## 11 **Abstract**

12 The myoelectric manifestation of fatigue (MMF) is predominantly assessed using median  
13 frequency and amplitude of electromyographic (EMG) signals. However, EMG has complex  
14 features so that fractals, correlation, entropy, and chaos MMF indicators were introduced to  
15 detect alteration of EMG features caused by muscle fatigue that may not be detected by linear  
16 indicators. The aim of this study was to determine the best MMF indicators. Twenty-four  
17 participants were equipped with EMG sensors on 9 shoulder muscles and performed a  
18 repetitive pointing task. They reported their rate of perceived exertion every 30 seconds and  
19 were stopped when they reached 8 or higher on the CR10 Borg scale. Partial least square  
20 regression was used to predict perceived exertion through 15 MMF indicators. In addition, the  
21 proportion of participants with a significant change between task initiation and termination  
22 was determined for each MMF indicator and muscle. The PLSR model explained 73% of the  
23 perceived exertion variance. Median frequency, mobility, spectral entropy, fuzzy entropy, and  
24 Higuchi fractal dimension had the greatest importance to predict perceived exertion and  
25 changed for 83.5% participants on average between task initiation and termination for the  
26 anterior and medial deltoids. The amplitude, activity, approximate, sample, and multiscale  
27 entropy, degree of multifractality, percent determinism and recurrent, correlation dimension,  
28 and largest Lyapunov exponent analysis MMF indicators were not efficient to assess MMF.  
29 Mobility, spectral entropy, fuzzy entropy, and Higuchi fractal dimension should be further  
30 considered to assess muscle fatigue and their combination with median frequency may further

## 1 1 **Introduction**

2 Muscle fatigue is defined as a transient decrease in the capacity to perform physical actions  
3 [1]. Since muscle fatigue is not a physical variable by itself, its assessment requires the  
4 identification of indicators based on measurable physical variables such as force, kinematics,  
5 or electromyography (EMG) [2–4]. Myoelectric manifestations of fatigue (MMF) [5,6],  
6 measured from EMG signals, have numerous advantages such as non-invasiveness,  
7 applicability in situ [7], real-time monitoring [8], and ability to monitor fatigue of a particular  
8 muscle [9]. Considering that wearable sensors are now common in the workplace [10–12],  
9 high standard of data processing is required to extract accurate MMF information from EMG  
10 signal and better prevent work-related musculoskeletal disorders due to muscle fatigue  
11 [11,13].

12 A consensual approach to assess MMF is the Joint Analysis of Spectrum and Amplitude  
13 (JASA) method [14]. As the name would suggest, JASA is a computational technique that  
14 accounts for both the spectrum and amplitude of EMG signal. According to this method,  
15 muscle fatigue is characterized by a power spectrum shift toward lower frequency and  
16 amplitude increase of EMG signals. The shift of power spectrum toward lower frequency,  
17 measured via the median frequency [15,16], is attributable to the increase in motor unit  
18 synchronization [17,18] and the decrease of muscle fibers conduction velocity [6,17] possibly  
19 triggered by altered distribution of H<sup>+</sup> and K<sup>+</sup> ions across the sarcolemma [19] and muscle  
20 membrane excitability that increase the duration of intracellular action potentials [20].  
21 Regarding amplitude increase, measured by the EMG activation level, it is attributable to the  
22 reduction of motor units firing rate and their increased synchronization [20,21]. However,  
23 changes in EMG activation level may not systematically reflect muscle fatigue, but rather  
24 strategies of motor unit rotation triggered by sensations related to general fatigue [22,23].  
25 Indeed, some studies have reported a decrease of EMG activation level with fatigue during  
26 low load fatiguing manual handling tasks [24] or no change during repetitive static arm  
27 abductions [25] and repetitive work in butchers [26]. Consequently, the JASA method may  
28 provide false negative results considering that the EMG activation level does not  
29 systematically increase in the presence of muscle fatigue.

