28 **Highlights**

29 □ Omicron fragments were detected in the sewershed samples prior to clinical
30 samples.

31 □ Omicron sub-lineages BA.2.12, BA.2.38, BA.2.75, BA.3, BA.4, and XBB were
32 prevalent.

33 □ Lineage composition analysis indicated transition from Delta to Omicron variant
34 indicated cause of third wave in India.

35 □ Overall, 426 lineages of 17 highly transmissible variants of SARS-CoV-2 were
36 detected in the study.

37

38 **Abstract**

39 The COVID-19 pandemic has emphasized the urgency for rapid public health
40 surveillance methods in early detection and monitoring of the transmission of
41 infectious diseases. The wastewater-based epidemiology (WBE) has emerged as a
42 promising tool to analyze and enumerate the prevalence of infectious pathogens in a
43 population ahead of time. In the present study, real time quantitative polymerase chain
44 reaction (RT-qPCR) and Illumina sequencing was performed to determine the SARS-
45 CoV-2 load trend and dynamics of variants over a longitudinal scale in 442
46 wastewater (WW) samples collected from 10 sewage treatment plants (STPs) of Pune
47 city, India, during November 2021 to April-2022. In total 426 distinct lineages
48 representing 17 highly transmissible variants of SARS-CoV-2 were identified. The
49 SARS-CoV-2 Omicron variant fragments were detected in WW samples prior to its
50 detection in clinical cases. Moreover, highly contagious sub-lineages of Omicron,
51 such as BA.2.12 (0.8-0.25%), BA.2.38 (0.8-1.0%), BA.2.75 (0.01-0.02%), BA.3
52 (0.09-6.3%), BA.4 (0.24-0.29%), and XBB (0.01-13.7%) fragments were significantly
53 detected. The longitudinal analysis also suggested the presence of the BA.5 lineage in
54 November 2021, which was not reported in the clinical settings throughout the
55 duration of this study, indicative of silent variant persistence. Overall, the present
56 study demonstrated the practicality of WBE in early detection of SARS CoV-2
57 variants, which could be useful in tracking future outbreaks of SARS-CoV-2. Such
58 approaches could be implicated in the monitoring of the infectious agents before they
59 appear in clinical cases.

69 **1. Introduction**

70 The SARS-CoV-2 pandemic, initially detected in Wuhan, China in 2019,
71 spreads rapidly all over the world (Global research on coronavirus disease (COVID-
72 19),” W.H.O). As the virus spreads, the emergence of new variants has become a
73 concern for public health officials. The clinical testings have limitations in detecting
74 and tracking the spread of variants (Faria et al., 2021; Li et al., 2020). Also, the
75 SARS-CoV-2 virus epidemic has sparked global efforts to understand its transmission
76 dynamics and the emergence of new variations (Kucirka et al., 2020; Rambaut et al.,
77 2020). To address this challenge, researchers have begun exploring alternative
78 methods for monitoring the spread of SARS-CoV-2, such as wastewater-based
79 epidemiology (WBE) (de Roda Husman et al., 2020; van der Meer et al., 2020).

80 WBE involves analyzing viral particles present in sewage to infer the spread
81 of infection within a population. WBE has been used to study other viral diseases,
82 such as influenza and hepatitis E (Heijnen and Medema, 2011; Rosa et al., 2014), and
83 has recently been applied to SARS-CoV-2. Studies by Peccia et al., 2020b and Ahmed
84 et al., 2022 have provided essential insights into the feasibility and applicability of
85 WBE for SARS-CoV-2, highlighting its potential as an early detection system for
86 population infection dynamics. Several studies have been conducted globally, with
87 notable contributions from researchers in Germany, Italy, Netherlands, Finland, USA,
88 Japan, France, Canada and India (Maida et al., 2022; Tiwari et al., 2022b; Prado et al.,
89 2021; Stephens et al., 2022; Ho et al., 2022; Amman et al., 2022; Kumar et al., 2020).
90 These studies provides essential information on the detection, quantification and
91 genetic characterization of SARS-CoV-2 in sewage samples (Srivastava et al., 2021;
92 Dharmadhikari et al., 2022; Lamba et al., 2023). The WBE has the potential to detect
93 viral signals earlier than clinical surveillance methods and can offer a less biased
94 assessment of viral heterogeneity and public health (Joshi et al., 2022; Jahn et al.,
95 2022; Morvan et al., 2022). The ongoing COVID-19 outbreak has brought attention to
96 the need for rapid and accurate surveillance of the spread of SARS-CoV-2.

