36 inversion probes

37 **ABSTRACT**

38 The Zanzibar archipelago of Tanzania has become a low-transmission area for *Plasmodium falciparum*.
39 Despite being considered an area of pre-elimination for years, achieving elimination has been difficult,
40 likely due to a combination of imported infections from mainland Tanzania, and continued local
41 transmission. To shed light on these sources of transmission, we applied highly multiplexed genotyping
42 utilizing molecular inversion probes to characterize the genetic relatedness of 282 *P. falciparum* isolates
43 collected across Zanzibar and in Bagamoyo District on the coastal mainland from 2016-2018. Overall,
44 parasite populations on the coastal mainland and Zanzibar archipelago remain highly related. However,
45 parasite isolates from Zanzibar exhibit population microstructure due to rapid decay of parasite
46 relatedness over very short distances. This, along with highly related pairs within *shehias*, suggests
47 ongoing low level local transmission. We also identified highly related parasites across *shehias* that reflect
48 human mobility on the main island of Unguja and identified a cluster of highly related parasites, suggestive
49 of an outbreak, in the Micheweni district on Pemba island. Parasites in asymptomatic infections
50 demonstrated higher complexity of infection than those in symptomatic infections, but have similar core
51 genomes. Our data support importation as a main source of genetic diversity and contribution to the
52 parasite population on Zanzibar, but they also show local outbreak clusters where targeted interventions
53 are essential to block local transmission. These results highlight the need for preventive measures against
54 imported malaria and enhanced control measures in areas that remain receptive for malaria reemergence
55 due to susceptible hosts and competent vectors.

56 INTRODUCTION

57 Malaria cases in Tanzania comprise 3% of globally reported cases, but transmission is heterogeneous,
58 with the coastal mainland witnessing declining but substantial transmission of *Plasmodium falciparum*
59 (Alegana et al., 2021; World Health Organization, 2022). On the other hand, the archipelago of Zanzibar is
60 a pre-elimination setting, with low level seasonal transmission (Björkman et al., 2019). This is largely due
61 to the routine implementation of a combination of effective control measures, including robust vector
62 control and routine access to effective antimalarials (Björkman et al., 2019). Despite these efforts, malaria
63 has been difficult to eliminate from the archipelago. There are several reasons this may be the case: (1)
64 frequent importation of malaria from moderate or high transmission regions of mainland Tanzania and
65 Kenya (Björkman et al., 2019; Le Menach et al., 2011; Lipner et al., 2011; Monroe et al., 2019; Morgan et
66 al., 2020; Tatem et al., 2009); (2) ongoing local transmission due to residual vector capacity despite strong
67 vector control (Björkman et al., 2019); and (3) a reservoir of asymptomatic infections (Björkman & Morris,
68 2020; Björkman et al., 2019).

69
70 Parasite genomics has the potential to help us better understand malaria epidemiology by uncovering
71 population structure and gene flow, providing insight into changes in the parasite population including how
72 parasites move between regions (Neafsey et al., 2021). Genomics has previously been used to study
73 importation and transmission chains in other low transmission settings in Africa and elsewhere (H. H.
74 Chang et al., 2019; Fola et al., 2023; Morgan et al., 2020; Patel et al., 2014; Roh et al., 2019; Sane et al.,
75 2019). Previously, we had investigated the importation of malaria into Zanzibar from the mainland using
76 whole genome sequencing, showing highly similar populations within the mainland and within the
77 archipelago, but also identifying highly related parasite pairs between locations suggesting a role for
78 importation (Morgan et al., 2020). However, this work lacked sufficient samples to assess transmission of
79 parasites within Zanzibar. The larger and spatially rich sample set analyzed in this manuscript offers an
80 opportunity for more refined analyses of transmission across Zanzibar and how parasites are related to
81 those from coastal mainland.

82 A panel of molecular inversion probes (MIPs), a highly multiplexed genotyping assay, were designed in a
83 previous study to target single nucleotide polymorphisms (SNPs) throughout the *P. falciparum* genome
84 (Aydemir et al., 2018). We leveraged this assay to investigate the genetic epidemiology of parasites in the
85 coastal mainland and Zanzibar utilizing 391 samples collected from cross-sectional surveys of both
86 asymptomatic infections and symptomatic, uncomplicated malaria cases during 2016-2018. Specifically,
87 we use identity by descent analyses to compare the genetic relatedness of mainland and Zanzibari
88 parasites, and to investigate the geography/spatial relationships of genetically related parasites on the
89 archipelago. We further characterize how the genetic complexity of infections differ by clinical status and
90 describe patterns of antimalarial drug resistance polymorphisms in the parasite populations. In this low
91 transmission setting, these analyses characterize fine-scale local parasite populations that contribute to
92 continued transmission within the region, highlighting a key barrier to malaria elimination in the Zanzibar
93 archipelago.

94 METHODS

95 Samples from coastal Tanzania (178) and Zanzibar (213) were previously sequenced through multiple
96 studies (**Table 1, Supplemental Figure 1**). These samples include 213 dried blood spots (DBS) collected
97 in Zanzibar between February 2016 and September 2017, coming from cross-sectional surveys of
98 asymptomatic individuals ($n = 70$) and an *in vivo* efficacy study of artesunate-amodiaquine (ASAQ) with
99 single low dose primaquine (SLDP) in pediatric uncomplicated malaria patients in the western and central
100 districts of Unguja island and Micheweni District on Pemba island ($n = 143$) (Msellem et al., 2020). These
101 samples were geolocalized to *shehias*, the lowest geographic governmental designation of land in
102 Zanzibar, across its two main islands, Unguja and the northern region of Pemba (**Supplemental Figure**
103 **1**). Mainland Tanzania samples were collected in rural Bagamoyo District, where malaria transmission
104 persists, and residents frequently travel to Dar es Salaam, the major port from where travelers depart for
105 Zanzibar. Of the mainland Bagamoyo samples, 138 were whole blood collected from 2015-2017 as part of
106 an *in vivo* efficacy study of artemether-lumefantrine (AL) in pediatric uncomplicated malaria patients
107 (Topazian et al., 2022), and the remaining 40 samples were leukodepleted blood collected in 2018 from
108 asymptomatic but RDT-positive children who participated in a study investigating the transmission of *P.*
109 *falciparum* to colony reared mosquitos. This project leveraged molecular inversion probe (MIP) data from
110 SRA including PRJNA926345, PRJNA454490, PRJNA545345, and PRJNA545347.