30 Linear indicators, such as median frequency and activation level, are based on the assumption  
31 that EMG signal is a Gaussian random process [27,28], which may have limitations to assess  
32 MMF. Indeed, EMG signals, as well as other neurophysiological signals such as  
33 electroencephalogram and electrocardiogram [29,30], have complex properties [31–34]. The

1 complexity of the EMG signal is attributed to the mechanisms underlying its generation that  
2 contain some non-linear or chaotic features [35,36]. As a result, in recent years, several  
3 complexity-based EMG indicators have been introduced [37–41] in order to detect alteration  
4 of EMG features caused by muscle fatigue that may not be detected by linear indicators. In a  
5 recent literature review, Rampichini et al., [28] classified four groups of complexity-based  
6 MMF indicators, namely, fractal and self-similarity, correlation, entropy, and deterministic  
7 chaos. The fractal and self-similarity group includes fractal dimension [42] and degree of  
8 multifractality. During sustained isometric contractions, fractal dimension was found to  
9 decrease with fatigue [18,43–45] while the degree of multifractality increased during  
10 fatiguing static and dynamic contractions and was a more sensitive MMF than median  
11 frequency [40,46–48]. Moreover Marri and Swaminathan., [49] demonstrated that the  
12 performance of multifractal indicators were more suitable for sEMG signals as compared to  
13 monofractal fractal dimension indicators such as Higuchi fractal dimension, in their study of  
14 the classification of muscular non-fatigue and fatigue conditions using EMG and fractal  
15 algorithms. The correlation group includes correlation dimension and recurrence  
16 quantification analysis. The latter was shown to increase with muscle fatigue during biceps  
17 brachii contractions [33,50,51]. Coelho et al., [34] and Ito et al.,[52] even showed that  
18 recurrence quantification analysis was better at detecting muscle fatigue than frequency-based  
19 indicators. Although there is no evidence to date that correlation dimension is a relevant  
20 indicator of MMF, Wang et al., [28] suggested that it may be a good candidate to assess  
21 muscle fatigue. The entropy group includes sample entropy, fuzzy entropy, spectral entropy,  
22 approximate entropy, and multiscale entropy that all have showed to decrease during fatiguing  
23 isometric [53–55] and dynamic contractions [48,56]. Particularly, fuzzy and multiscale  
24 entropy were found to have a superior robustness and performance to assess MMF than  
25 frequency-based [54] and approximate and sample entropy indicator [57,58]. Finally, the  
26 chaotic properties of a non-linear system can be assessed through the largest Lyapunov  
27 exponent [59] that was shown to decrease during a fatiguing task involving the low back  
28 muscles [60]. However, as stated by Rampichini et al., [28], future standardized fatiguing  
29 protocols are needed to confirm whether the largest Lyapunov exponent could be an  
30 appropriate indicator to assess MMF. Taken together, the literature on the identification of  
31 muscle fatigue based on EMG signal has shown that complexity-based indicators seemed  
32 efficient to detect MMF. Consequently, it is now essential to determine what are the best  
33 MMF indicators to assess muscle fatigue during multi-joint movement such as repetitive  
34 fatiguing tasks.

1 To this end, an interesting approach is to predict the rate of perceived exertion (RPE), which  
2 is known to increase with muscle fatigue [61], from MMF indicators. Interestingly, several  
3 studies have also shown a close relationship between the RPE [62] and MMF indicators  
4 [24,63–68]. For instance, Goubault et al., [24] used correlation analyses between six MMF  
5 indicators and RPE scores assessed using the CR-10 Borg scale [69] during a laboratory  
6 simulated manual handling task. They showed that spectral entropy, median frequency, and  
7 mobility were the MMF indicators that explained the largest percentage of the RPE variance,  
8 with R-square ranging from 11% to 39%. In comparison, activity explained between 17% and  
9 21% of the RPE variance, and activation level showed no significant relationship with the  
10 RPE [56,70,71]. In a recent study, Ni et al., [68] showed that time, frequency, and time-  
11 frequency domains MMF indicators are strongly correlated to RPE. Consequently, predicting  
12 RPE through MMF indicators is a relevant experimental paradigm to determine the best  
13 EMG-based indicators to assess muscle fatigue.