97 The impact of SARS-CoV-2 has been felt globally since its emergence in 2019
98 (Chakraborty and Maity, 2020). The virus, which causes COVID-19, has resulted in
99 substantial interruptions to everyday life and economic activities, as well as
100 widespread disease and death. (Shang et al., 2021, Li et al., 2020). One of the critical

101 concerns in the COVID-19 epidemic is the advent of novel SARS-CoV-2 variants,
102 which may be more transmissible and lead to more severe disease (Aleem et al., 2022).
103 Omicron variant is known to be associated with a high number of cases across the
104 globe (Nyberg et al., 2022). The virus has significantly impacted India, with several
105 clinical cases and deaths reported (Ranjan, 2022). Among the Indian cities affected,
106 Pune has recorded one of the highest numbers of SARS-CoV-2 Omicron cases. To
107 comprehend the propagation and evolution of SARS-CoV-2, researchers have used
108 next-generation sequencing (NGS) platforms to analyze genomic sequences of the
109 virus. These studies have shown that different SARS-CoV-2 variants have emerged in
110 vast geographical areas, with varying infectivity and transmission capability levels. In
111 light of this, NGS platforms have proven to be a valuable tool in understanding the
112 evolution of the virus and the dangers it poses to society. Studies by Agrawal et al.,
113 2022 in Germany, Landgraff et al., 2021 in Canada, Wilton, 2021 in London, Crits-
114 Christoph, 2021 in California, and Dharmadhikari et al., 2022 in India have used NGS
115 platforms to identify SARS-CoV-2 mutations in wastewater. These studies have
116 proven that WBE can capture SARS-CoV-2 and its mutants in wastewater, providing
117 insight into the spread of the virus in communities.

118 The present study is the first in-depth longitudinal study employing
119 wastewater-based SARS-CoV-2 sequencing to delineate the overall dynamics of
120 SARS-CoV-2 lineages in Pune city, India. Here, we utilized WBE to monitor the
121 emergence of SARS-CoV-2 variants, specifically the Omicron lineage in Pune City,
122 analyzing its presence in wastewater samples and assessing its impact on the local
123 population and healthcare system. Understanding the dynamics of the Omicron
124 variant and its sub-lineages will provide insights that can inform public health
125 response and help mitigate the spread of the virus. To achieve our objectives, we
126 systematically analyzed wastewater samples collected from different locations in
127 Pune City, using RT-qPCR and sequencing techniques to detect and quantify the
128 presence of the Omicron variant. This study will provide critical insights into the
129 dynamics of the Omicron variant in Pune City and inform the development of
130 effective public health measures to combat its spread.

131 **2. Materials and Methods**

132 **2.1. Wastewater sample collection and SARS-CoV-2 sequencing**

133 Sewage wastewater samples were taken from the inlets of 10 sewage treatment
134 plants (STPs) in Pune (Fig.1, Table.S1). The sample collection included a grab-
135 sampling method, executed following the CDC, USA guidelines of COVID-19
136 wastewater sampling, and approved by the Institutional Biosafety Committee (IBSC).
137 Sampling was carried out two times in a week from 10 STPs, in the period of
138 November 2021 - April 2022 in 1L sterile polypropylene bottles and stored at 4°C
139 until processing. The processing was carried out immediately as per CDC, USA
140 guidelines of COVID-19 sewage water sampling. The sampling bottle was wiped
141 with 70% ethanol and subjected to heat inactivation at 60°C. 80 ml of the sample was
142 aliquoted in a 250 ml HDPE bottle (HiMedia, India) and subjected to viral RNA
143 concentration using the polyethylene glycol (PEG) precipitation method. The detailed
144 protocol of sample processing and RT-qPCR is given in supplementary information
145 (Supplementary File.2) Sequencing was carried out at Next Generation Genomics
146 facility at IISER, Pune, India. The library preparation was carried out using Illumina
147 Covid seq RUO kits (Illumina, USA). Sequencing was carried out using Illumina
148 NextSeq 550 sequencer.

