figure 2B, displays results from a set of univariate GWASs on
246 the cerebellar morphological features (which yielded 8370 candidate SNPs and 57 genomic loci,
247 corrected for multiple comparisons using the min-P approach^{40,41}, see also Supplementary Figures
248 6-7 for univariate Manhattan and QQ-plots), as well as the 4044 candidate SNPs and 10 significant
249 loci resulting from the univariate GWAS on total cerebellar grey matter volume (marked in orange).
250 52 of the 57 loci identified in the univariate analyses of regional cerebellar features overlapped 55 of
251 the 351 loci identified using the multivariate method, while 9 out of 10 loci identified in the univariate
252 analysis of total cerebellar volume were also identified in the multivariate analysis (the slightly
253 mismatching numbers are due to loci of unequal lengths, causing some larger loci to overlap with
254 several smaller loci). Thus, our multivariate analysis of regional cerebellar features increased the
255 locus yield ~35-fold relative to analyzing total cerebellar volume and ~6-fold relative to performing a
256 set of univariate analyses on the same regional features.

257 We next compared the current findings with previously reported genetic loci for cerebellar
258 morphology by extracting summary statistics from two recent GWAS studies using the UKBB sample
259 ($n = 19k^{42}$ and $33k^{43}$) that included regional cerebellar volumes among the full set of analyzed brain
260 imaging-derived phenotypes (101^{42} and $3,144^{43}$, respectively), as well as two recent GWASs on total
261 cerebellar volume ($n = 33k^{13}$ and $27k^{14}$, respectively). Candidate SNPs and independent GWS loci
262 were identified in FUMA using the same settings as for our primary analyses and employing a liberal
263 p -value threshold of $5e-8$ (i.e., not correcting for the total number of brain imaging features analyzed).

264 Results are displayed in Figure 2c and Supplementary Data 8 and 10. In brief, we found that 19,527
265 of the 51,803 candidate SNP (i.e., 36%) and 123 of the 351 identified genomic loci (i.e., 35%)
266 overlapped with candidate SNPs and loci extracted from these three previous studies. Thus, 228 of
267 the 351 (i.e., 65%) genetic loci reported here are novel to the literature on of cerebellar morphology
268 genetics (see Supplementary Data 10).

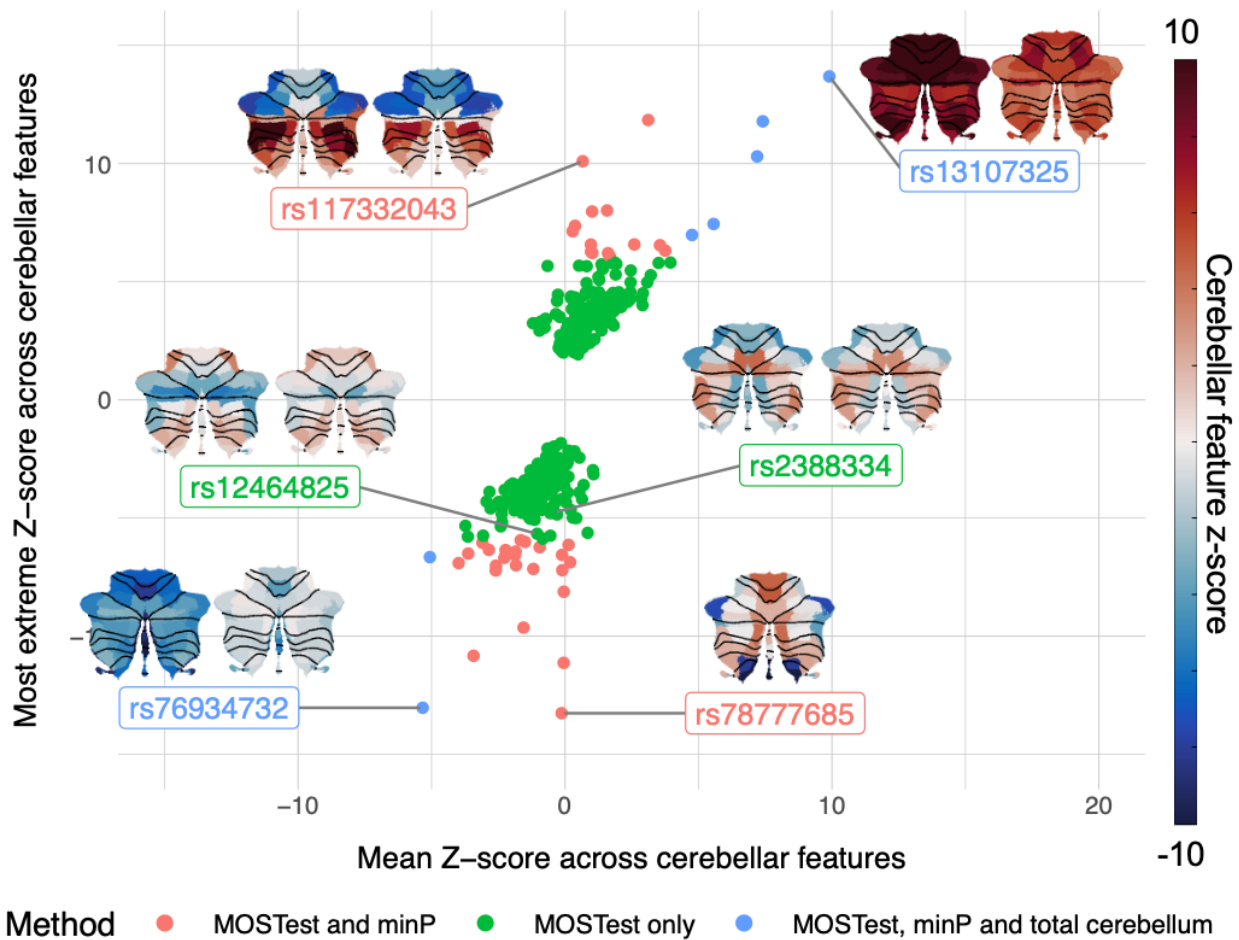

269 Overlap of cerebellar candidate SNPs and genetic loci with results from recent multivariate
270 analyses of hippocampal and cerebrocortical morphology are displayed in Figure 2D and
271 Supplementary Data 8 and 10 (final columns). Of note, we found that 32 and 29 percent of the
272 candidate SNPs discovered here for the cerebellum overlapped with candidate SNPs for vertex-wise
273 cerebrocortical surface area and thickness⁴⁴, respectively, while 11.4 percent overlapped with
274 candidate SNPs found for hippocampal subregions⁴⁵. 95 of the 351 genetic loci overlapped loci
275 linked to the other multivariate brain phenotypes (Supplementary Data 10). Thus, 64% of the
276 candidate SNPs and 73% of genetic loci appeared to be specifically associated with cerebellar
277 morphology.

278

279 **Significant genetic variants show heterogeneous effects across the cerebellar cortex,**
280 **influencing both regional and total volumes.**

281 A major advantage of our multivariate analysis approach is its sensitivity to both highly localized and
282 more generally distributed effects of SNPs on cerebellar morphology. This is illustrated in Figure 3,
283 which displays the 351 loci lead SNPs as a function of both the most extreme individual Z-score
284 across all cerebellar features (e.g, analogous to the strongest “local” effect) and of the mean Z-score
285 across these features (i.e. analogous to the main effect on overall cerebellar volume).

286

287

288 **Figure 3: Loci lead SNPs show spatially heterogeneous and replicable effects across the cerebellar**
289 **cortex.** The 351 loci lead SNPs identified by MOSTest are plotted as a function of main overall effect across
290 all cerebellar features (x-axis: mean Z-score) and most extreme effect for any single cerebellar feature (y-axis:
291 most extreme Z-score across features), and colour coded by SNP discovery method. The cerebellar flat-maps
292 show discovery (left) and replication (right) sample regional distributions of Z-scores (color-scale range from -
293 10 to 10) for a few selected lead SNPs (see Supplementary Data 10 for individual feature Z-scores for all 351
294 discovery sample loci lead SNPs). SNP rs78777685 was only present in the discovery sample.

295

296 As can be seen, some loci lead SNPs (e.g. rs13107325; rs76934732) show pronounced positive or
297 negative mean z-scores, indicating a relatively consistent direction of effect across cerebellar
298 features. See also inset figures displaying feature Z-scores projected back onto the cerebellar cortex.
299 Many of these SNPs also emerged in the univariate analysis of total cerebellar volume and were
300 recently reported in GWASs on total cerebellar volume^{13,14}.

301

302 Many other loci lead SNPs, however, show strong “local” signals with opposite effect
303 directions across features, yielding very weak global signals (e.g. rs117332043; rs78777685). Thus,
304 while several of the most significant SNPs in this category have previously been reported in GWASs
305 including local cerebellar morphological features^{42,43}, they did not emerge from analyses of total
cerebellar volume, neither in the current nor in previous studies.