14 Consequently, the aim of the present study was to determine the best MMF indicators, from  
15 15 MMF indicators identified in the literature as potentially relevant to assess muscle fatigue  
16 during a repetitive pointing task (RPT) performed with the upper limb. We hypothesized that  
17 for the anterior and medial deltoids, which are the muscles showing the largest signs of  
18 fatigue during the upper limb repetitive task used in the present studies [72–74], the mobility,  
19 median frequency, spectral entropy, fuzzy entropy, multiscale entropy [24,28,41,75,76], and  
20 degree of multifractality [40,47,49,53] will have greater importance to predict the evolution of  
21 the RPE. In addition, these MMF indicators will significantly change for a large proportion of  
22 the participants in the anterior and medial deltoid in comparison to approximate and sample  
23 entropy, recurrence quantification analysis, correlation dimension, and the largest Lyapunov  
24 exponent [28,40,46,55].

## 25 2 **Materials and methods**

### 26 **2.1 Participants**

27 Twenty-four right-handed participants (12 ♀; age:  $32.9 \pm 8.9$  years old; mass:  $66.8 \pm 10.9$  kg;  
28 height:  $166 \pm 9$  cm) were recruited among workers exposed to repetitive tasks in a tea  
29 packaging factory. To be eligible, participants had to be free of upper-limb disabilities or  
30 musculoskeletal disorders at the time of the experiment. All participants read and signed a  
31 written informed consent form before any experimental procedure. The experimental protocol  
32 was approved by the Université de Montréal's Ethics Committee (#CERC-19-086-D).

## 1 **2.2 Instrumentation**

2 *EMG recordings.* Participants were equipped with 10 wireless surface EMG electrodes  
3 (Trigno EMG Wireless System, Delsys, USA) positioned on specific anatomical landmarks of  
4 the right side of the upper limb [77,78]; namely, the anterior, medial, and posterior deltoids,  
5 the upper, middle, and lower trapezius, long head of the biceps brachii, lateral head of the  
6 triceps brachii and the serratus (Figure 1-A). Before electrode positioning, hair was shaved  
7 with a razor and skin was cleaned with alcohol swabs at the electrode sites. EMG signals were  
8 recorded at a sampling frequency of 2000 Hz.

9 *Repetitive pointing task (RPT).* Two cylindrical touch-sensitive sensors (length: 6 cm, radius:  
10 0.5 cm, Quantum Research Group Ltd, Hamble, UK) were used as proximal and distal targets  
11 for the RPT (Figure 1-B and C). The sensors were placed at shoulder height in front of the  
12 participant's midline and at 30% (proximal target) and 100% (distal target) of the chest-arm  
13 distance. When participants touched the sensors, they delivered auditory feedback that helped  
14 participants to synchronize with the metronome as well as a transistor-transistor logic pulse  
15 recorded at 2000 Hz using Nexus software (Vicon, Oxford, UK).

16 *Force.* A unidirectional S-shape load cell (363-D3-300-20P3, InterTechnology Inc., Don  
17 Mills, Ontario, Canada) was used to measure the maximal voluntary isometric upward force  
18 of the right shoulder. The load cell was attached to a fixed horizontal bar located above the  
19 RPT setup (Figure 1-B).

## 20 **2.3 Experimental protocol**

21 Participants performed a maximal voluntary isometric contraction (MVIC) before and after  
22 the RPT described earlier. The MVIC consisted of performing a 3-sec upward maximum  
23 contraction against a fixed bar with the arm flexed at 90°. Verbal encouragement was given to  
24 participants.