111

112 In order to place coastal Tanzanian and Zanzibari samples in the context of African *P. falciparum*
113 population structure across multiple regions, MIP data from 147 whole blood samples collected in Ahero
114 District, Kenya from the same parasite clearance study were used (Topazian et al., 2022) in conjunction
115 with a subset of data from 2,537 samples genotyped for a study of the 2013 Demographic Health Survey
116 of the Democratic Republic of the Congo which included samples from DRC, Ghana, Tanzania, Uganda
117 and Zambia (Verity et al., 2020) (see **Supplemental Figure 2**).

118

119 Molecular Inversion Probe (MIP) Sequencing: Sequence data for the coastal Tanzanian and Zanzibari
120 samples were generated in a similar fashion across studies. Chelex extracted DNA from DBS and Qiagen

121 Miniprep (Qiagen, Germantown, MD) extracted DNA from leukodepleted blood were used in MIP
122 captures, which were then sequenced as previously described (Aydemir et al., 2018; Verity et al., 2020).
123 Control mixtures of 4 strains of genomic DNA from *P. falciparum* laboratory lines were also sequenced as
124 described previously (Verity et al., 2020). We utilized two MIP panels, one being a genome-wide single
125 nucleotide polymorphism (SNP) MIP panel and the second being a panel with the known drug resistance
126 markers in *Plasmodium falciparum* (Verity et al., 2020). These libraries were sequenced on Illumina
127 Nextseq 500 instrument using 150bp paired end sequencing with dual indexing using Nextseq 500/550
128 Mid-output Kit v2.

129

130 MIP variant Calling and Filtering:

131 MIP sequencing data was processed using *MIPTools* (<https://github.com/bailey-lab/MIPTools>), which first
132 merges reads and removes errors and Unique Molecular Identifier (UMI) redundancy with *MIPWrangler*
133 (Aydemir, unpublished). For the genome-wide panel, variant calling was performed using *FreeBayes* within
134 *MIPTools*, for a pooled continuous sample that was filtered for a minimum UMI depth of 10, a within
135 sample allele frequency threshold of 0.01 and a minimum alternate read count of 2 to obtain 5174 variant
136 SNP sites. Utilizing *bcftools* (version 1.15.1), the samples and loci were filtered to only the known targeted
137 SNPs, requiring a minor allele frequency threshold of 0.01, a sample missingness threshold of 10% and
138 loci missingness threshold of 15%. After filtering and subsetting to biallelic sites, 282 samples were left at
139 1270 loci. The final numbers of samples used for analysis by group are shown in **Table 1**. Sequencing
140 coverage estimates for loci are shown in **Supplemental Figure 3**.

141 For the drug resistance panel, variant calling was performed as above, with additional *FreeBayes*
142 parameters of a haplotype length of 3 and using the 30 best alleles at a given locus. Three aggregate
143 amino acid summary tables were created with reference amino acid UMI counts, alternate amino acid UMI
144 counts and the coverage depth for each variant, for a total of 309 samples at 2265 SNPs. We focused
145 analysis on the following key known and putative drug resistance molecular marker genes and
146 corresponding mutations: *P. falciparum* (*Pf*) chloroquine resistance transporter (*Pf*cr: C72S, M74I, N75E,
147 K76T, T93S, H97Y, F145I, I218F, A220S, Q271E, N326S, M343L, C350R, G353V, I356T, R371I), *Pf*

148 multidrug resistance 1 (Pfm₁: N86Y, Y184F, S1034C, N1042D, D1246Y), *Pf* dihydrofolate reductase
149 (Pfdhfr: A16V, N51I, C59R, S108N, I164L), *Pf* dihydropteroate synthase (Pfdhps: S436A, S436F, A437G,
150 K540E, A581G, A613T, A613S), *Pf* cytochrome *b* (Pfcy_{tb}: Y268N, Y268S, Y268C) and *Pf* kelch 13 (Pfk₁₃:
151 P441L, F446I, G449A, N458Y, C469F, C469Y, M476I, A481V, Y493H, R515K, P527H, N537I, N537D,
152 G538V, R539T, I543T, P553L, R561H, V568G, P574L, C580Y, R622I, A675V) (World Health
153 Organization, 2020). Prevalence was calculated separately in Zanzibar or mainland Tanzania for each
154 polymorphism by the number of samples with alternative genotype calls for this polymorphism over the
155 total number of samples genotyped and an exact 95% confidence interval using the Pearson-Klopper
156 method was calculated for each prevalence.

157

158 Analysis of Population Relatedness and Structure

159 To investigate genetic relatedness of parasites across regions, identity by descent (IBD) estimates were
160 assessed using the within sample major alleles (coercing samples to monoclonal by calling the dominant
161 allele at each locus) and estimated utilizing a maximum likelihood approach using the *inbreeding_mle*
162 function from the *MIPanalyzer* package (Verity et al., 2020). This approach has previously been validated
163 as a conservative estimate of IBD (Verity et al., 2020). Next, Principal Component Analysis (PCA) was
164 performed to query the comparative genetic variation of the samples through utilizing the genome-wide
165 SNP panel. We pruned 51 samples that had a pairwise IBD of greater than 0.90 to one randomly selected
166 sample as a representative of the clonal population to avoid clonal structure from dominating the analysis.
167 Within-sample allele frequencies were calculated, with an imputation step replacing missing values with
168 the median per each locus, and PCA was performed using the *prcomp* function (Verity et al., 2020) (*R*
169 version 4.2.1).