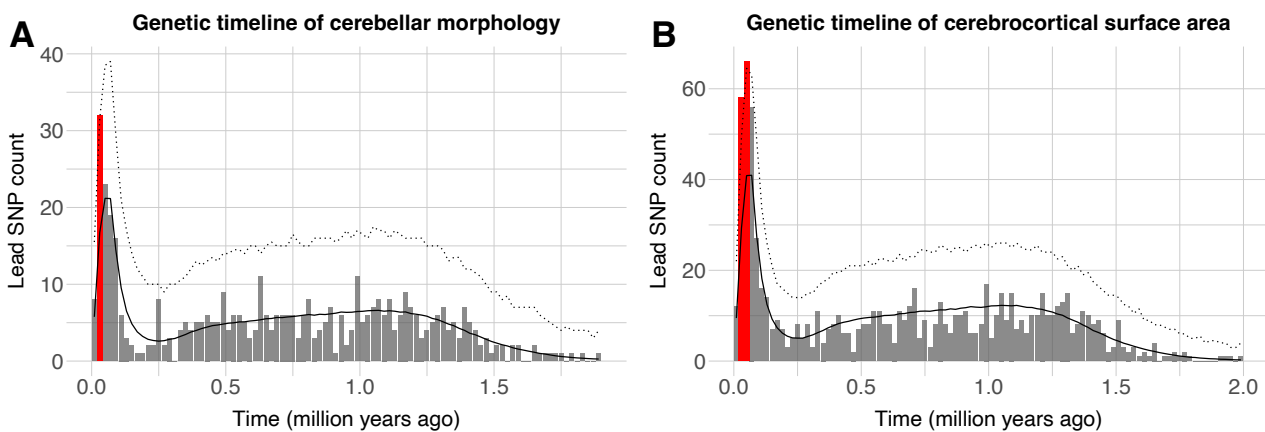

306 Finally, our multivariate MOSTest approach is also sensitive to SNPs displaying weaker
307 effects distributed across several cerebellar features, often with opposite effect directions (e.g.
308 rs12464825; rs2388334). For this category of SNPs, neither of the univariate methods have sufficient
309 power at the current sample size. In contrast, these two example SNPs robustly emerged from the
310 multivariate analysis (discovery sample p-values < 1e-56; replication sample p-values < 1e-15).

311

312 **Genetic variants associated with cerebellar morphology are enriched for evolutionary recent** 313 **mutations in the human genome.**

314 We next mapped the evolutionary age of cerebellar lead SNPs (thresholded for linkage
315 disequilibrium at $r^2 < 0.1$) by merging them with a recently published dataset on dated mutations in
316 the human genome⁴⁶. Following the analysis procedure established by Libedinsky et al.⁴⁷, we plotted
317 the histogram of dated lead SNPs over the last 2 million years in bins of 20,000 years (Figure 4A
318 and Supplementary Data 11), and tested for positive or negative enrichment by comparing them to
319 empirical null distributions derived from 10,000 randomly drawn and equally sized sets of all SNPs
320 in the full human genome dating dataset (after matching them to cerebellum-associated lead SNPs
321 in terms of minor allele frequency; see Online Methods for details).

322

323

324 **Figure 4: Lead SNPs associated with cerebellar morphology are enriched for evolutionary recent**
325 **mutations in the human genome. A:** Histogram of estimated SNP age (ranging from 0 to 2 million years, in
326 bins on 20,000 years) for 548 independent lead SNPs associated with cerebellar morphology. The solid black
327 and dotted lines denote the mean and upper 95th confidence interval (Bonferroni corrected across 100 time-
328 bins) derived from a null model constructed from 10,000 of equally sized sets of SNPs randomly drawn from
329 the Human Genome Dating Atlas of Variant Age (after matching these to cerebellar lead SNPs in terms of
330 minor allele frequencies). Red bars denote time-bins of significant positive enrichment. **B:** Histogram showing
331 comparative evolutionary enrichment effects for lead SNPs identified in a multivariate GWASs of
332 cerebrocortical area (for cerebrocortical thickness, see Supplementary Figure 12), See Supplementary Data
333 11-12 for full numerical results.

334

335 Results revealed positive enrichment for cerebellar lead SNPs in the time bin ranging from 20-40,000
336 years ago, i.e., overlapping the Upper Paleolithic, a period characterized by rapid cultural evolution

337 and the first evidence of several uniquely human behaviors (often referred to as behavioral
338 modernity), such as the recording of information onto objects⁴⁸.

339 For comparison, Figure 4B also shows results from an analysis of lead SNPs identified in a
340 previous multivariate GWAS study of regional cerebrocortical surface area⁴⁴, while Supplementary
341 Figure 12 shows the corresponding histogram for regional cerebrocortical thickness. As can be seen,
342 both these cerebrocortical phenotypes also showed significant enrichment in overlapping time bins
343 (i.e., 20-60,000 years ago). For full numerical results in Supplementary Data 12. Given the relatively
344 low number of independent lead SNPs (range: 548-862 SNPs across phenotypes) , we also ran
345 validation analyses using all independent significant SNPs (LD-thresholded at $r^2 < 0.6$, range: 1574-
346 2883 SNPs), which yielded very similar results (see Supplementary Figure 13 and Supplementary
347 Table 13).

348

349 **Genes associated with cerebellar morphology show selective expression in cerebellar and**
350 **prenatal brain tissue, as well as enrichment for genes linked to human accelerated regions.**

351 To functionally characterize the multivariate GWAS signal, we mapped the full set of GWAS p-values
352 to 19,329 protein coding genes using MAGMA⁴⁹ and used the resulting gene-level p-values to test
353 for 1) GWS genes, 2) gene expression in brain tissue; and 3) enrichment for genes linked to human
354 accelerated regions (HARs), i.e. sections of DNA that have remained relatively conserved
355 throughout mammalian evolution, before being subject to a burst of changes in humans since
356 divergence of humans from chimpanzees^{50,51}. These analyses yielded a total of 534 GWS genes
357 (i.e., 2.78% of all protein coding genes, see Figure 5A and Supplementary Data 14). Using the full
358 set of 19,329 gene-level p-values in MAGMA gene property analyses revealed significant and
359 specific gene expression in cerebellar and prenatal brain tissue (Figure 5B-C and Supplementary
360 Data 15-16), with the selective cerebellar expression seen in two independent datasets (Allen
361 Human Brain Atlas³⁵ and The Genotype-Tissue Expression (GTEx) Project).

362 The MAGMA gene set analysis of HAR-linked genes revealed significant enrichment ($p =$
363 $7.09e-08$) for genes associated with cerebellar morphology (Figure 5D, Supplementary Data 17). Of
364 note, running this same HAR gene set analysis on summary statistics from recent multivariate GWAS
365 studies on cerebrocortical⁴⁴ or hippocampal⁴⁵ morphological features yielded similar (for cortical
366 features) or significantly weaker (hippocampal features) enrichment effects (Figure 5d, see Online
367 Methods for processing pipeline).

Figure 5: Gene mapping reveals selective enrichment for cerebellar and prenatal brain tissue, as well as for genes linked to human accelerated regions. **A:** MAGMA mapped the full range of SNPs from the multivariate GWAS to 19,329 protein-coding genes, 534 of which were genome-wide significant (Bonferroni corrected threshold marked with red line), with the 30 most significant genes labeled in the gene-based Manhattan plot. **B-C:** MAGMA gene-property analyses revealed selective brain expression in the cerebellum and during prenatal developmental stages. **D:** MAGMA gene-set analysis revealed significant enrichment for sets of genes previously linked to human accelerated regions (HARs). Figure 4d also shows results from comparative analyses using summary statistics from other multivariate GWASs of MRI-based brain, as well as significant results from statistical tests comparing beta-weights for HAR-linked genes across multivariate brain features. Horizontal red lines mark the Bonferroni-corrected significance threshold for each subplot. See Supplementary Data 14-17 for full results.

Genes linked to human cerebellar morphology show enrichment for gene sets linked to selective cerebellar gene expression, altered cerebellar morphology in mouse models, human clinical/anthropometric traits, as well as specific biological processes and pathways. In line with the continuous brain tissue gene expression results described above, we also observed significant and relatively selective enrichment for smaller curated sets of genes previously found to be highly and selectively expressed in mouse (Figure 6A, Supplementary Data 18) and human (Figure 6C, Supplementary Data 20) cerebellar brain tissue, as well as for sets of genes previously shown to affect cerebellar morphology in mouse gene perturbation experiments (Figure 6B,

390 Supplementary Data 19) and various clinical conditions and anthropometric traits in humans (Figure
 391 6D, Supplementary Data 21). The most significant gene ontology and curated gene sets from the
 392 MSigDB^{52,53} database were related to brain development (e.g., neurogenesis, axon guidance and
 393 neuron differentiation, Figure 6E, Supplementary Data 22), and highlighted the reelin signaling
 394 pathway (Figure 6F, Supplementary Data 23).
 395

396
 397 **Figure 6: Gene mapping reveals selective enrichment across brain tissues and curated gene sets.**
 398 MAGMA gene-set analyses revealed significant enrichment for sets of genes previously linked to preferential
 399 expression in human (A) and mouse (C) cerebellar tissue, as well as effects on cerebellar morphology (and
 400 other brain phenotypes) in mouse gene perturbation experiments (B) and human clinical disorders and
 401 phenotypes (D). Significant gene ontology terms were related to neural development (E), while curated gene
 402 sets highlighted the Reelin signaling pathway (F). Across all subplots the x-axis shows the $-\log_{10}(p)$, the
 403 y-axis marks the number of gene sets, and the top 10 most significant gene-sets are labelled. Red lines mark
 404 the Bonferroni-corrected significance threshold for each subplot. See Supplementary Data 18-23 for full
 405 results.
 406

407 As can be seen in Figure 5A (and Supplementary Data 14), *RELN* (encoding the protein Reelin) was
408 also the most significant gene mapped by MAGMA. See also Supplementary Figure 14 for a regional
409 locus plot showing the 12 lead SNPs mapped to *RELN* and their associated z-score maps.