25 The RPT consisted of alternatively pointing the proximal and distal targets with the index  
26 finger with the arm constrained to move in a horizontal plane, at a rhythm of one flexion-  
27 extension cycle per two seconds [79] with the aid of an external metronome. To this end,  
28 participants stood upright with the right arm in horizontal plane and the feet parallel at  
29 shoulder width. To ensure that participants maintained their arm horizontal, a mesh barrier  
30 was placed under the elbow trajectory. Participants' left arm rested on the side of the body.  
31 This task has been shown to fatigue the anterior and medial deltoid [72–74]. Every  
32 30 seconds, participants reported their RPE using the CR-10 Borg scale (RPE) [62] without

1 interrupting the RPT movement. Additionally, every 2 minutes, the RPT was interrupted so  
2 that participants could perform a MVIC as described above. Immediately after the MVIC,  
3 participants resumed the RPT without resting. Participants were asked to “perform the task for  
4 as long as possible”. They were stopped as soon as they reached a score of 8 or higher on the  
5 RPE scale but were not aware of this stoppage criteria.

6 This figure includes material that was not allowed for preprint. Please, contact the  
7 corresponding author to request access to this figure.

8 Figure 1. (A) Participant equipped with EMG’s sensors (black rectangle boxes). (B) Picture of  
9 the MVIC setup. (C) Schematic top view of the RPT. Note that data collected from reflective  
10 markers are not used in the present study and results obtained from inertial measurements  
11 units sensors (orange rectangle boxes) were presented in a previous study [80].

## 12 **2.4 Data preprocessing**

13 Data processing was performed using Matlab R2019a (The MathWorks Inc., Natick, MA,  
14 USA). EMG data were filtered using a 2<sup>nd</sup> order Butterworth zero-lag 10-400 Hz bandpass  
15 filter. Data were then zero-aligned by subtracting the mean signal value and resampled to  
16 1000 Hz to reduce computation time. For the calculation on each indicator, each participant's  
17 data was segmented into flexion-extension cycles. Each indicator described below was  
18 calculated for the 5 cycles preceding each RPE for the PLSR analysis, and for the first 10  
19 (RPT initiation) and last 10 (RPT termination) for the analysis of the proportion of change of  
20 MMF indicators among participants.

### 21 **2.4.1 Data processing: linear MMF indicators**

22 *Median frequency* was calculated using the following formula:

$$23 \int_0^{MDF} TFR(t) = \int_{MDF}^{\infty} TFR(t) = \frac{1}{2} \int_1^{\infty} TFR(t) \quad Eq. 1$$

24 *TFR* is the power spectral density calculated in the time-frequency resolution; the time-  
25 frequency analysis was performed by applying a continuous Morlet wavelet transform (wave  
26 number: 7, frequency range: 1 to 400 Hz in 1 Hz steps) to the pre-processed EMG signals [81]  
27 (WavCrossSpec Matlab package),  $t$  is a time instant.

28 *Spectral entropy* was computed as follow [24]:

$$29 SpecEn(t) = -\frac{1}{\log(L)} \cdot \sum_{t=1}^n TFR(t) \cdot \log [TFR(t)] \quad Eq. 2$$

1 where,  $L$  is the number of spectral components in the EMG spectrum,  $TFR$  is a power spectral  
2 density calculated in time-frequency,  $t$  is a time instant,  $n$  is the number of seconds in the trial.  
3 *Activation levels* were obtained from 9 Hz low-pass filtering of the full-wave rectified EMG  
4 signals normalized by the maximum voluntary muscle activation [24] obtained using the  
5 average of the maximum 2-sec non-consecutive window across all MVIC tests.

$$6 \quad \text{Activation level} = \frac{1}{N} \sum_{x_1}^{x_2} y_0 \quad \text{Eq. 3}$$

7 where  $x_1$  and  $x_2$  represent the muscle activation segment,  $N$  represents the number of  
8 elements between  $x_1$  and  $x_2$ , and  $y_0$  represents the normalized EMG envelop of the signal.

9 *Activity* is the measure of the variance ( $\sigma_0$ ) of the signal [56,70,71].