170 To include geographic information with querying genetic variation, Discriminant Analysis of Principal
171 Components (DAPC) analysis was used (Jombart, 2008). Pseudohaplotypes were created by pruning the
172 genotype calls at all loci for each sample into a single haplotype, and redundant haplotypes were removed
173 (282 reduced to 272 with unique pseudohaplotypes). DAPC was conducted at the district level, and
174 samples from districts with less than five samples (272 samples to 270 samples in 6 districts) were

175 retained (**Supplemental Figure 4B**). For the main DAPC analysis (**Figure 1B**), highly related isolates
176 were pruned to a single representative infection (272 reduced to 232) and then included districts with at
177 least 5 samples (232 reduced to 228 samples in 5 districts). The DAPC was performed using the
178 *adegenet* package (Jombart, 2008) with the first 80 PCs based on the cross-validation function *xvalDapc*.
179 To perform K-means clustering, a cluster K of 1 was assigned to the mainland samples while the *kmeans*
180 package was used to find the optimal K to cluster the Zanzibar *shehias* by latitude and longitude. The K-
181 means clustering experiment was used to cluster a continuous space of geographic coordinates in order
182 to compare genetic relatedness in different regions. We selected K = 4 as the inflection point based on the
183 elbow plot (**Supplemental Figure 5**) and based the number to obtain sufficient subsections of Zanzibar to
184 compare genetic relatedness.

185 To investigate how genetic relatedness varies as distance between pairs increases, isolation by distance
186 was performed across all of Zanzibar and within the islands of Unguja and Pemba. The greater circle (GC)
187 distances between each *shehia* centroid were calculated (within *shehia* distances were equal to 0) to find
188 the distance between each *shehia* in geographic space. Distances were then binned at increments
189 reflecting the max GC distances between regions, which was smallest in Pemba at 12km and much larger
190 for both Unguja (58km) and all of Zanzibar (135km). Within each binned group, mean IBD with 95% CIs
191 are plotted. For graphing IBD connections at the between and within *shehia* level, an IBD threshold of 0.25
192 (half-siblings) or greater was used (**Figure 4, Supplemental Figure 6, Supplemental Figure 7**). In
193 graphing IBD connections at larger distances between islands or between coastal mainland Tanzania and
194 Zanzibar, a between IBD value of 0.125 (quarter-siblings) or greater was used (**Supplemental Figure 8,**
195 **Supplemental Figure 9**). These plots were created utilizing *ggraph* in *R* with the nodes being samples
196 and the edges being IBD estimates.

197 Complexity of Infection (COI), or the number of parasite clones in a given sample, was determined using
198 *THE REAL McCOIL* (v2) categorical method (H.-H. Chang et al., 2017) and the 95% CI was calculated
199 utilizing a nonparametric bootstrap. Fws statistic, which is used to compare the diversity within and
200 between samples in a population, was calculated in *R* version 4.2.1 through the formula, $(1 - H_w)/H_p$,
201 where H_w is the within-sample heterozygosity and H_p is the heterozygosity across the population, and

202 95% CIs were calculated utilizing a nonparametric bootstrap. The mean prevalence of antimalarial drug
203 resistance polymorphisms and 95% CIs were calculated using a nonparametric bootstrap method.

204 RESULTS

205 Zanzibari falciparum parasites were closely related to coastal mainland parasites but showed higher within
206 than between population IBD and evidence of microstructure on the archipelago. To examine geographic
207 relatedness, we first used principal component analysis (PCA). Zanzibari parasites are highly related to
208 other parasites from East Africa and more distantly related to Central and West African isolates
209 (**Supplemental Figure 2**). PCA analysis of 232 coastal Tanzanian and Zanzibari isolates, after pruning 51
210 samples with an IBD of greater than 0.9 to one representative sample, demonstrates little population
211 differentiation (**Figure 1A**).

212 However, after performing K-means clustering of *shehias* in Zanzibar and mainland Tanzania, parasites
213 within each population show more highly related pairs within their respective clusters than between
214 clusters (**Figure 2**). Comparisons of parasite pairs between Zanzibar and coastal Tanzania showed no
215 pairs with an IBD greater than 0.20 (**Figure 2, Supplemental Figure 8**). Similarly, no pairs with an IBD of
216 0.20 or greater were present in pairwise comparisons between Unguja and Pemba (**Supplemental Figure**
217 **9**).

218 To further assess the differentiation within the parasite population in Zanzibar, we conducted Discriminant
219 Analysis of Principal Components (DAPC) according to the districts of origin for each isolate. Parasites
220 differentiated geographically, with less variation near the port of Zanzibar town and more differentiation in
221 isolates collected in districts further from the port (**Figure 1B**). This underlying microstructure is also
222 supported by classic isolation by distance analysis (**Figure 3, Supplemental Figure 10**). Isolation by
223 distance analysis across all of Zanzibar and within Unguja showed rapid decay of relatedness over very
224 short geographic distances (**Figure 3A and 3B**). Interestingly in Pemba, mean IBD remained at a similar
225 relatively high level even at longer distances (**Figure 3C**).

226 Within Zanzibar, parasite clones are shared within and between shehias suggesting local outbreaks.

227 Among the sample pairs in Zanzibar that are highly related (IBD of 0.25 or greater), we see different
228 patterns of genetic relatedness suggesting common local and short distance transmission of clones and

229 occasional long distance transmission (**Figure 4**). In Unguja (**Figure 4A**), we see multiple identical or near
230 identical parasite pairs shared over longer distances, suggesting longer distance gene flow, as well as
231 multiple *shehias* containing highly related pairs. In Northern Pemba, there is one large cluster of highly
232 related parasites shared within and between six *shehias* (**Figure 4B**). Network analysis (**Figure 4C**) for all
233 sample pairs with an IBD of greater than 0.25 from these *shehias* illustrates this, with pairs linked by
234 yellow lines showing the highest IBD. The largest network represents two highly related clusters (groups
235 linked by yellow edges, mean IBD of 0.99) connected by a highly related intermediate (FMH42),
236 suggesting that the clusters are related though parasites that have recombined while on the archipelago.
237 FMH42 links the lower cluster with pairwise IBD of 0.65 and the upper cluster with a pairwise IBD of 0.27.
238 These symptomatic isolates collected from February 2016 to September 2017 in northern Pemba likely
239 derive from sustained transmission from a seeding event.