410

411 **Gene mapping reveals sets of plausible causal genes.**

412 In addition to the gene-based mapping strategy using all SNPs described above (MAGMA), we also
413 mapped candidate SNPs to genes using two complementary gene mapping strategies: 1) positional
414 mapping of deleterious SNPs (defined as having a CADD-score⁵⁴ > 12.37); and 2) mapping of SNPs
415 previously shown to affect gene expression in cerebellar tissues (i.e., eQTL mapping). Across all
416 three strategies, we mapped a total of 674 unique genes; 531 using MAGMA, 310 using positional
417 and 197 using eQTL mapping (see Figure 7A and Supplementary Data 24). 298 genes were
418 identified by at least two strategies, while 65 genes were mapped by all three strategies. Out of these
419 674 genes, 61 have previously been associated with cerebellar pathology in humans and/or altered
420 cerebellar morphology in mouse gene perturbation experiments, while 121 have been linked to
421 human accelerated regions (Supplementary Data 24). As can be seen in Figure 7B and
422 Supplementary Data 24, the 674 genes mapped to cerebellar morphology showed some overlap
423 with genes mapped to hippocampal⁴⁵ and cerebrocortical⁴⁴ morphology using the same mapping
424 strategies, but 264 genes (39%) appeared relatively specific to the cerebellum.

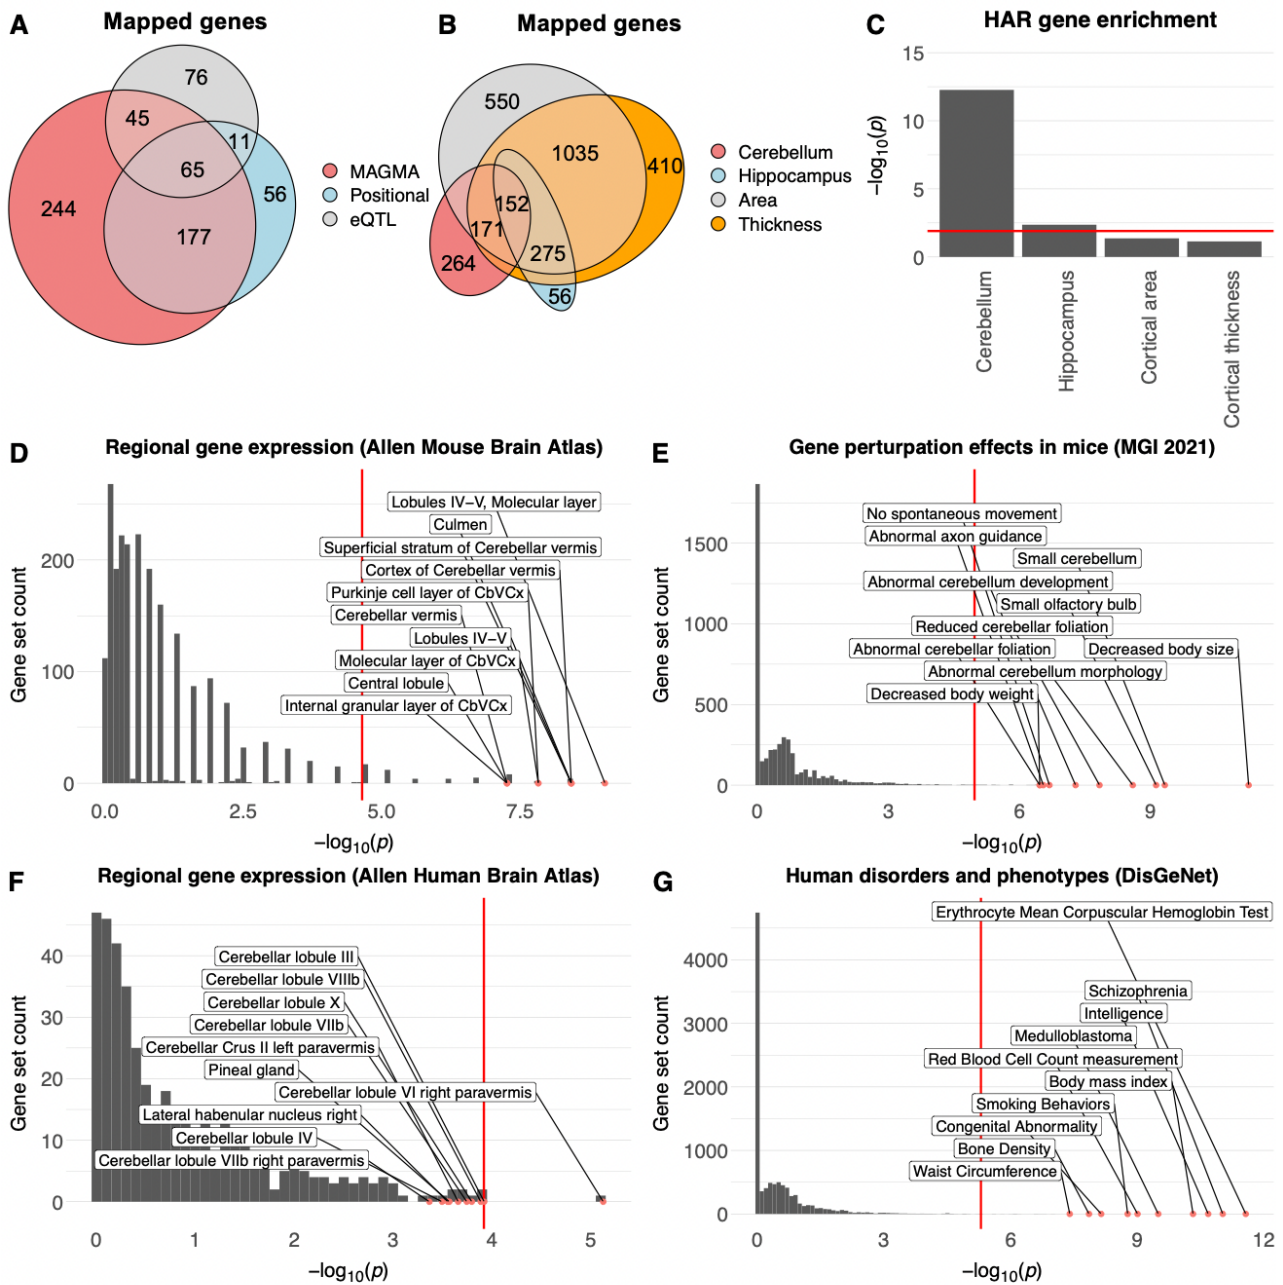

425 Results from gene set analyses on the 674 mapped genes (Figure 7, Supplementary Data
426 25-29) largely mirrored results from the MAGMA analyses described above, but in addition revealed
427 that this set of 674 mapped genes was also enriched for gene sets associated with several complex
428 clinical phenotypes and anthropometric traits in humans, including cognitive ability, neuroticism and
429 schizophrenia (Figure 7F, Supplementary Data 29).

430 Of note, while the full set of mapped genes showed significant enrichment for sets of genes
431 known to alter cerebellar morphology in mouse mutation or knock-down experiments
432 (Supplementary Data 27), we also note that 613 of the 674 mapped genes have not to our knowledge
433 previously been linked to cerebellar development, anatomy or pathology in mice or humans
434 (Supplementary Data 24), and thus constitute potential targets for future gene perturbation
435 experiments in animal models.

436 Restricting the above analyses to the 298 genes mapped across at least two strategies did
437 not markedly affect the results (Supplementary Data 25-29, final columns).

Figure 7: Mapping and functional characterization of plausible causal genes. The 674 plausible causal genes mapped using three complementary strategies (A) show partial overlap with genes mapped to hippocampal⁴⁵ and cerebrocortical⁴⁴ morphology (B); significant enrichment for sets of genes linked to human accelerated regions (HAR) (C); selective expression in the cerebellum in mice (D) and humans (E), as well as effects on cerebellar morphology in mouse gene perturbation studies (F) and human disorders and anthropometric phenotypes (G). Across all subplots the x-axis shows the $-\log_{10} p$ -value, the y-axis marks the number of gene sets, and the top 10 most significant gene-sets are labelled. Red lines mark the Bonferroni-corrected significance threshold for each subplot. See Supplementary Data 24-29 for full results.

Cerebellar morphology shows significant genetic overlap with psychiatric disorders.

We finally tested for overlap between the multivariate genetic profile for cerebellar morphology and genetic profiles for five major developmental/psychiatric disorders (attention deficit hyperactivity disorder: ADHD; autism spectrum disorder: ASD; bipolar disorder: BIP; major depressive disorder:

454 MDD; and schizophrenia: SCZ) using conditional/conjunctive FDR analysis⁵⁵. As can be seen in
 455 the conditional QQ-plots in Figure 8, these analyses revealed clear patterns of enriched association
 456 with the clinical phenotypes when selecting subsets of SNPs with increasingly stronger association
 457 with cerebellar morphology (Fig. 8A and figure insets in (C-F).

458
 459 **Figure 8: Genetic variants influencing cerebellar morphology overlap with variants associated with**
 460 **five major mental disorders.** Conditional QQ plots (A and figure insets in C-F) show an incremental
 461 incidence of association with five mental disorders (leftward deflection) as a function of the significance of
 462 association with cerebellar morphology. Manhattan plots show SNPs with significant association with both
 463 traits, thresholded at a conjunctive FDR threshold of $p > .01$ (red dotted line). SCZ: Schizophrenia; BIP:
 464 Bipolar Disorder; MDD: Major Depressive Disorder; ADHD: Attention Deficit Hyperactivity Disorder; ASD:
 465 Autism Spectrum Disorders.
 466

467 See also Supplementary Figure 15 for QQ-plots depicting the reverse association, i.e., enriched
468 association with cerebellar morphology when conditioning on the association with
469 developmental/psychiatric disorders. Specific genetic variants jointly influencing the two phenotypes
470 were identified using conjunctive FDR analyses at a conservative statistical threshold of $p < .01$.
471 Results revealed shared genetic loci with all disorders; namely 48 with SCZ, 22 with BIP, 2 with
472 MDD, 5 with ADHD and 5 with ASD (Figure 6; Supplementary Data 30-34). We mapped lead and
473 candidate SNPs for each of these loci to genes using positional and eQTL mapping and checked for
474 gene overlap across disorders (Supplementary Data 35). Of note, the *LRP8* gene (a HAR-linked
475 gene^{50,51} encoding a Reelin receptor) emerged from the conjunctive FDR analyses of both BIP and
476 SCZ, thus again highlighting the Reelin signaling pathway.