149 **2.2. Bioinformatics Analysis**

150 In this study, an in-house bioinformatics pipeline was designed to identify the
151 predominant lineages and their signature mutations of SARS-CoV-2 in the sample.
152 The pipeline consisted of several crucial steps to ensure the accuracy of the results.
153 The first step involved quality control and filtering of the raw reads using fastp (Chen
154 et al., 2018), which helps to ensure the quality of the data being analyzed. The filtered
155 reads were then aligned with the reference genome of SARS-CoV-2 (MN908947.3)
156 using BWA-Mem (Li and Durbin, 2010), providing basic alignment and coverage
157 statistics using SAMtools coverage/bedcov (Li et al., 2009). To determine single
158 nucleotide variants (SNVs), iVar (Grubaugh et al., 2019) tool was used with
159 parameters of a minimum base quality score of 20, minimum frequency of 0.03, and
160 minimum read depth of 10. To predict the lineage composition of the SARS-CoV-2
161 variants in a sample, we utilized LCS (Valieris et al., 2022b), a mixture model
162 designed to determine the variant composition in environmental samples. We used
163 LCS lineage abundance estimates to compute Shannon diversity and Bray-Curtis
164 dissimilarity metrics, as well as an Adonis statistical analysis using R-programming

165 packages such as vegan v2.5-7, ggplot, and phyloseq. Finally, data analysis was
166 performed using scripting in R/Python/Bash to manually check variant-associated
167 mutations and to plot the results.

168 **3. Results**

169 **3.1. Quantification and correlation of SARS-CoV2**

170 We analyzed data collected from 10 sewage treatment plants (STPs) located
171 across the Pune city, covering an estimated 92% of the city's population between
172 November 2021 and April 2022 (Fig.1, Table.S1). An average of two samples were
173 taken from each location per week to assess the level of community spread.
174 Wastewater samples were processed and analyzed within 24h of sample collection.
175 RT-qPCR was employed to test 442 samples for the presence of SARS-CoV-2 genetic
176 material using three different genetic target regions: N, RdRp, and E gene. A sample
177 was considered positive for SARS-CoV-2 when any two genes showed Ct values
178 lower than 35. In total, 142 out of 442 samples were positive, while the remaining 300
179 were negative, representing a total positive detection rate of 32.12%. (Table.S2)

180 To gain insights to the prevalence of SARS-CoV-2 infection in the community,
181 we calculated the amount of virus present in each sample using a viral load
182 calculation tool. The results of this analysis, depicting the levels of SARS-CoV-2 in
183 wastewater and clinically reported cases in Pune
184 (<http://cms.unipune.ac.in/~bspujari/Covid19/Pune2/>) are illustrated in (Fig.2, Fig.3).
185 A strong correlation for the entire city viral load exhibits a significant association with
186 daily clinically reported COVID-19 positive cases ($R^2=0.81$, $p<22e-16$; Fig.S1.A) and
187 7-day moving average COVID-19 cases ($R^2=0.83$, $p<22e-16$; Fig.S1.B). The RT-
188 qPCR analysis revealed an increase in viral load during the SARS-CoV-2 surge in
189 January 2022, with the virus detected in the samples throughout the period from
190 November 2021 to April 2022. The viral load was observed lowered in November and
191 December 2021, with an average viral copy of 3.2 gc/ml and 2.2 gc/ml, respectively,
192 while a sharp increase in viral load was noted in January 2023, with an average
193 detection of 83.9 gc/ml. Overall wastewater viral trend forms an early mirror image
194 over clinically reported COVID-19 cases, demonstrating the usefulness of WBE in
195 detecting the early transmission of SARS-CoV-2 infection in the community.

196 The SARS-CoV-2 signals were detected across all STPs throughout the study.
197 When COVID-19 entered Pune in its third wave, all STPs began to give early
198 warnings 08 to 17 days before the city's clinical COVID-19 cases substantially
199 increased. STP sites such as Old Naidu, Mundhwa, and New Naidu and Kharadi gave
200 early warning signals from December 8th to December 16th, 2021, sequentially,
201 whereas STP sites like Tanajiwadi, BhairobaNala, Bopodi, and Erandwane began
202 providing early warning signals after December 20th, 2021. However, STP sites of
203 Vitthalwadi and Baner gave signals at the same time the clinical cases substantially
204 started increasing (Fig.2, Fig.3), which probably indicates the effective clinical testing
205 in the region. This phenomenon of detecting 08 to 17 days early viral signals from
206 wastewater proves the usefulness of WBE as a system for early detection.