240 Network analysis of within *shehia* pairwise IBD sharing in Unguja again shows that there is close
241 relatedness on this small geographic scale (**Supplemental Figure 6**). A cluster of four isolates in the
242 Shakani *shehia* on Unguja island with pairwise IBDs of 0.99 likely reflects ongoing transmission within
243 Shakani, with similar connections in Bambi and Dimani. Meanwhile, a few distant connections likely reflect
244 the extent of human mobility on the island (**Figure 4A**). Similar within district networks on the mainland are
245 shown in **Supplemental Figure 7**.

246 Compared to symptomatic infections, asymptomatic infections demonstrate greater genetic complexity,
247 especially in coastal Tanzania. Asymptomatic infections were compared to roughly contemporaneously
248 collected isolates from those presenting with acute, uncomplicated malaria. Asymptomatic infections
249 demonstrated greater COI than symptomatic infections, on both the coastal mainland (mean COI 2.5 vs.
250 1.7, $p < 0.05$, Wilcoxon-Mann-Whitney test) and in Zanzibar (mean COI 2.2 vs. 1.7, $p = 0.05$, Wilcoxon-
251 Mann-Whitney test) (**Figure 5A**). A similar pattern was seen when evaluating Fws, which measures the
252 diversity within a sample compared to the population, with lower Fws in asymptomatic samples consistent
253 with higher within host complexity, with a more pronounced difference on the mainland (**Figure 5B**).
254 Despite these differences, parasites from asymptomatic and symptomatic infections tended to cluster

255 together in PCA analysis, suggesting their core genomes are genetically similar and do not vary based on
256 clinical status (**Figure 1A**).

257 *Drug resistance mutations did not vary between populations.* The prevalence of the drug resistance
258 genotypes were quite similar in Zanzibar and coastal Tanzania (**Table 2**). The frequencies of five
259 mutations associated with sulfadoxine/pyrimethamine resistance (Pfdhfr: N51I, C59R, S108N, Pfdhps:
260 A437G, K540E) were quite high with prevalences at or above 0.90. Pfcrt mutations associated with
261 chloroquine and amodiaquine resistance (M74I, N75E, K76T) were all present at approximately 0.05
262 prevalence (Djimdé et al., 2001; Holmgren et al., 2006). For Pfmdr1, wild type N86 and D1246 were
263 dominant at 0.99 prevalence, which are associated with reduced susceptibility to lumefantrine (Sisowath
264 et al., 2005). No World Health Organization validated or candidate polymorphism in Pfk13 associated with
265 artemisinin resistance were found.

266

267 DISCUSSION

268 In this study, we leverage high-throughput targeted sequencing using molecular inversion probes (MIPs)
269 to characterize the populations and the relationships of *P. falciparum* isolates in Zanzibar and coastal
270 mainland Tanzania. The parasite populations appear to be highly related to each other (**Figure 1A**) when
271 evaluated using SNPs in the core genome. Interestingly, within Zanzibar, structure could be observed,
272 with parasites closer to the main ferry terminal in Zanzibar town clustered more closely with coastal
273 mainland parasites (**Figure 1B, Supplemental Figure 1**) compared to parasites that were more
274 geographically distant. This, in combination with the evidence of rapid decline of genetic relatedness with
275 distance on the archipelago (**Figure 3**), is consistent with population microstructure within the island chain.
276 This microstructure within the archipelago is supported by K-means clustering where Zanzibari isolates
277 show higher within cluster than between cluster IBD (**Figure 2**). It is also consistent with isolates with
278 higher IBD (**Figure 4A and B**) in Unguja and Pemba compared to a maximum IBD of 0.20 between
279 Zanzibar and coastal mainland Tanzania (**Supplemental Figure 8**) or between Unguja and Pemba
280 (**Supplemental Figure 9**). Parasite populations within the very low transmission region of Zanzibar may
281 be more isolated than expected, allowing them to differentiate from each other. This may be indicative of
282 very effective local malaria control, yet with continued micro-transmission remaining. Thus, directly
283 targeting local malaria transmission, including the asymptomatic reservoir which contributes to sustained
284 transmission (Barry et al., 2021; Sumner et al., 2021), may be an important focus for ultimately achieving
285 malaria control in the archipelago (Björkman & Morris, 2020). Currently, a reactive case detection program
286 within index case households is being implemented, but local transmission continues and further
287 investigation into how best to control this is warranted ([Mkali et al., 2023](#)).

288 Despite the overall genetic similarity between archipelago populations, we did not find parasite pairs with
289 high levels of IBD between the coastal mainland and Zanzibar, with the highest being 0.20. While this
290 level still represents a significant amount of genetic sharing, similar to a cousin, the lack of higher levels
291 does not allow us to identify specific importation events. This is largely due to the study design, which is

292 based on convenience sampling, the relatively low numbers of samples and lack of sampling from all
293 mainland travel hubs (Bisanzio et al., 2023). Sampling was also denser in Unguja compared to Pemba.
294 On the other hand, we see clear transmission of highly related parasites within each population (IBD >
295 0.99). In Zanzibar, highly related parasites mainly occur at the range of 20-30km. These results are similar
296 to our previous work using whole genome sequencing of isolates from Zanzibar and mainland Tanzania,
297 showing increased within population IBD compared to between population IBD (Morgan et al., 2020). The
298 network of highly related *P. falciparum* parasites from 6 *shehias* in North Pemba provides an excellent
299 example of likely recent near clonal transmission, consistent with an outbreak (**Figure 4C**). A recent study
300 investigating population structure in Zanzibar also found local population microstructure in Pemba
301 (Holzschuh et al., 2023). Further, both studies found near-clonal parasites within the same district,
302 Micheweni, and found population microstructure over Zanzibar. Overall, given the findings of
303 microstructure with significant local sharing of highly related strains, these small clusters still potentially
304 drive much of the malaria transmission that occurs within the archipelago through routine human
305 movement or mosquito travel between locales (Huestis et al., 2019). Less frequent longer distance
306 transmission events also occur, likely due to longer range human migration within the islands.