477 To complement these multivariate analyses, we also conducted a set of univariate analyses,
478 using LD-score regression³² to calculate the genetic correlations between each individual cerebellar
479 feature and the five developmental/psychiatric disorders.

480

481

482 **Figure 9: Univariate genetic correlations between cerebellar morphological features and five**
483 **major mental disorders are negative.** The top row display unthresholded genetic correlations,
484 while these are filtered at increasingly strict statistical thresholds in the following rows, i.e. nominal
485 p -value $< .05$ (second row); Bonferroni correction for the 23 cerebellar features tested (third row);
486 Bonferroni correction for both 23 features and 5 clinical conditions (bottom row). Black dotted
487 lines denote lobular boundaries.

488

489 As can be seen in the first row of Figure 9 (and Supplementary Data 36), genetic correlations with
490 cerebellar morphological features were predominantly negative across diagnoses, indicating that
491 genetic variants associated with a clinical diagnosis tended to also be associated with reduced
492 cerebellar volumes (with 42 out of 115 tested associations showing nominally significant negative
493 correlations; Fig 9, second row). However, all univariate genetic correlations were relatively weak,
494 and only a few negative genetic correlations with BIP and SCZ survived Bonferroni correction for the
495 23 features tested. When also correcting for the five clinical conditions, only the negative correlation
496 between BIP and cerebellar feature 23 (primarily overlapping vermal lobules VIIIa and VIIIb)
497 remained significant.

498 Supplementary Data 37 show genetic correlations between the five disorders and the ten
499 comparison brain phenotypes, as well as total cerebellar volume. In general agreement with the
500 observed pattern for regional cerebellar features, total cerebellar grey matter volume showed
501 nominally significant negative genetic correlations with BIP (rg: -.10; p = 0.0052) and SCZ (rg: -.09;
502 p = 0.0133). Pallidal volume also showed nominally significant negative genetic correlations with
503 these two disorders (BIP: rg: -.10; p = 0.0087; SCZ: rg: -.08; p = 0.0172, while ADHD displayed
504 negative genetic correlations with estimated total intracranial volume (rg: -.15; p = 0.0003) and total
505 cortical surface area (rg: -.14 ; p = 0.0065), as well as a positive genetic correlation with hippocampal
506 volume (rg: .13; p = 0.0164). Finally, MDD showed nominally significant negative genetic correlations
507 with volumes of the hippocampus (rg -.08: p = 0.025) and thalamus (rg: -.09; p = 0.0258). Only the
508 negative genetic correlation between ADHD and estimated total intracranial volume survived
509 Bonferroni correction across the 55 tests performed.

510

511

512 Discussion

513

514 The current study identified novel features of the genetic architecture of cerebellar morphology,
515 supported the notion of recent changes over human evolution, implicated specific neurobiological
516 pathways, and demonstrated genetic overlap with major mental disorders.

517 With respect to the main features of cerebellar morphology, it is worth noting that results from
518 our data-driven decomposition of cerebellar grey matter maps (which was not informed by genetic
519 data), the genetic correlation analyses of the chosen 23-feature solution and gene expression data
520 from the Allen Human Brain Atlas all converge on a similar general pattern. The first boundary to
521 emerge in the data-driven decompositions ran along the horizontal fissure separating Crus I and II
522 of lobule VII, reflecting its centrality in characterizing phenotypic variability in cerebellar morphology
523 at the population level. Of note, this boundary also emerged from clustering of the 23 cerebellar
524 morphological features based on their bivariate genetic correlations or gene expression profiles
525 (based on the Allen Human Brain Atlas). This latter finding essentially mirrors results from a recent
526 report using a different analysis strategy on the same gene expression data⁵⁶. Interestingly, the
527 horizontal fissure has been suggested to mark the border between two separate cerebellar

528 representations of the cerebral cortex, with a possible third representation in lobules IX-X⁵⁷. The
529 current cerebellar results thus complement previous work on the hierarchical genetic organization of
530 the cerebral cortex, which has identified the Rolandic fissure (separating the frontal and parietal
531 lobes) as a main boundary with respect to genetic effects of effects of surface area⁵⁸, as well as a
532 superior-inferior gradient for genetic influences on cortical thickness⁵⁹

533 Our multivariate GWAS using MOSTest identified 351 independent GWS loci associated with
534 cerebellar morphology, increasing the yield ~35-fold relative to analyzing total cerebellar volume and
535 ~6-fold relative to performing a set of univariate analyses on the same regional features in our current
536 sample. 329 (94%) loci from the multivariate analyses were replicated in an independent sample,
537 indicating robust results. After applying a liberal threshold to summary statistics from previous well-
538 powered studies, we find that 228 (65%) of our reported loci are novel. Importantly, among the genes
539 mapped to these novel loci we find several that are known to play important roles in cerebellar
540 development in mice (e.g., *RORA*⁶⁰, *FGF8*⁶¹ and *BAHRL1*⁶², see Supplementary Data 23). While
541 candidate SNPs associated with cerebellar morphology partially overlap with SNPs previously
542 mapped to other multivariate brain phenotypes, we note that a substantial number of SNPs appear
543 to be relatively selectively linked to cerebellar morphology, a finding that is in line with the distinct
544 gene expression profile found for the cerebellum³⁵.

545 SNP- and gene-level results from the current study also bolster – and refine – the notion of
546 relatively recent changes in cerebellar morphology over human evolution^{2,4,15,16}. Specifically, we
547 found that lead SNPs associated with cerebellar morphology were enriched for SNPs with an
548 estimated age of 20-40 thousand years. This overlaps the Upper Paleolithic (10-50k years ago), a
549 period characterized by rapid cultural evolution, and coinciding with the first evidence of several
550 uniquely human behaviors (often referred to as behavioral modernity), such as the recording of
551 information onto objects⁴⁸. Converging evidence for changes in brain anatomy around this
552 evolutionary period comes from the fossil skull record, where only fossils dated less than 35,000
553 years old fall within the range of shape-variation seen in modern humans^{63,64}. Of note, one key
554 feature of modern skulls is their “globular” shape, in part characterized by an enlarged posterior
555 fossa (the cranial compartment housing the cerebellum)^{63,64}. A similar pattern of enrichment for
556 recent evolutionary time bins (20-60 thousand years ago) was also found when analyzing lead SNPs
557 derived from previous studies on multivariate cerebro-cortical⁴⁴ morphology.

558 Gene level analyses further showed that genes associated with inter-individual variation in
559 cerebellar morphology are enriched for genes linked to human accelerated regions (HARs)⁵⁰ of the
560 genome. HARs denote previously conserved regions of the genome that were subject to a burst of
561 changes in humans after the divergence of humans from chimpanzees about 6-8 million years ago⁵⁰.
562 Of note, a recent GWAS on total cerebellar volume found no enrichment for HAR-linked genes¹⁴,
563 suggesting that SNPs associated with regional cerebellar variation may be driving this effect. When
564 comparing this finding with results from other multivariate brain phenotypes, we observed that HAR
565 gene enrichment was nominally stronger for cerebellar morphology than for vertex-wise

566 cerebrocortical thickness and area, and significantly stronger than for hippocampal regional volumes
567 (Figure 5D).

568 Together, these SNP- and gene-level results suggest that genetic variants influencing
569 cerebellar morphology in modern humans have been subject to selection over relatively recent
570 human evolution, and that cerebellar changes – in concert with other brain regions – may thus have
571 played a central part in the emergence of uniquely human cognitive abilities.

572 Results from the MAGMA gene property and gene set analyses bolster our confidence in the
573 genetic signal by showing selective gene expression in human cerebellar brain tissue across two
574 independent datasets (Allen Human Brain Atlas and GTEx.8) and significant enrichment for sets of
575 genes which have previously been shown to affect cerebellar morphology in mouse gene
576 perturbation experiments. The MAGMA results further show significant enrichment for sets of genes
577 known to play key roles in neurodevelopment (e.g., neurogenesis & axon guidance) and preferential
578 expression in prenatal brain tissue, thus supporting a primarily developmental origin of genetically
579 determined effects on adult cerebellar morphology. Of note, our MAGMA enrichment analysis of
580 curated gene sets strongly implicated the Reelin signaling pathway. Indeed, both the gene coding
581 for the Reelin protein (*RELN*) and genes coding for its two receptors (*LRP8* & *VLDLR*) were identified
582 across at least two gene mapping strategies, with *RELN* emerging as the single most significant
583 gene by MAGMA. The Reelin pathway is known to play important roles in neurodevelopment (e.g.
584 neuronal migration), and mutations in the *RELN* and *VLDLR*⁶⁵ (and to a lesser extent *LRP8*; also
585 known as ApoER2⁶⁶) have been associated with cerebellar malformations and/or dysfunction. *LRP8*
586 is also among the genes linked to human accelerated regions (HARs) of the genome.