207 **3.2. Prediction and diversity of SARS-CoV-2 variants in wastewater**

208 To understand the dynamics of SARS-CoV-2 variants in the city, we
209 conducted a large-scale SARS-CoV-2 sequencing effort on 442 samples collected
210 over six months from November 2021 to April 2022 (Table.S3). A significant
211 proportion of the samples which is 52%, failed to yield sufficient sequencing data due
212 to low viral load as evidenced by high cycle threshold (Ct) values. However, the
213 remaining 48% of samples met our stringent quality criteria, including detection
214 confidence of SARS-CoV-2 and minimum genome coverage of 55%, and were
215 subsequently used for lineage prediction analysis. The study's findings offer insightful
216 information on the evolution and propagation of SARS-CoV-2 variants within our
217 study population.

218 The relative frequencies and diversity of SARS-CoV-2 lineages in wastewater
219 were analyzed using the *LCS* tool in a study conducted from November 2021 to April
220 2022. A total of 426 distinct lineages representing 17 highly transmissible variants of
221 SARS-CoV-2 were identified in WW during this period (Fig.2, Fig.3). The Delta
222 lineage was found to be the most dominant during November and December 2021,
223 with an overall percentage of 80% and 55% respectively (Table.S5), followed by the
224 Kappa lineage, which accounted for 12% and 30% of the total lineages during the
225 same period, while BA.3 and BA.2 lineages accounts for 2.4-6.3% and 0-3%
226 respectively. The BA.1 lineage accounted for only 0.3% and 0.2% in January and
227 February'2022, respectively. The remaining 8% of lineages were classified as "others".

228 However, small signals of the Omicron lineage started to be detected during
229 November 2021 (2.6%) and December 2021 (7.9%), with a 10-fold increase in
230 January 2022 (70%) to become the most prevalent lineage from January 2022
231 onwards (Fig.4). Interestingly, the study also detected strong signals of the XBB
232 lineage in March samples accounts for 13.7% to total lineages. This emphasizes the
233 significance of continuing monitoring of SARS-CoV-2 variants in WW to better
234 understand their spread and transmission dynamics. Identifying highly transmissible
235 variants in WW may also affect public health interventions and measures.

236 **3.3. Diversity and correlation between Wastewater and Clinical SARS-CoV-2** 237 **data**

238 We aimed to correlate the lineage composition between clinical and
239 wastewater samples of SARS-CoV-2 in Pune city, India. We retrieved 3223 SARS-
240 CoV-2 genomes from GISAID from November 2021 to April 2022, submitted from
241 Pune city (Table.S6). A total of 98 distinct lineages and sub lineages were identified
242 during this period. Based on the predominance of each lineage in India, the lineages
243 were categorized according to the INSACOG categorization for further study
244 (INSACOG Dashboard, Table.S7). The results showed that the overall clinical
245 lineages followed a similar pattern as the wastewater samples. The Omicron lineage
246 and its sub lineages were the dominant lineages from January to April 2022. Omicron
247 BA.2 accounted for 51.6% of all lineages, followed by Omicron BA.2.10 (14.8%),
248 Omicron BA.2.X (13.8%), Omicron BA.1.X (6.3%), Omicron BA.1 (5.6%), and
249 Omicron BA.2.38 (4.9%). (Fig.S3). However, the Delta lineage was the most
250 dominant lineage during November and December 2021. Specifically, the
251 Delta_B.1.617.2 lineage accounted for 88.1% of the total lineages, followed by early
252 signals of Omicron_BA.1.X (5.2%), Omicron_BA.2 (2.8%), and Omicron_BA.1
253 (2.1%). Similarly, the wastewater samples had dominant lineages of Delta_B.1.617.2
254 and Kappa during November and December 2021. Later, the Omicron variant
255 takeover the Delta variant and became a dominant variant by January' 2022 (Fig.4).
256 This transition from Delta to the omicron variant highlights the significance of
257 ongoing monitoring and observation of SARS-CoV-2 lineages in both clinical and
258 wastewater samples to gain a better understanding of their spread and transmission
259 dynamics.