307 Asymptomatic parasitemia has been shown to be common in falciparum malaria around the globe and has
308 been shown to have increasing importance in Zanzibar (Lindblade et al., 2013; Morris et al., 2015). What
309 underlies the biology and prevalence of asymptomatic parasitemia in very low transmission settings where
310 anti-parasite immunity is not expected to be prevalent remains unclear (Björkman & Morris, 2020). Similar
311 to a few previous studies, we found that asymptomatic infections had a higher COI than symptomatic
312 infections across both the coastal mainland and Zanzibar parasite populations (Collins et al., 2022;
313 Kimenyi et al., 2022; Sarah-Matio et al., 2022). Other studies have found lower COI in severe vs. mild
314 malaria cases (Robert et al., 1996) or no significant difference between COI based on clinical status
315 (Conway et al., 1991; Earland et al., 2019; Kun et al., 1998; Lagnika et al., 2022; Tanabe et al., 2015). In
316 Zambia, one study suggested that infections that cause asymptomatic infection may be genetically
317 different than those that cause symptomatic infection (Searle et al., 2017). However, this study included

318 samples collected over different time periods and relied on a low-density genotyping assay which only
319 investigated the diversity of 24 single nucleotide polymorphisms across the genome. Here, based on
320 SNPs throughout the core genome, we did not see differential clustering of asymptomatic or symptomatic
321 infections in Zanzibar or the mainland (**Figure 1A**), suggesting that these parasite populations remain
322 similar when comparing clinical status. However, this genotyping approach does not address potential
323 variation in the many hypervariable gene families that encode genes known to be associated with
324 pathogenesis (e.g. *var*, *rifin* and *stevor* genes) and does not address differences in expression of genes
325 associated with pathogenesis that may reflect differences in the populations. Investigation with other
326 methods, such as long-read genome sequencing and transcriptional profiling, would be needed to address
327 these differences.

328 While mutations for partial artemisinin resistance were not observed in K13, other antimalarial resistant
329 mutations of concern were observed. Validated drug resistance mutations linked to
330 sulfadoxine/pyrimethamine resistance (Pfdhfr-N51I, Pfdhfr-C59R, Pfdhfr-S108N, Pfdhps-A437G, Pfdhps-
331 K540E) were found at high prevalence (**Table 2**). Prevalence of polymorphisms associated with
332 amodiaquine resistance (Pfcrt-K76T, Pfmdr1-N86Y, Pfmdr1-Y184F, Pfmdr1-D1246Y) were seen at similar
333 proportions as previous reports (Msellem et al., 2020). The wild-type Pfmdr1-N86 was dominant in both
334 mainland and archipelago populations, concerning for reduced lumefantrine susceptibility. Although
335 polymorphisms associated with artemisinin resistance did not appear in this population, continued
336 surveillance is warranted given emergence of these mutations in East Africa and reports of rare resistance
337 mutations on the coast consistent with spread of emerging Pfk13 mutations (Moser et al., 2021).

338 Overall, parasites between Zanzibar and coastal mainland Tanzania remain highly related, but population
339 microstructure on the island reflects ongoing low level transmission in Zanzibar, partially driven by
340 asymptomatic infections that potentially constitute a long-term reservoir. This is likely the result of the
341 continued pressure on the population through the implementation of effective control measures. In this
342 study, parasite genomics allows us to parse differences in parasite populations and reveals substructure
343 in an area of low transmission intensity. A recent study identified “hotspot” *shehias*, defined as areas with

344 comparatively higher malaria transmission than other *shehias*, near the port of Zanzibar town and in
345 northern Pemba (Bisanzio et al., 2023). These regions overlapped with *shehias* in this study with high
346 levels of IBD, especially in northern Pemba (**Figure 4**). These areas of substructure represent parasites
347 that differentiated in relative isolation and are thus important locales to target intervention to interrupt local
348 transmission (Bousema et al., 2012). While a field cluster-randomized control trial in Kenya targeting these
349 hotspots did not confer much reduction of malaria outside of the hotspot (Bousema et al., 2016), if areas
350 are isolated pockets, which genetic differentiation can help determine, targeted interventions in these
351 areas are likely needed, potentially through both mass drug administration and vector control (Morris et
352 al., 2018; Okell et al., 2011). Such strategies and measures preventing imported malaria could accelerate
353 progress towards zero malaria in Zanzibar.

354 **ETHICAL APPROVALS AND CONSENT TO PARTICIPATE**

355 This analysis was approved by the IRBs at the University of North Carolina at Chapel Hill (15-1989, 17-
356 0166, 18-1090), Muhimbili University of Health and Allied Sciences (MUHAS), Zanzibar Medical Research
357 Ethical Committee and the Regional Ethics Review Board, Stockholm, Sweden.

409 ‡Prevalence was calculated as described in the methods. 95% CI of these polymorphisms were
 410 calculated through the Pearson-Klopper method.

411 §The number of genotyped samples per loci is also shown for each polymorphism.