587 The sets of genes mapped by the three complementary mapping strategies provide a
588 database for future studies investigating the genetic architecture of cerebellar morphology. For
589 instance, we mapped 616 genes associated with inter-individual variability in human cerebellar
590 morphology that have not yet to our knowledge been examined in mouse gene perturbation
591 experiments and/or associated with cerebellar pathology in humans. Among these, we highlight
592 *MAP2K5* and *GRB14*, two HAR-linked genes mapped across all strategies and associated with lead
593 SNP p-values <1e-50, but whose functions in the brain are largely unknown.

594 The reported results for previously discovered variants, loci and genes add important
595 information regarding regional effects on cerebellar morphology. For instance, while genetic variants
596 linked to the *RELN* gene have previously been associated with volumes of cerebellar vermal lobules
597 VI-X and hemispheric lobule IX^{42,43}, we here mapped 12 lead SNPs to *RELN* showing heterogeneous
598 effects across the entire cerebellar cortex (but with peak effects overlapping previously described
599 midline and posterior cerebellar regions, see Supplementary Figure 13).

600 The observed genetic overlap between cerebellar morphology and the five mental disorders
601 reinforces the recent notion of the cerebellum as a key brain structure in complex clinical traits and
602 disorders⁶⁻¹⁰. Across the five diagnoses, the strongest evidence for genetic overlap with cerebellar
603 morphology was found for SCZ and BIP, likely at least in part because these disorder GWASs were

604 relatively well-powered. While an in-depth discussion of genetic loci jointly influencing psychiatric
605 disorders and cerebellar morphology is beyond the scope of this report, we note that the Reelin
606 pathway again emerges in the genetic overlap analyses for SCZ and BIP. Specifically, the current
607 finding of *LRP8* (a reelin receptor, and HAR-linked gene) as one of the genes jointly associated with
608 cerebellar morphology and the aforementioned severe mental disorders points towards a potential
609 molecular pathway involved in the cerebellar abnormalities previously reported in SCZ^{10,67,68} and
610 BIP^{67,68}. Indeed, in line with its key importance for brain development and function, the Reelin
611 pathway is also increasingly seen as relevant for a wide range of neurodevelopmental, psychiatric
612 and neurodegenerative disorders⁶⁹. Of particular relevance to the current findings, converging
613 evidence supports *LRP8* as a key susceptibility gene for psychosis⁷⁰.

614 The main limitations of the current study concern the ancestral homogeneity of the sample,
615 the sample size, the exclusion of very rare genetic variants and the limitations on follow-up analyses
616 placed by multivariate (relative to univariate) test-statistics. Limiting the sample to participants of
617 European ancestry was deemed necessary considering the current state of the multivariate GWAS
618 methods used but may limit the generalizability of our findings. Second, while the current sample
619 size is large in comparison with previous imaging genetics studies, it is still relatively small in
620 comparison to GWASs of other complex human phenotypes (e.g., intelligence, with a current n of >
621 3 million⁷¹). Moreover, very rare genetic variants ($MAF < 0.005$) were excluded from the current
622 multivariate GWAS, but are likely to include a number of variants with relatively large effect sizes on
623 complex human traits⁷². Thus, future studies using larger and more diverse samples – as well as
624 whole exome and/or genome sequencing – are likely to discover more of the genetic variants
625 associated with cerebellar structure. Finally, while multivariate GWAS increases the power to detect
626 genetic variants associated with brain phenotypes relative to univariate approaches, it also places
627 important limitations on the possible follow-up analyses (e.g., genetic correlations or Mendelian
628 randomization), which require directional effects. Although comprehensive follow-up analyses of
629 univariate GWAS results fall beyond the scope of the current report, we have made all summary
630 statistics (univariate and multivariate) publicly available for the research community.

631 In conclusion, the current results enhance our understanding of the genetic architecture of
632 human cerebellar morphology, provide supporting evidence for cerebellar morphological changes
633 during the last ~6-8 million years of human evolution, and reinforce the notion of cerebellar
634 involvement in several mental disorders by demonstrating significant genetic overlap.

638
639
640
641

642 **Materials and Methods:**

643

644 **Participants**

645 For our main analyses, T1-weighted MR images, demographic and genetic data from 39,178 UK
646 Biobank participants were accessed using access number 27412. After removing 1043 participants
647 who either had missing genetic data or had withdrawn consent (as of 19.11.2019), data from 38,135
648 participants remained for the main analysis (age range: 44.6-82.1; mean age: 64.1, 51.9% female).
649 Following quality control procedures (QC, see below), 28,212 UK Biobank participants of European
650 descent remained for the main analyses (age range: 45.1-82.1; mean age: 64.1, 55.1% female), 910
651 of which were identified as close relatives and removed prior to genetic analyses (see below), leaving
652 a final sample for the primary analyses of 27,302 (age range: 45.1-82.1; mean age: 64.1, 54.9%
653 female). For the replication sample, we accessed a newer release of UK Biobank participants (n =
654 48,045) and removed the 27,302 participants included in the primary analyses. After running through
655 identical QC procedures as for the main sample (although applied only to the cerebellar features of
656 primary interest and covariates included when analyzing these), the replication sample consisted of
657 11,264 unrelated UK Biobank participants of European descent (age range: 46.1-83.7; mean age:
658 66.8, 46.9% female). The UK Biobank was approved by the National Health Service National
659 Research Ethics Service (ref. 11/NW/0382),

660

661 **Initial MR image processing**

662 MRI data was first processed using the recon-all pipeline in FreeSurfer 5.3⁷³, yielding a large number
663 of brain features. Of these, we retained measures of estimated total intracranial volume (eTIV), total
664 cerebro-cortical surface area, average cerebro-cortical thickness as well as the volumes of seven
665 subcortical structures (hippocampus, amygdala, thalamus, pallidum, putamen, caudate nucleus and
666 nucleus accumbens) as cerebral (or global, in the case of eTICV) comparison regions for our main
667 cerebellar analyses. These anatomical features were averaged across hemispheres, yielding a total
668 of ten comparison phenotypes.

669 Next, the bias-field corrected T1-images from the FreeSurfer analyses were analyzed using
670 the cerebellum-optimized SUIT-toolbox⁷⁴. In brief, SUIT isolates the cerebellum and brain stem from
671 T1-images, segments cropped images into grey and white matter, and normalizes these tissue
672 probability maps to a cerebellum-specific anatomical template. After multiplying the grey matter
673 maps with the Jacobian of the transformation matrix (i.e. preserving information about absolute
674 volumes), we extracted grey matter intensity values overlapping the 28 cerebellar lobular labels in
675 the probabilistic SUIT-atlas. Since cerebellar volumetric indices showed high correlations across the
676 two hemispheres (range: .87-.96; mean: .94), we created mean volumetric measures by averaging
677 across hemispheres. Finally, we also combined the two smallest regions in the SUIT-atlas (Vermis
678 Crus I and II located in the midline, average volumes: 2.9 and 293.4 mm², respectively) to create a
679 new Vermis Crus region (average volume: 296.2 mm²). This procedure reduced the 28 cerebellar

680 lobular volumes to 16 morphological indices. Total cerebellar grey matter volume was defined as the
681 sum of all 28 lobular labels in the SUIT-atlas.

682

683 **Quality control procedures**

684 After excluding 4,818 UKBB participants of non-European origin, anatomical indices from the
685 remaining 33,317 participants went through an iterative quality control (QC) procedure. First, we
686 excluded 639 subjects with a mean Euler number below -217, indicating poor MRI quality³¹, as well
687 as 12 subjects with missing and 90 subjects with zero values for any of the key cerebellar or cerebral
688 brain measures of interest. Next, we used general additive models (GAM, implemented in the R-
689 package “mgcv”) in order to model the effects of age (estimated as smooth functions for males and
690 females separately, using cubic splines with 10 knots), sex, and scanner site on estimated total
691 intracranial volume (eTIV) and mean thickness of the cerebral cortex. Specifically, we used the
692 following formula:

693

```
694 GAM_model<-gam(Anatomical feature ~ s(Age, bs = "cs", by = Sex, k = 10) + as.factor(Sex)  
695 + as.factor(Scanner), data = UKBB_cerebellum_GWAS, select = TRUE, method = "REML")
```

696

697 Adjusted eTIV and mean cortical thickness indices were then created by reconstructing the data
698 using the intercept and residuals from this model (i.e., removing effects of age, sex and scanner),
699 before identifying and rejecting potential outliers, defined as +/- 3 median absolute deviations
700 (MAD)⁷⁵ from the median of these adjusted values. Data from 350 subjects were rejected based on
701 these criteria.

702 For the remaining cerebral anatomical measures, as well as total cerebellar volume, this
703 procedure was then repeated, with scaled eTIV as an additional predictor. Since previous studies
704 have demonstrated that the relationship between regional brain volumes and intracranial volume is
705 not strictly allometric^{76,77}, we estimated the effect of eTIV using cubic splines with 10 knots.
706 Specifically, we used the following formula:

707

```
708 GAM_model<-gam(Anatomical feature ~ s(Age, bs = "cs", by = Sex, k = 10) + as.factor(Sex)  
709 + as.factor(Scanner) + s(eTIV_scaled, bs = "cs", k = 10), data = UKBB_cerebellum_GWAS,  
710 select = TRUE, method = "REML")
```

711

712 In order to be maximally sensitive to outliers in relative cerebellar volumes, we replaced eTIV with
713 total cerebellar volume in the GAM models of cerebellar regions of interest (i.e., SUIT atlas regions),
714 using the following formula:

715

```
716 GAM_model<-gam(Anatomical feature ~ s(Age, bs = "cs", by = Sex, k = 10) + as.factor(Sex)
717 + as.factor(Scanner) + total cerebellar volume, data = UKBB_cerebellum_GWAS, select =
718 TRUE, method = "REML")
```

719
720 Adjusted cerebral and cerebellar indices were then created by reconstructing the data using the
721 intercept and residuals from these models (i.e., removing estimated effects of age, sex and eTIV or
722 total cerebellar volume), before rejecting 1792 participants with potential outlier cerebral indices and
723 2222 participants with potential outlier cerebellar indices (MAD > +/- 3).