260 To understand the diversity of SARS-CoV-2 lineages circulating in the
261 community, we calculated Simpson indices for all the samples collected from various
262 sites. These indices measure the total diversity of a community and are commonly
263 used in ecology and epidemiology. The results of our analysis revealed a significant
264 difference in diversity between months (Kruskal-Wallis, $p=2.6e-12$) but no significant
265 difference by location (Fig.S2.A, Fig.S2.B). To further investigate the variation in
266 diversity across time, we used the Bray-Curtis dissimilarity matrix with the Adonis
267 test to compute beta diversity. This approach allows for comparing community
268 composition between different samples or groups. The analysis found a significant
269 difference in beta diversity across the months ($R^2 = 0.55$, $P>0.001$) but no significant
270 variation by location (Fig.S2.C, Fig.S2.D). These results suggest that temporal rather
271 than geographic factors primarily influence the diversity of SARS-CoV-2 lineages in
272 Pune. Overall, these findings discern the dynamics of SARS-CoV-2 lineage diversity
273 in the population and highlight the importance of continued monitoring to track
274 emerging variants of concern.

275 **3.4. Early detection of Omicron and its sub-lineages**

276 To determine the population's exposure to SARS-CoV-2 variants, we utilized
277 the *iVar* tool to analyze each sample for co-occurring signature mutations of the
278 Omicron variant (BA.1, BA.2, BA.3, BA.4, BA.5, BA.1.x, BA.2.x, BA.3.x, BA.4.x,
279 BA.5.x). Despite some limitations in the sequencing data due to low RNA
280 concentrations in certain samples, we could still detect characteristic signals of the
281 Omicron variant. Our analysis revealed that wastewater samples taken from the STP
282 at Bhairobanala was the first one to have the Omicron signals : S: D614G, S: H655Y,
283 S: N679K, S: P681H, N: P13L) and Tanajiwadi (S: N440K, S: S477N, S: T478K, S:
284 E484A, S: Q493R, S: Q498R, S: N501Y, S: Y505H, S: T547K, S: D614G, E: T9I, on
285 November 1st, 2021, before it was classified as a VOC by the World Health
286 Organization (“Tracking SARS-CoV-2 variants,” WHO) on November 26th, 2021
287 (Table.S8). The Omicron was also detected in samples collected from the STP at
288 Bopodi ((S: L452R, S: T478K, E: T9I) on November 2nd, 2021, before it was
289 confirmed in Pune's first clinical case on December 5th, 2021. Furthermore, our
290 analysis revealed that Omicron and its sub lineages were detected in wastewater
291 samples collected from nine out of ten STPs in Pune, indicating widespread

292 community exposure to this variant before its detection in clinical cases (Table.S9).
293 These findings emphasize the use of wastewater-based surveillance in tracking the
294 emergence and spread of SARS-CoV-2 variants in the community. It is important to
295 note that our investigation was carried out in India, and the Omicron variant was
296 discovered in Botswana on November 2011. As such, our data suggest that Omicron
297 may have been circulating in wastewater prior to its detection in clinical cases. The
298 findings of this investigation offer crucial insights into the early detection and spread
299 of SARS-CoV-2 in the community and support the implementation of WBE as a
300 complementary approach to traditional clinical surveillance.

301 Moreover, to evaluate the rise of variation in the lineage of SARS-CoV-2 in
302 the population, we employed a linear mixed model analysis to examine the correlation
303 between the initial detection of variant of concern in wastewater and the date when
304 clinical samples were collected from Pune city and submitted to GISAID. Our
305 examination revealed a trend of increasing presence of the Omicron variant
306 (B.1.1.529) and its sub lineages (BA.1, BA.2, BA.2.12, BA.2.X, BA.2.38, BA.3,
307 BA.4, BA.5) starting from January 2022. As time progressed, however, we noted a
308 reduction in the frequency of the Kappa (B.1.617.1) and Delta (B.1.617.2) lineages,
309 with the Omicron variant completely dominating by February 2022 (Fig.5).
310 Additionally, we observed an upward trend in the prevalence of the XBB lineage
311 starting from January 2022. These findings emphasize the crucial importance of
312 ongoing monitoring of the variations in SARS-CoV-2 in order to inform public health
313 strategies.

314 4. Discussion

315 The emergence of new SARS-CoV-2 variants has been a key cause of concern
316 in the ongoing COVID-19 epidemic. One such variant, Omicron, has been identified
317 in India (Gao et al., 2021). This variant has raised concerns due to its high
318 transmissibility and potential to evade immunity from previous infections or vaccines
319 (Shrestha et al., 2021; Zhang, 2022; Yadav and Kumar, 2022). Our study utilizes
320 WBE to identify, track, and assess the SARS-CoV-2 genetic variants in Pune city,
321 India. We collected 442 wastewater samples from 10 locations, representing an
322 estimated 7.4 million individuals. WBE has been used in several studies globally to
323 identify and quantify the SARS-CoV-2 fragments in wastewater (Srivastava et al.,

324 2021; Dharmadhikari et al., 2022; Joshi et al., 2022; Jahn et al., 2022; Morvan et al.,
325 2022). By applying this model at the city level, we aim to prevent the spread of
326 COVID-19 and better understand the dynamics of SARS-CoV-2 transmission in Pune
327 city.