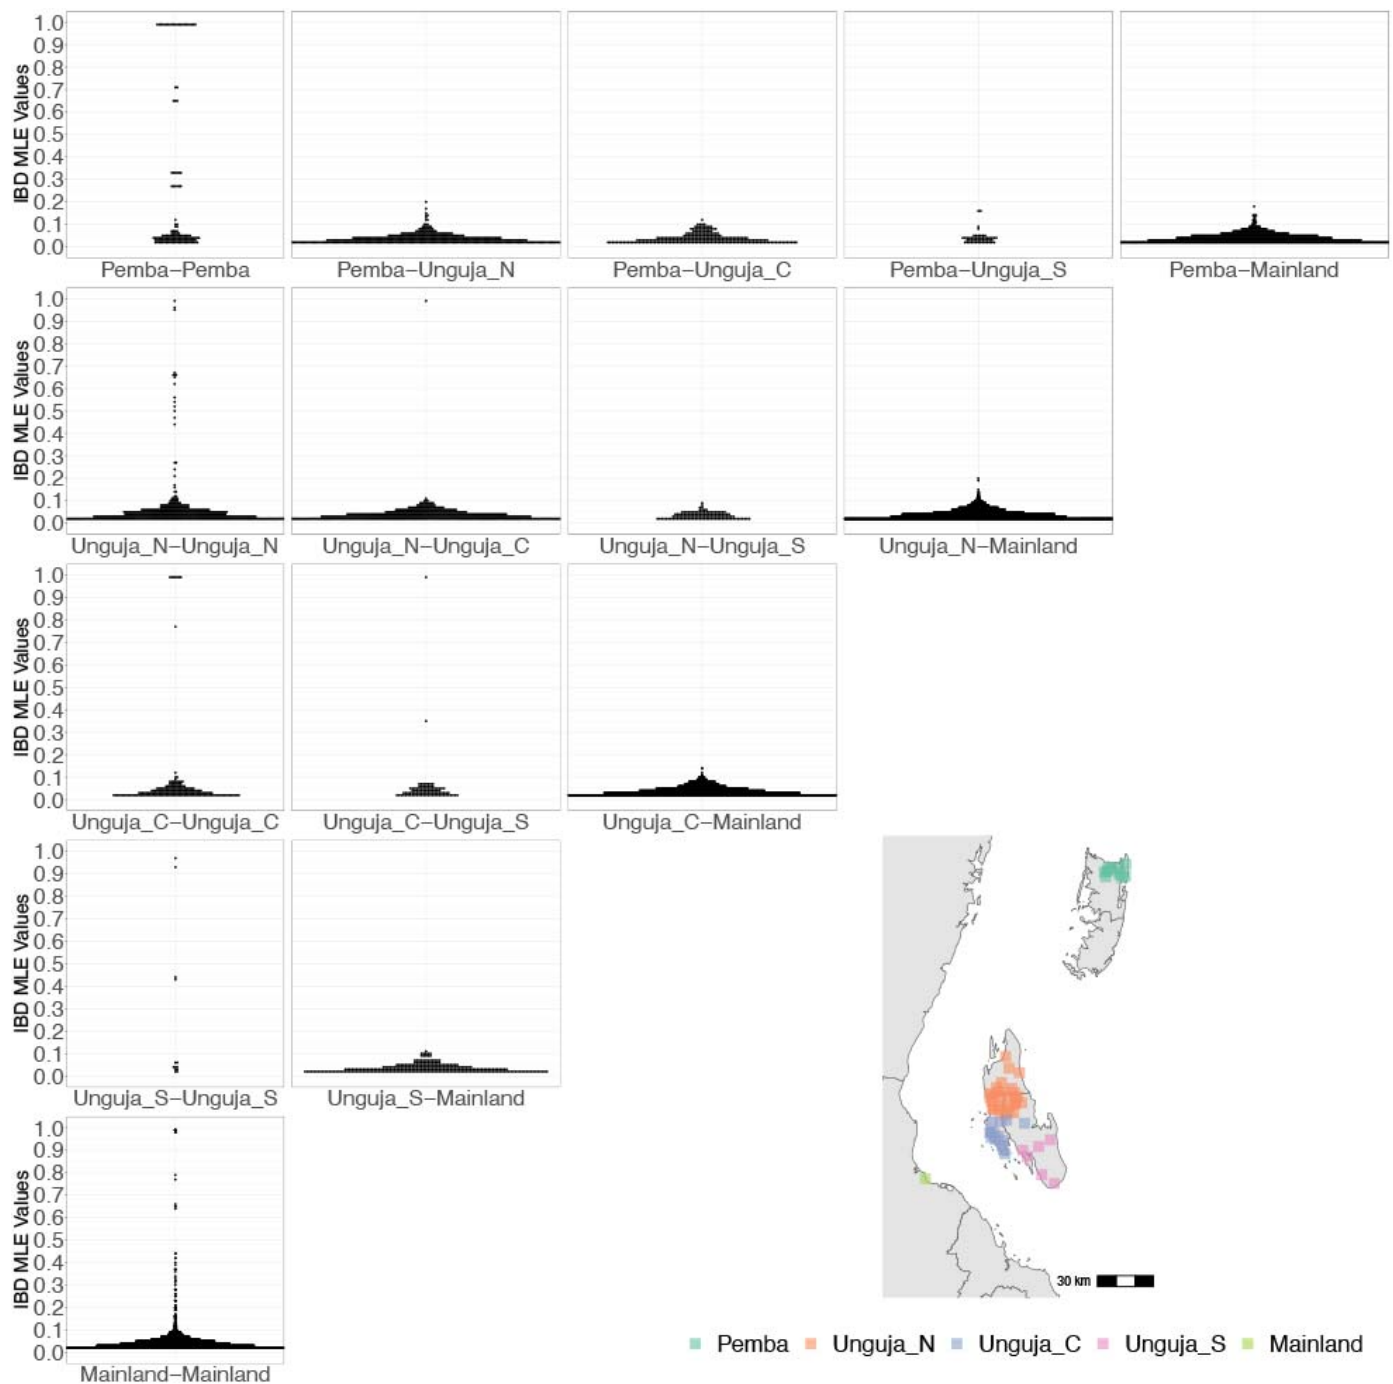

412 **FIGURES**

413

414 **Figure 1. Parasites between Zanzibar and coastal mainland Tanzania are highly related but**
415 **microstructure within Zanzibar is apparent. A)** Principal Component Analysis (PCA) comparing
416 parasites from symptomatic vs. asymptomatic patients from coastal Tanzania and Zanzibar. Clusters with
417 an identity by descent (IBD) value of greater than 0.90 were limited to a single representative infection to
418 prevent local-structure of highly related isolates within *shenhias* from driving clustering. **B)** A Discriminant
419 Analysis of Principal Components (DAPC) was performed utilizing isolates with unique pseudohaplotypes,
420 pruning highly related isolates to a single representative infection. Districts were included with at least 5
421 isolates remaining to have sufficient samples for the DAPC. For plotting the inset map, the district
422 coordinates (e.g. Mainland, Kati, etc.) are calculated from the averages of the *shenhia* centroids within each
423 district.