724
725 This iterative QC procedure resulted in the rejection of 5,105 (i.e., 15.3%) of the original 33,317
726 datasets, leaving 28,212 datasets for further analysis.

727 728 **Non-negative matrix factorization**

729 Cerebellar grey matter maps from 28,212 subjects passing the iterative QC procedure were
730 smoothed with a 4mm full-width-half-maximum gaussian kernel in SPM12⁷⁸, concatenated across all
731 subjects and multiplied with a binary mask to isolate voxels located in the cerebellar cortex. This
732 cerebellar cortical mask was constructed by multiplying a binary mask containing all 28 cerebellar
733 lobules of the SUIT-atlas with the thresholded (at a value of 0.1) mean (unsmoothed) grey matter
734 segmentation across all 28,212 participants.

735 The smoothed, concatenated and masked grey matter maps were then subjected to
736 orthogonal projective non-negative matrix-factorization (OPNMF)²⁶, in order to derive data-driven
737 parcellations of regional cerebellar grey matter volume.

738 Non-negative matrix factorization (NNMF) is a blind source separation technique that allows
739 structural brain networks to be described in a hypothesis-free, data-driven way by identifying patterns
740 of covariation in the data. In contrast to alternative techniques, such as principal component analysis
741 and independent component analysis, which yield components with both positive and negative
742 weights that are often difficult to interpret, NNMF produces a sparse, positive-only, parts-based
743 representation of the data. Importantly, NNMF has previously been proven effective in estimating
744 covariance patterns in neuroimaging data while providing an easier interpretation of the results than
745 other matrix decomposition techniques such as principal component analysis (PCA) or independent
746 component analysis (ICA)²⁶⁻³⁰.

747 Briefly, NNMF decomposes an input matrix (voxels×subjects) into two matrices; a component
748 matrix W (voxels×k) and a weight matrix H (k×subjects) where k is the number of components that
749 needs to be specified by the user. Here, we used an implementation of orthogonal projective non-
750 negative matrix factorization previously used in a number of publications²⁶⁻³⁰ and downloaded from
751 <https://github.com/asotiras/brainparts>. Given the large number of participants, we used the
752 `opnmf_mem.m` function, which has been optimized for high-dimensional data. The function was run

753 with default parameter settings, except for maximal number of iterations, which was increased to
754 200k, in order to ensure full convergence across all tested model orders.

755

756 **Model order selection**

757 Since the resulting parcellations are highly dependent on the requested number of components (or
758 model order) specified, we tested model orders ranging from 2 to 30 in steps of 1, as well as from
759 30 to 100 in steps of 10. Binarized winner-takes-all (i.e. assigning each voxel to the NNMF
760 component with the highest loading) maps of the resulting decompositions projected onto a flattened
761 representation of the cerebellar cortex are shown in Supplementary Figure 1.

762 Resulting NNMF decompositions were then evaluated based on two criteria; 1) how much of the
763 variance in the original input data a given NNMF solution (i.e., component maps and subject weights)
764 could explain and on 2) how reproducible the component maps were. As a metric of change in
765 explained variance we used the change of the Frobenius norm of the reconstruction error. With
766 increasing model orders the variance explained will always increase and the reconstruction error
767 decrease, but if the decrease in the reconstruction error (or gradient) levels off, this indicates that
768 the intrinsic dimensionality of the data might have been approximated (and that the subsequent
769 increase in explained variance can largely be attributed to fitting random noise in the input data). In
770 order to assess reproducibility, we split the full dataset into two equal sets (matched with respect to
771 scanner site, $n = 14,105$ and $14,107$, respectively), and ran NNMF on each split-half sample. For
772 each set of independent NNMF parcellations, we computed two reproducibility indices. First, for each
773 model order we matched components across split-half runs using the Hungarian algorithm⁷⁹, before
774 computing the spatial correlations between matched component maps, and extracting the median
775 correlation across all matched components as our first reproducibility index. For our second
776 reproducibility index, we first computed one overall – and categorical – component map using a
777 “winner-takes-all”-approach, i.e., assigning each voxel to the NNMF component with the highest
778 loading. Next, we calculated the adjusted Rand index (ranging from 0 to 1, with higher values
779 indicating greater similarity⁸⁰, across the two categorical parcellation maps for each model order as
780 our second metric of reproducibility.

781 As can be seen in Supplementary Figure 2A, for lower model orders, increasing the model
782 order resulted in a sharp decrease in the reconstruction error, indicating that models with more
783 components resulted in a significantly better fit to the data. However, after reaching model orders
784 between 15 and 30, the incremental improvement in fit from adding another component appeared to
785 level off. As expected, the reproducibility results showed a largely inverse pattern, with both
786 reproducibility indices decreasing with increasing model orders (Supplementary Figure 2B). Of note,
787 for model orders up to 8, median spatial correlations across all matched components was above .99,
788 indicating almost identical parcellations derived from the two independent samples. However, even
789 for a model order of 100, the median pairwise correlation was still pretty high (.85), with 60% of
790 components showing pairwise spatial correlations above 0.8, suggesting a reasonable level of

791 reproducibility even for the most fine-grained parcellation. Our reproducibility index for the
792 categorical parcellations showed very similar results; the adjusted Rand index remained above .9
793 for model orders up to 8, and then decreased to 0.56 at a model order of 100.

794 Given that the change in reconstruction error appeared to stabilize between 15 and 30
795 components, indicating that the intrinsic dimensionality of the data had been approximated, we
796 searched for the most reproducible parcellations within this range. Since the reliability estimates for
797 model orders of 16 and 23 were very similar, with the 23-component solution explaining more of the
798 variance in the original data, we used the 23-component parcellation for all further analyses.

800 **Adjustment and rank-order normalization of anatomical indices**

801 Prior to being subjected to genome-wide association analyses, we adjusted all anatomical indices
802 for effects of age, sex, estimated total intracranial volume, scanner site, 40 genetic population
803 components, genetic batch and mean Euler number (i.e, an index of MRI image quality³¹, averaged
804 across hemispheres), using general additive models. Finally, all adjusted anatomical indices were
805 inverse rank normalized⁸¹.

806 **Pre-processing of genetic data**

808 For all genetic analyses we made use of the UKB v3 imputed data, which has undergone extensive
809 quality control procedures as described by the UKB genetics team⁸². After converting the BGEN
810 format to PLINK binary format, we additionally carried out standard quality check procedures. We
811 first selected White Europeans, as determined by a combination of self-identification as 'White
812 British' and similar genetic ancestry based on genetic principal components, that had undergone the
813 neuroimaging protocol. We then filtered out individuals with more than 10% missingness, removed
814 SNPs with low imputation quality scores (INFO <.5), SNPs with more than 10% missingness, and
815 SNPs failing the Hardy-Weinberg equilibrium test at $p=1*10^{-9}$. We further set a minor allele
816 frequency threshold of 0.005 leaving 9,061,238 SNPs. After estimating the genetic relationship
817 matrix (GRM) using genetic complex trait analysis (GCTA³³), we finally removed 910 participants
818 defined as close relatives using a threshold of 0.05 (approximately corresponding to 3rd cousins).

819 **Heritability estimation and genetic correlation analyses**

820 SNP-based heritability estimates for all morphological features – as well as the pairwise genetic
821 correlations between cerebellar features - were estimated using genetic complex trait analysis
822 (GCTA³³).

824 **Univariate genome-wide association analyses**

825 Univariate analyses of total cerebellar grey matter volume and the ten cerebral comparison
826 phenotypes were conducted using Plink v1.9.

828

829 **Genetic correlation analyses across discovery and replication samples and with previous**
830 **published GWASs**

831 Genetic correlation analyses across different samples were conducted using LD-score
832 regression³².

833

834 **Multivariate genome-wide association analyses**

835 For our main analysis, we used a recently developed multivariate analysis method (MOSTest³⁶), to
836 conduct a multivariate genome-wide association (GWA) analysis on cerebellar morphological
837 features. MOSTest identifies genetic effects across multiple phenotypes, yielding a multivariate
838 GWAS summary statistic across all 23 features, and provides robust (permutation based) test
839 statistics. For mathematical details of the implementation, see van der Meer et al. (2020)³⁶, for details
840 on the software implementation see github.com/precimed/mostest. MOSTest has been extensively
841 validated in the original methods paper, including simulations and comparisons with other methods
842 that have confirmed its solid discovery performance as well as an order of magnitude shorter runtime
843 compared to other tools³⁶. For comparison to standard univariate approaches, we also performed
844 univariate GWASs (extracted from the univariate stream of MOSTest³⁶ and identical to results from
845 analyses using Plink).

846

847 **Multivariate replication analysis**

848 To ensure that not only single locus lead SNP associations replicate, but that also the multivariate
849 pattern of these associations are consistent in the discovery and replication sample, we implemented
850 a multivariate replication procedure established in Loughnan et al.³⁹. In brief, for each locus lead
851 SNP identified in the multivariate analysis in the discovery sample, this procedure derives a
852 composite score from the mass-univariate z-statistics and tests for associations of the composite
853 score with the genotype in the replication sample (for mathematical formulation see Loughnan et
854 al.³⁹). 12 of the 351 locus lead SNPs could not be tested as they were not available in the replication
855 sample after QC. For the remaining SNPs we report the percent of loci replicating at $P < 0.05$, the
856 percent remaining significant after Bonferroni correction for 339 conducted tests, and the percent of
857 lead SNPs showing the same effect direction.