328 In this study, we used RT-qPCR and Illumina sequencing to quantify and
329 monitor the genetic characteristics of SARS-CoV-2 variants. Our findings show a
330 strong correlation between the viral load and clinical cases of COVID-19.
331 Additionally, our data suggest that a significant amount of viral shedding likely
332 occurs early in infection, particularly from asymptomatic individuals, before they seek
333 medical attention and are tested for Covid-19 (Lamba et al., 2023). The SARS-CoV-2
334 persists in faeces samples longer than in respiratory and serum samples (Prakash et al.,
335 2021). In the present study, the SARS-CoV-2 was detected before an increase in
336 clinical cases highlighting the potential utility of WBE as a tool for early detection
337 and prevention of SARS-CoV-2 transmission. By monitoring STPs, public health
338 officials can identify outbreaks and implement strict management strategies at the
339 earliest stages of severe disease.

340 The SARS-CoV-2 genetic material was quantified using RT-qPCR, followed
341 by Illumina sequencing to determine the trends of SARS-CoV-2 lineages
342 disseminated in the community. Detecting SARS-CoV-2 titers in wastewater is
343 challenging amid the fragmentation and PCR inhibitors, making it difficult to quantify
344 and sequence for estimating lineage/variant composition (Baaijens et al., 2021).
345 However, in this study, LCS (Lineage decomposition for SARS-CoV-2), a model for
346 predicting the lineage composition in a sample, was utilized, which captures and
347 classifies variant-specific mutations (Valieris et al., 2022). Our results showed that
348 relative to the clinical testing, SARS-CoV-2 RNA content in wastewater provides a
349 more accurate indicator for local infection dynamics (Karthikeyan, 2021); Randazzo
350 et al., 2020; Polo et al., 2020). We found a wide range of SARS-CoV-2 lineages in
351 wastewater, with some lineages that infect a substantial proportion of people
352 exhibiting similar patterns. Additionally, we discovered low prevalent mixed lineages
353 in wastewater that were undetectable from clinical data, suggesting that such lineages
354 infected only a small number of individuals.

355 Furthermore, weak signals from novel variants imply the arrival of a new
356 lineage into the population that could not be emphasized in clinical data- indicating
357 the limited testing or testing for symptomatic individuals exclusively. We discovered

358 early XBB signals and other Omicron sub-lineages that were not previously reported
359 in clinical data. This discrepancy highlights the lack of required sequencing, i.e. at
360 least 0.5% of the positive cases (Grimaldi et al., 2022), which impacts the ability to
361 detect SARS-CoV-2 variants quickly and undermines the global pandemic
362 preparedness. Our research emphasizes the effects of socioeconomic disparities,
363 population density, and wastewater treatment as powerful strategies to stop the spread
364 of SARS-CoV-2 (Sharifi and Khavarian-Garmsir, 2020). It is imperative to continue
365 monitoring and testing wastewater for SARS-CoV-2 to prevent the spread of new
366 variants and to ensure global pandemic preparedness. We aimed to quantify the
367 SARS-CoV-2 genetic material in wastewater samples and determine the genomic
368 trends of SARS-CoV-2 lineages circulating in the community. Our results showed
369 that wastewater samples exhibit greater alpha diversity than clinical samples.
370 Additionally, the viral composition of the city did not show regional variability, as the
371 beta diversity of SARS-CoV-2 did not differ by STP locations. However, there was a
372 significant variation (35%) across clinical and wastewater samples, and distinct and
373 common clusters of SARS-CoV-2 lineages were formed over time, suggesting
374 introduction and elimination of various lineages in the community over time
375 (Karthikeyan et al., 2022; Gu et al., 2022). These findings emphasize the significance
376 of wastewater surveillance as a complementary tool to clinical testing in
377 understanding the dynamics of SARS-CoV-2 transmission in the community.