424

425

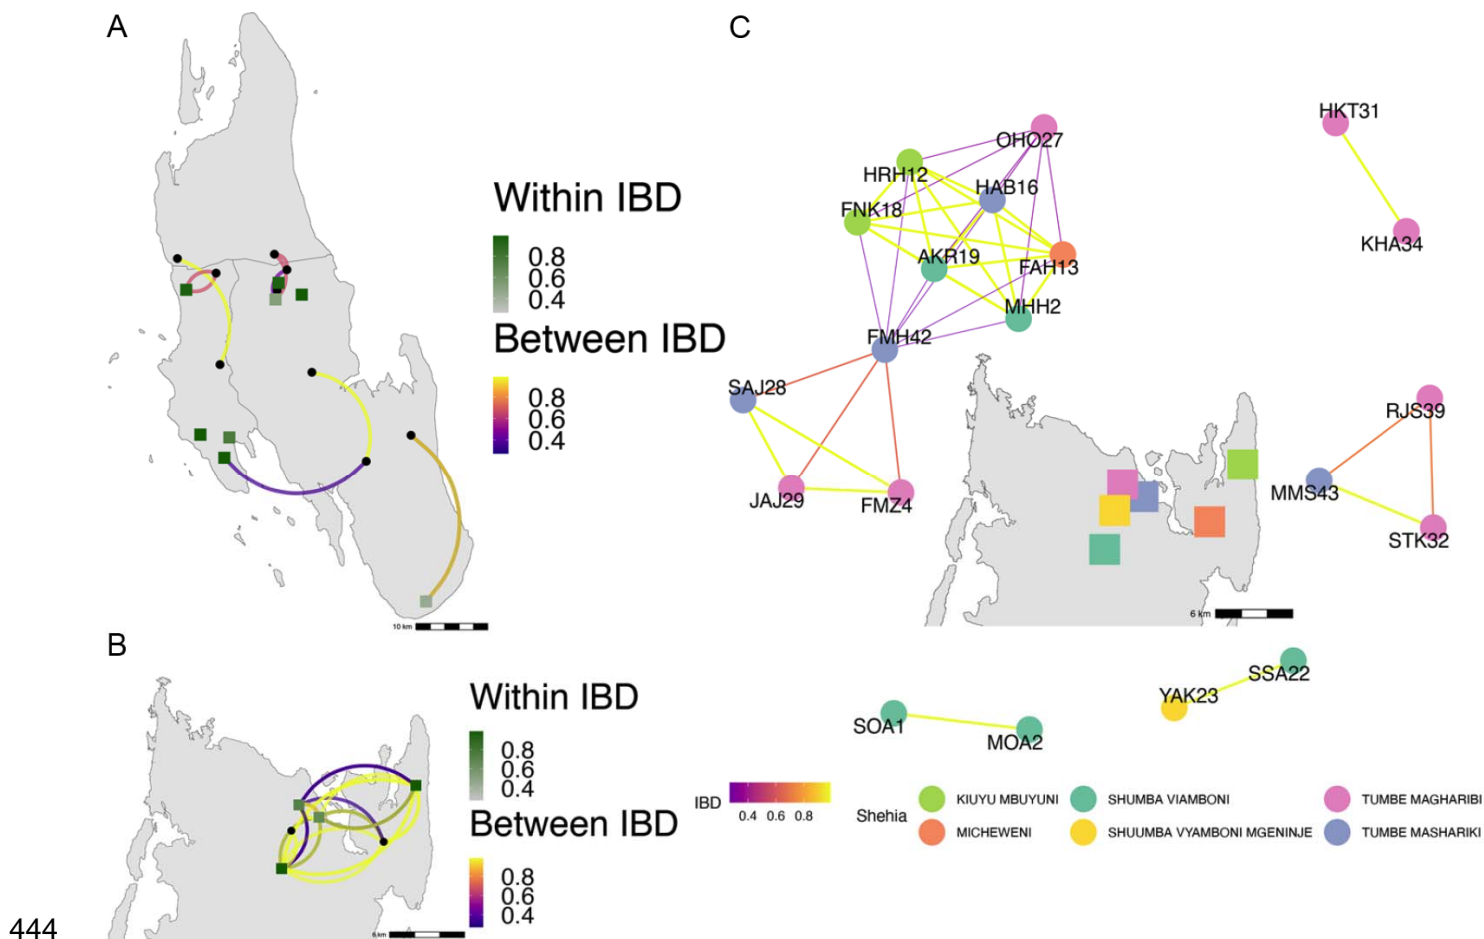

426 **Figure 2. Coastal Tanzania and Zanzibari parasites have more highly related pairs within their**
 427 **given region than between regions.** K-means clustering of *shehia* coordinates was performed using
 428 geographic coordinates all *shehias* present from the sample population to generate 5 clusters (colored
 429 boxes). All *shehias* were included to assay pairwise IBD between differences throughout Zanzibar. K-
 430 means cluster assignments were converted into interpretable geographic names Pemba, Unguja North
 431 (Unguja_N), Unguja Central (Unguja_C), Unguja South (Unguja_S) and mainland Tanzania (Mainland).
 432 Pairwise comparisons of within cluster IBD (column 1 of IBD distribution plots) and between cluster IBD
 433 (column 2-5 of IBD distribution plots) was done for all clusters. All IBD values greater than 0 were plotted
 434 for each comparison. In general, within cluster IBD had more pairwise comparisons containing high IBD

435 identity.