858

859 **Multivariate cerebral comparison phenotypes**

860 To compare key multivariate cerebellar results with other multivariate brain phenotypes, we
861 downloaded summary statistics from two recent studies on cerebrocortical⁴⁴ and hippocampal⁴⁵
862 regional morphology. These comparison summary statistics were next analyzed using FUMA³⁷ as
863 described for the main cerebellar results below.

864

865 **Locus identification and SNP annotation**

866 To identify genetic loci we uploaded summary statistics to the FUMA platform v1.4.1³⁷ Using the
867 1000GPhase3 EUR as reference panel, we identified independent SNPs as SNPs below the
868 significance threshold of $P < 5e-8$ that were also in linkage equilibrium with each other at $r^2 < 0.6$.
869 For each independent SNP, all candidate variants are identified as variants with LD $r^2 \geq 0.6$ with the
870 independent SNP. A fraction of the independent significant SNPs in approximate linkage equilibrium
871 with each other at $r^2 < 0.1$ were considered as lead SNPs. For a given lead SNP, the borders of the
872 genomic locus are defined as min/max positional coordinates over all corresponding candidate
873 SNPs. Finally, loci are merged if they are separated by less than 250kb.

874 FUMA further annotates associated SNPs based on functional categories, Combined
875 Annotation Dependent Depletion (CADD) scores which predicts the deleteriousness of SNPs on
876 protein structure/function⁵⁴, RegulomeDB scores which predicts regulatory functions⁸³; and
877 chromatin states that shows the transcription/regulation effects of chromatin states at the SNP
878 locus⁸⁴. For all these analyses, we used default FUMA parameters.

879

880 **Genome-wide gene-based association and gene-set analyses**

881 We conducted genome-wide gene-based association and gene-set analyses using MAGMA v.1.10⁴⁹
882 (<http://ctg.cncr.nl/software/magma>). MAGMA performs multiple linear regression to map the input
883 SNPs to 19,190 protein coding genes and estimates the significance value of that gene. Genes were
884 considered significant if the P value was < 0.05 after Bonferroni correction for 19,190 genes. The
885 same procedure was used for MAGMA analysis of summary statistics for the three multivariate
886 cerebral comparison phenotypes (cerebrocortical thickness and surface area⁴⁴ and regional
887 hippocampal volumes⁴⁵).

888 MAGMA gene-level statistics were next used as input to gene-property and gene-set
889 analyses in MAGMA. Gene-property analyses test for associations between tissue specific gene
890 expression profiles and disease-gene associations. The gene-property analysis is based on the
891 regression model: $Z \sim \beta_0 + E_t \beta_E + A \beta_A + B \beta_B + \epsilon$, where Z is a gene-based Z-score converted from
892 the gene-based P-value, B is a matrix of several technical confounders included by default (e.g.,
893 gene size, gene density, sample size), E_t is the gene expression value of a testing tissue type and A
894 is the average expression across all tissue types in a data set (ensuring a test of expression
895 specificity). We performed a one-sided test ($\beta_E > 0$) which is essentially testing the positive
896 relationship between tissue specificity and genetic association of genes.

897 We tested associations with two regional brain gene expression datasets (Allen Human
898 Brain Atlas³⁵ and GTEx) and one developmental brain gene expression dataset (BrainSpan). For
899 extraction and processing of gene expression data, see below.

900

901 **Extraction and processing of gene expression data**

902 *Allen Human Brain Atlas*: Regional microarray expression data were obtained from 6 post-mortem
903 brains (1 female, ages 24.0--57.0, 42.50 +/- 13.38) provided by the Allen Human Brain Atlas³⁵. Data

904 were processed with the abagen toolbox (version 0.1.3)³⁴ using two volumetric atlases; 1) the
905 binarized 23-region NMF-derived parcellation of the cerebellar cortex; and 2) a modified version of
906 the Desikan atlas were ROIs were merged to construct 9 bilateral regions: cerebellum, cerebral
907 cortex, pallidum, caudate, putamen, thalamus, amygdala, nucleus accumbens and hippocampus.

908 First, microarray probes were reannotated using data provided by Arnatkeviciute, Fulcher
909 and Fornito⁸⁵; probes not matched to a valid Entrez ID were discarded. Next, probes were filtered
910 based on their expression intensity relative to background noise⁸⁶, such that probes with intensity
911 less than the background in $\geq 50.00\%$ of samples across donors were discarded, yielding 31,569
912 probes. When multiple probes indexed the expression of the same gene, we selected and used the
913 probe with the most consistent pattern of regional variation across donors (i.e., differential stability⁸⁷),
914 calculated with:

$$\Delta_S(p) = \frac{1}{\binom{N}{2}} \sum_{i=1}^{N-1} \sum_{j=i+1}^N \rho[B_i(p), B_j(p)]$$

915

916 where ρ is Spearman's rank correlation of the expression of a single probe, p , across regions
917 in two donors B_i and B_j , and N is the total number of donors.

918 Here, regions correspond to the structural designations provided in the ontology from the
919 AHBA. The MNI coordinates of tissue samples were updated to those generated via non-linear
920 registration using the Advanced Normalization Tools (ANTs; <https://github.com/chrisfilo/alleninf>).
921 Samples were assigned to brain regions in the provided atlas if their MNI coordinates were within 2
922 mm of a given parcel. To reduce the potential for misassignment, sample-to-region matching was
923 constrained by hemisphere and gross structural divisions (i.e., cortex, subcortex/ brainstem, and
924 cerebellum, such that e.g., a sample in the left cortex could only be assigned to an atlas parcel in
925 the left cortex⁸⁵). All tissue samples not assigned to a brain region in the provided atlas were
926 discarded. \n\nInter-subject variation was addressed by normalizing tissue sample expression
927 values across genes using a robust sigmoid function⁸⁸:

$$x_{norm} = \frac{1}{1 + \exp\left(-\frac{(x - \langle x \rangle)}{IQR_x}\right)}$$

928

929 where $\langle x \rangle$ is the median and IQR_x is the normalized interquartile range of the expression of a
930 single tissue sample across genes. Normalized expression values were then rescaled to the unit
931 interval:

$$x_{scaled} = \frac{x_{norm} - \min(x_{norm})}{\max(x_{norm}) - \min(x_{norm})}$$

932

933 Gene expression values were then normalized across tissue samples using an identical
934 procedure. Samples assigned to the same brain region were averaged separately for each donor

935 and then across donors, yielding two regional expression matrices with 23 and 9 rows, corresponding
936 to brain regions, and 15,631 and 15,633 columns, corresponding to the retained genes. Prior to
937 inclusion in MAGMA gene property analyses, we converted gene names for the modified Desikan
938 atlas to ENSEMBL IDs, and calculated the mean expression value across tissue types (in order to
939 include this as a covariate in MAGMA analyses testing for gene expression specificity), resulting in
940 a 10 (regions) by (15,490) gene expression matrix.

941

942 *GTeX*: Text files containing median transcript per millimeter (TPM) values for 53 tissue types
943 (*GTEX_Analysis_2017-06-05_v8_RNASeqCv1.1.9_gene_median_tpm.gct.gz*) were down-loaded
944 from the *GTEX* portal (<https://gtexportal.org/home/datasets/>). After selecting only expression data
945 from the seven (out of nine) comparison brain regions present in the *GTEX* dataset (i.e., amygdala,
946 caudate, cerebellum, cortex, hippocampus, nucleus accumbens and putamen), we filtered the data
947 by only including genes with median TPM values above 1 for at least one of these tissue type
948 (retaining 19,578 of 56,200 annotated genes). Following the procedure used by FUMA³⁷, we next
949 winsorized median TPM values at 50 (i.e., replaced TPM>50 with 50), before log transforming TPM
950 with pseudocount 1 ($\log_2(\text{RPKM}+1)$). Finally, we calculated the mean expression value across tissue
951 types (in order to include this as a covariate in MAGMA analyses testing for gene expression
952 specificity).

953

954 *BrainSpan data*: The analysis of BrainSpan data testing for developmentally specific brain
955 expression was performed entirely within FUMA v1.4.1., using default parameters.

956

957 **Analysis of Human Dating Genome Data.** The Atlas of Variant Age for chromosomes 1-22 was
958 downloaded from the Human Genome Dating (HGD) website: <https://human.genome.dating/>. This
959 atlas contains more than 45 million SNPs which has been assigned dates of origin based on a
960 recombination clock and mutation clock applied to two large-scale sequencing datasets (1000
961 Genomes Project⁸⁹ and The Simons Genome Diversity Project⁹⁰), with no assumptions made about
962 demographic or selective processes⁴⁶. The current study used the median joint age estimates from
963 both clocks when analyzing SNPs present in both datasets in combination (i.e., 13,694,493 SNPs).

964 After merging dated SNPs with the 40,405,505 SNPs also present in the Haplotype
965 Reference Consortium reference data (to add minor allele frequencies, MAF) and removing 715,083
966 (5.2%) SNPs with missing MAF values as well as the very few (14,549, 0.1%) SNPs dated older
967 than 2 million years, 12,960,066 SNPs remained.