378 We investigated the presence of different lineages and sub-lineages of SARS-
379 CoV-2 in wastewater samples collected from Pune, India. Our findings showed the
380 presence of several variants of the Omicron lineage, which have been linked to
381 increased transmissibility, adverse health impacts, and hospitalization (Khandia et al.,
382 2022; Araf et al., 2022.). Importantly, our results indicated that three out of the ten
383 catchment areas had detectable levels of Omicron in the wastewater samples before
384 the first clinical case of Omicron-positive in Botswana on November 11th, 2021: 10
385 days earlier in Bhairobanala, 9 days earlier in Bopodi, and 10 days earlier in
386 Tanajiwadi. Additionally, nine out of the ten catchment areas had Omicron signals in
387 the wastewater samples before the first reported clinical case of Omicron in Pune city
388 on December 5th, 2021: 19 days earlier in Baner, 34 days earlier in Bhairobanala, 33
389 days earlier in Bopodi, 23 days earlier in Erandwane, 24 days earlier in Kharadi, 18
390 days earlier in New Naidu, 25 days earlier in old Naidu, 34 days earlier in Tanajiwadi,
391 and 24 days earlier in Mundhwa. This implies that a substantial portion of the

392 population was infected and shedding the virus before being diagnosed through
393 clinical testing (He et al., 2020).

394 Furthermore, we discovered six highly transmissible lineages of Omicron in
395 the wastewater samples before their detection in clinical samples from the city:
396 BA.2.12, BA.2.38, BA.2.75, BA.3, BA.4, and XBB detected 20, 8, 153, 242, 127, and
397 279 days earlier, respectively. Additionally, we found weak indications of lineage
398 BA.5 in November 2022, which has yet to be reported in any clinical cases from Pune
399 city. Our findings demonstrate the utility of WBE for detecting and monitoring the
400 presence of SARS-CoV-2 variants in the community. Testing of wastewater captures
401 the combined contributions of every individual in a catchment region, providing a less
402 biased representation of viral diversity and public health (Karthikeyan et al., 2022). In
403 contrast, delays in detection from clinical samples may be due to limited testing and
404 sequencing or asymptomatic or home-testing cases (Mercer and Salit, 2021).
405 Additionally, our study showed that sequencing data from wastewater samples could
406 be used to monitor the prevalence of variants and estimate their growth rate, using
407 significantly fewer samples than required for clinical samples. Overall, these results
408 substantiates the importance of WBE as a complementary approach to traditional
409 clinical surveillance for detecting and monitoring the spread of SARS-CoV-2 variants.
410 Furthermore, it also highlights the potential of WBE to detect the emergence of new
411 variants before they are identified in clinical samples.

412 5. Conclusion

413 The present study highlighted the efficacy of wastewater-based epidemiology (WBE)
414 as a formidable tool in the early warning, detection, and monitoring of SARS-CoV-2
415 variants. By conducting a comprehensive analysis of wastewater samples collected
416 between November 2021 and April 2022, we could detect the Omicron variant
417 fragments before clinical cases, providing valuable insights for public health officials
418 to implement preventative measures. Our findings highlight the potential of WBE as a
419 practical approach for real-time surveillance of infectious outbreaks, not only for
420 SARS-CoV-2 but also for other pathogens. Integrating WBE into existing public
421 health surveillance methods can significantly enhance our ability to understand the
422 transmission dynamics and evolution of infectious diseases and, ultimately, help in
423 preventing future outbreaks.

424 **Data availability:** All data produced in the present study are available upon
425 reasonable request to the authors. Clinical COVID-19 data was used from CMS
426 dashboard (<http://cms.unipune.ac.in/~bspujari/Covid19/Pune2/>)

427 **Declaration of competing interest:** The authors declare that they have no known
428 competing financial interests or personal relationships that could have appeared to
429 influence the work reported in this paper.

430 **Funding**

431 This work was financially supported by Rockefeller Foundation, USA (project code
432 GAP 332926).

433 **Acknowledgments**

434 Authors wish to thank Directors of CSIR-NCL, IISER-Pune, and PKC for
435 encouragement and support. We gratefully acknowledge Pune Municipal Corporation
436 (PMC) for permission to carry out the sampling and use clinical COVID-19 data.
437 Authors are indebted to Prof. Aurnab Ghose, IISER-Pune (for grant administration
438 support and discussions), Dr. Dayanand Panse-ESF (for support and pre-preparations
439 in sampling logistics) and Ms. Rachel Samson (for processing and RNA extractions of
440 the subset samples). Authors also acknowledge <https://biorender.com/> for creation of