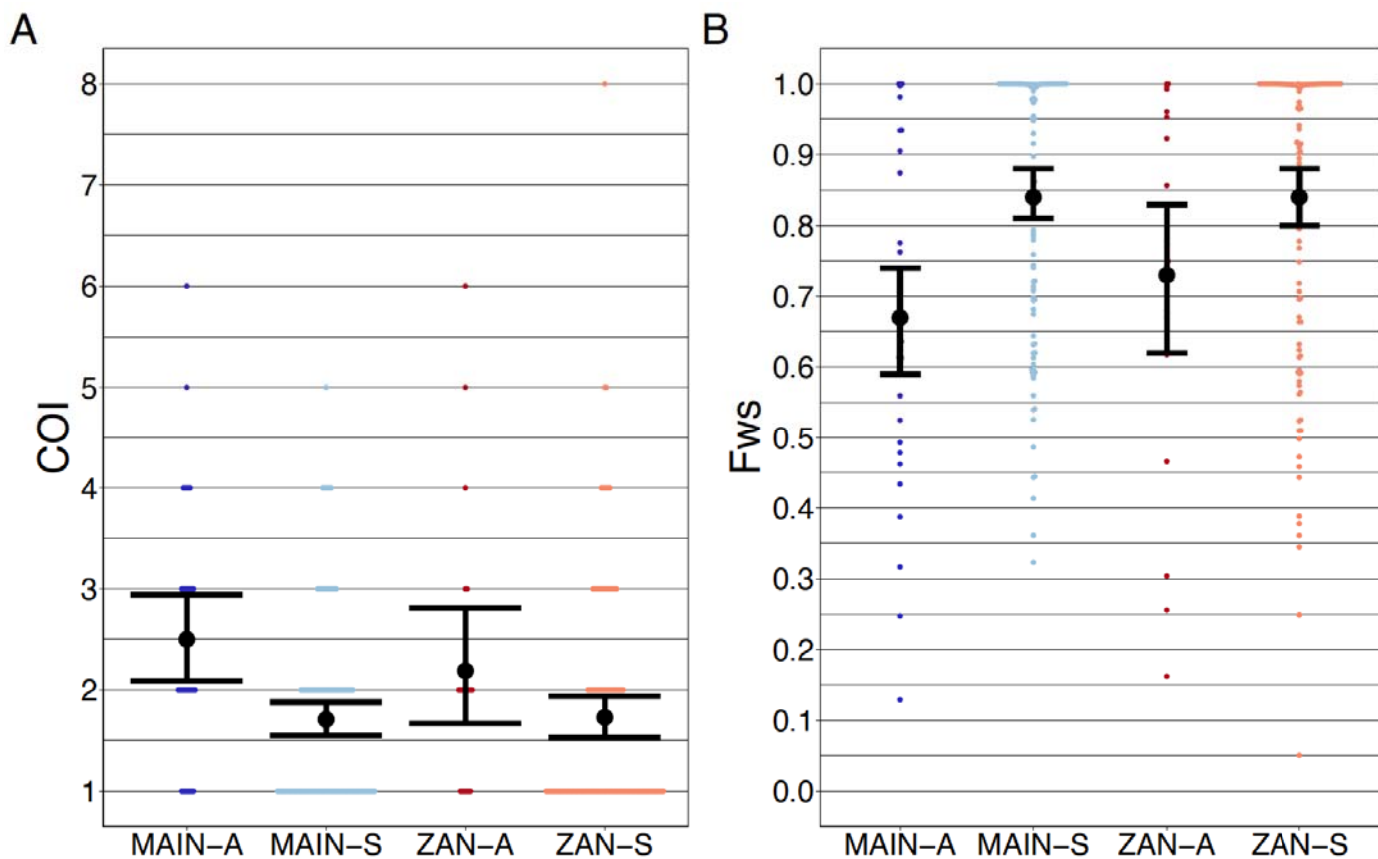

436

437 **Figure 3. Isolation by distance is shown between all Zanzibari parasites (A), only Unguja parasites**
438 **(B) and only Pemba parasites (C).** Samples were analyzed based on geographic location, Zanzibar
439 (N=136) (A), Unguja (N=105) (B) or Pemba (N=31) (C) and greater circle (GC) distances between pairs of
440 parasite isolates were calculated based on *shehia* centroid coordinates. These distances were binned at
441 4km increments out to 12 km. IBD beyond 12km is shown in **Supplemental Figure 8**. The maximum GC
442 distance for all of Zanzibar was 135km, 58km on Unguja and 12km on Pemba. The mean IBD and 95% CI
443 is plotted for each bin.

444

445 **Figure 4. Highly related pairs span long distances across Zanzibar.** Sample pairs were filtered to
 446 have IBD estimates of 0.25 or greater. Within *shehia* pairwise IBD estimates are shown within Unguja
 447 (**Panel A**) and Pemba (**Panel B**) as single points, with dark orange representing the greatest degree of
 448 IBD. *Shehias* labeled with black dots do not have within IBD estimates of .25 or greater. Between *shehia*
 449 IBD reflects pairs of parasites with IBD greater than or equal to 0.25, with the color of the connecting arc
 450 representing the degree of IBD and yellow representing maximal connectivity. **Panel C** shows the network
 451 of highly related pairs (IBD >0.25) within and between the 6 northern Pemba *shehias* (note: Micheweni is
 452 a *shehia* in Micheweni district). Samples (nodes) are colored by *shehia* and IBD estimates (edges) are
 453 represented on a continuous scale with increasing width and yellow-shading indicating higher IBD.

454

455 **Figure 5. Complexity of infection (COI) and Fws metric shows a higher COI and lower Fws in**
456 **asymptomatic than symptomatic infections in both mainland Tanzania and Zanzibar isolates.** COI
457 (A) was estimated by the REAL McCOIL's categorical method (H.-H. Chang et al., 2017). Mean COI for
458 asymptomatic was greater than symptomatic infections for all regions (MAIN-A: 2.5 (2.1-2.9), MAIN-S: 1.7
459 (1.6-1.9), $p < 0.05$, Wilcoxon-Mann-Whitney test and ZAN-A: 2.2 (1.7-2.8), ZAN-S: 1.7 (1.5-1.9), $p = 0.05$,
460 Wilcoxon-Mann-Whitney test). Fws (B) was estimated utilizing the formula, $(1 - H_w)/H_p$, where H_w is the
461 within-sample heterozygosity and H_p is the heterozygosity across the population. Mean Fws was less in
462 asymptomatic than symptomatic samples (MAIN-A: 0.67 (0.6-0.7), MAIN-S: 0.85 (0.8-0.9), $p < 0.05$,
463 Wilcoxon-Mann-Whitney test and ZAN-A: 0.73 (0.6-0.8), ZAN-S: 0.84 (0.8-0.9), $p = 0.05$, Wilcoxon-Mann-
464 Whitney test). A nonparametric bootstrap was applied to calculate the mean and 95% confidence interval
465 (C) from the COI and Fws values.