968 548 of these dated SNPs were matched to lead SNPs linked to cerebellar morphology
969 (defined as being in mutual LD at an r^2 threshold < 0.1), hereafter referred to as cerebellar-SNPs.
970 Partially because very rare variants (Minor Allele Frequency/MAF < 0.005) had been removed prior
971 to the multivariate GWAS analysis, MAF was not equally distributed between these cerebellar-SNPs
972 and the full range of dated SNPs in the HGD dataset. Importantly, MAF has been shown to be

973 systematically related to the estimated age of SNPs, with a higher proportion of low-MAF SNPs in
974 more recent than in older time-bins^{46,47}. Consequently, following the analysis approach established
975 by Libedinsky et al.⁴⁷, we first determined the MAF-distribution of cerebellar-SNPs (across eight
976 bins: <0.0001; 0.0001-0.001; 0.001-0.01; 0.01-0.1; 0.1-0.2; 0.2-0.3; 0.3-0.4; 0.4-0.5) and selected
977 random set of 2,892,270 SNPs from the HGD dataset that were matched to the cerebellar-SNPs in
978 terms of MAF-bin distribution. Similar MAF-matched HDG subsets were created for lead SNPs
979 associated with the two cerebrocortical comparison phenotypes, i.e., regional cerebrocortical surface
980 area and thickness (862 and 714 lead SNPs, respectively).

981 For statistical inference we constructed null models (separate for each brain phenotype) by
982 randomly drawing sets of SNPs (of equal size to the number of phenotype-linked lead SNPs) from
983 the MAF-matched HGD-datasets and computing the histograms of estimated dates from 0 to 2
984 million years ago (divided into 100 bins of 20,000 years) over 10,000 iterations. From these null
985 models we extracted bin means as well as significance thresholds (defined as the upper and lower
986 99.95th percentile of the null model (i.e. corresponding to a two-tailed threshold of 0.05 Bonferroni
987 corrected across 100 bins).

988 For the validation analyses, we ran the same analyses based on the larger number (range
989 across phenotypes: 1574-2883) of individual significant SNPs (defined as being in mutual LD at an
990 r^2 threshold < 0.6).

991

992 **Positional and eQTL mapping of SNPs to plausible causal genes**

993 In addition to using MAGMA, we also mapped candidate SNPs to plausible causal genes using two
994 complementary gene mapping strategies implemented in FUMA³⁷: 1) Positional mapping of
995 deleterious SNPs (defined as having a CADD-score > 12.37) and 2) eQTL-mapping of SNPs
996 previously shown to alter gene expression in cerebellar tissue (from the BRAINEAC and GTEx v8
997 databases). These analyses were run with default FUMA parameters. For the three multivariate
998 cerebral comparison phenotypes (i.e., cerebrocortical thickness, cerebrocortical surface area and
999 hippocampal regional volumes), we employed identical gene mapping procedures to our cerebellar
1000 morphology results, except for the tissues chosen for eQTL mapping (cerebrocortical and
1001 hippocampal, respectively).

1002

1003 **Gene set analyses using lists of mapped genes**

1004 All gene set analyses using mapped genes were conducted using the hypeR R-package⁹¹. This
1005 package implements the hypergeometric test (also known as Fisher's exact test), which assigns a
1006 p-value to gene-set overlaps given gene set sizes and the number of background genes. This R-
1007 package also contains functions for downloading and/or formatting gene sets. The following gene
1008 sets were accessed using hypeR: "Allen_Brain_Atlas_up" (regional overexpression in the Allen
1009 Muse Brain Atlas), "MGI_Mammalian_Phenotype_Level_4_2021", "DisGeNet" (all from the enrichR
1010 platform. In addition, we downloaded sets of genes with regional overexpression in the Allen Human

1011 Brain Atlas from the Harmonizome platform⁹² and accessed a list of genes mapped to human
1012 accelerated regions⁹³. For all gene-set analyses we employed Bonferroni-correction by dividing the
1013 p-value threshold of 0.05 by the number of gene sets included in each analysis.

1014

1015 **Genetic overlap between cerebellar morphology and brain disorders**

1016 We accessed GWAS summary statistics for attention deficit hyperactivity disorder (ADHD)⁹⁴, autism
1017 spectrum disorder (ASD)⁹⁵, bipolar disorder (BIP)⁹⁶ and major depressive disorder (MDD)⁹⁷ from the
1018 Psychiatric Genomics Consortium. In order to avoid sample overlap, for MDD we used summary
1019 statistics based on a sample with the UK Biobank participants removed. 23&me participants included
1020 in the original MDDGWAS were also excluded, since these data are not freely available). Finally,
1021 we included data from a recent study of schizophrenia (SCZ)⁹⁸. Shared variants associated with
1022 cerebellar morphology and each of the above-mentioned brain disorders were identified using
1023 conjunctive FDR statistics ($FDR < 0.05$)^{99,100}. In contrast to genetic correlation analysis,
1024 conjunctive FDR does not require effect directions and can therefore be applied to summary
1025 statistics from multivariate GWAS, which do not contain effect directions. Two genomic regions, the
1026 extended major histocompatibility complex genes region (hg19 location Chr 6: 25119106–33854733)
1027 and chromosome 8p23.1 (hg19 location Chr 8: 7242715–12483982) for all cases and *APOE* region
1028 for ASD, were excluded from the FDR-fitting procedures because complex correlations in regions
1029 with intricate LD can bias FDR estimation. We further controlled for spurious enrichment by
1030 calculating all conditional Q-Q plots after random pruning averaged over 500 iterations. At each
1031 iteration, one SNP in every LD block (defined by an $r^2 > 0.1$) was randomly selected and the empirical
1032 cumulative distributions were computed using the corresponding p-values. Finally, we submitted
1033 the results from conjunctive FDR to FUMA v1.3.7³⁷ to annotate the genomic loci with conjFDR
1034 value < 0.10 having an $r^2 \geq 0.6$ with one of the independent significant lead SNPs. Genetic
1035 correlations between univariate results for the 23 cerebellar features, the 10 comparison brain
1036 phenotypes, and each of the five mental disorders were computed using LD-score regression as
1037 described above.

1358
1359 **Acknowledgements**
1360

1361 This work was performed on the Tjeneste for Sensitive Data (TSD) facilities, owned by the University of
1362 Oslo, operated and developed by the TSD service group at the University of Oslo, IT-Department (USIT)
1363 and on resources provided by UNINETT Sigma2—the National Infrastructure for High Performance
1364 Computing and Data Storage in Norway. The research has been conducted using the UK Biobank
1365 Resource (access code 27412) and using summary statistics for various brain disorders. We would like
1366 to thank the research participants and employees of UK Biobank and the consortia contributing
1367 summary statistics for making this work possible.
1368

1369 **Funding:** The authors were funded by the South-Eastern Norway Regional Health Authority (TM: 2021-
1370 040; OAA: 2013-123, 2017-112, 2019-108. LTW: 2014-097, 2015-073, 2016-083), the Research
1371 Council of Norway (TK: 276082, 323961. OAA: 213837, 223273, 248778, 273291, 262656, 229129,
1372 283798, 311993. LTW: 204966, 249795, 273345), Norwegian Health Association (SB: 22731), Stiftelsen
1373 Kristian Gerhard Jebsen, and the European Research Council (LTW: ERCStG 802998). The funding
1374 bodies had no role in the analysis or interpretation of the data; the preparation, review or approval of
1375 the manuscript; nor in the decision to submit the manuscript for publication.
1376

1377 **Author contributions:** TM originally conceived of the project. TM, DvdM and SB performed the
1378 analyses. TM, LTW and OAA wrote the initial draft of the manuscript. All authors discussed the results
1379 and contributed to the final manuscript.
1380

1381 **Competing interests:** O.A.A. has received speaker's honorarium from Lundbeck and is a consultant to
1382 HealthLytix. A.M.D. is the founder of and holds equity in CorTechs Labs Inc. and serves on its Scientific
1383 Advisory Board. A.M.D. is also a member of the Scientific Advisory Board of Human Longevity Inc. and
1384 receives funding through research agreements with General Electric Healthcare and Medtronic Inc. The
1385 terms of these arrangements have been reviewed and approved by UCSD in accordance with its
1386 conflict-of-interest policies. A.M.D. is an inventor on a patent related to this work, filed by CorTechs Labs
1387 Inc. (9 US-7324842B2, filed 22 January 2002, published 29-01-2008). The other authors declare that
1388 they have no competing interests.
1389

1390 **Data availability**

1391 In this study we used brain imaging and genetics data from the UK Biobank
1392 [<https://www.ukbiobank.ac.uk/>], and GWAS summary statistics obtained from the Psychiatric Genomics
1393 Consortium [<https://www.med.unc.edu/pgc/shared-methods/>] and GWAS catalog
1394 [<https://www.ebi.ac.uk/gwas/>]. The summary statistics for cerebellar morphology derived in this study
1395 are available both in the GWAS Catalog [<https://www.ebi.ac.uk/gwas/>] and in our github repository
1396 [<https://github.com/norment/open-science>] (will make this public upon acceptance). FUMA results are
1397 available online (will make this public upon acceptance). The Human Genome Dating Dataset (HGD) is
1398 available at <https://human.genome.dating>.

1399

1400 **Code availability**

1401 All code and software needed to generate the results is available as part of public resources, specifically
1402 FreeSurfer (<https://surfer.nmr.mgh.harvard.edu>), SUIT (<https://github.com/jdiedrichsen/suit>), OPNMF
1403 (<https://github.com/asotiras/brainparts>), MOSTest (<https://github.com/precimed/mostest>), FUMA
1404 (<https://fuma.ctglab.nl/>), MAGMA (<https://ctg.cncr.nl/software/magma>), abagen
1405 (<https://github.com/rmarkello/abagen>), conjuncional FDR (<https://github.com/precimed/pleiofdr/>) and
1406 LD score regression (<https://github.com/bulik/ldsc>).