10 *Mobility* is defined as the root square of the ratio between the variance of the first derivative  
11 of the signal and the variance of the signal [24,56,70,71]. The first-time derivative of the  
12 EMG signal was calculated on the entire signal using the following equation:

$$13 \quad EMG'(t) = \frac{EMG(t+1) - EMG(t)}{dt} \quad \text{Eq. 4}$$

14 The variance of the first-time derivative of the EMG signal and the variance of the EMG  
15 signal were then calculated on each muscle activation segment, before calculating the root  
16 square of the ratio between both.

$$17 \quad \text{Mobility} = \sqrt{\frac{\sigma_1^{x_2}}{\sigma_0^{x_1}}} \quad \text{Eq. 5}$$

18 where  $\sigma_1^{x_2}$  represents the variance of the first derivative of the EMG signal for muscle  
19 activation segment between  $x_1$  and  $x_2$ , and  $\sigma_0^{x_2}$  is the variance of the EMG signal for muscle  
20 activation segment between  $x_1$  and  $x_2$ .

## 21 **2.4.2 Data processing: Non-linear MMF indicators**

### 22 **2.4.2.1 Fractals Self-Similarity**

23 *Higuchi fractal dimension (HFD)* was computed using the algorithm proposed by Higuchi  
24 (1988). Briefly, EMG is analyzed in time, as a sequence of samples  $x(1), x(2), \dots, x(N)$ , and  $k$   
25 new self-similar time series  $X_k^m$  constructed as [42,82]:

$$26 \quad X_k^m: x(m), x(m+k), x(m+2k) \dots x(m + \text{int} \left[ \frac{N-m}{k} \right] k) \quad \text{Eq. 6}$$

1 for the initial time  $m = 1, 2, \dots, k$ ; the time interval  $k = 2, \dots, k_{max}$  [82]; and  $Int[r]$  the integer  
 2 part of a real number  $r$ . Then, the length of every  $L_m(k)$  is calculated for each time series or  
 3 curves  $X_k^m$  as:

$$4 \quad L_m(k) = \frac{1}{k} [(\sum_{i=1}^{int[\frac{N-m}{k}]} |x(m+ik) - x(m+(i-1)k)|)] \frac{N-1}{int[\frac{N-m}{k}]k} \quad Eq. 7$$

5 and is averaged for all  $m$ , therefore forming an average value of a curve length  $L(k)$  for each  
 6  $k=2, \dots, k_{max}$  such as:

$$7 \quad L(k) = \frac{\sum_{m=1}^k L_m(k)}{k} \quad Eq. 8$$

8 Finally, *HFD* is evaluated as the slope of the best-fit form of  $\ln(L(k))$  vs.  $\ln(1/k)$ :

$$9 \quad HFD = \frac{\ln(L(k))}{\ln(\frac{1}{k})} \quad Eq. 9$$

10 *HFD* was calculated using the Higuchi FD Matlab function [83] using  $k_{max} = 8$ .

11 *Degree of multifractality (DOM)* was calculated from the *multifractal detrended fluctuation*  
 12 *analysis (MFDFA)* [40,47]. For an EMG signal  $\{x(t), t = 1, 2, \dots, N\}$ , *MFDFA* analysis first  
 13 involves a random walk construction in this form [84]:

$$14 \quad Y(t) = \sum_{i=1}^t x(i) \quad Eq. 10$$

15 where  $\{Y(t), t = 1, 2, \dots, N\}$ . Next, a moving average function is computed in a moving  
 16 window  
 17 represented as:

$$18 \quad \tilde{y}(t) = \frac{1}{n} \sum_{k=-[(n-1)\theta]}^{[(n-1)(1-\theta)]} y(t-k) \quad Eq. 11$$

19 where  $n$  is window size,  $[(n-1)(1-\theta)]$  is largest integer not greater than  $x$ ,  $[(n-1)\theta]$  is  
 20 smallest integer not smaller than  $x$ , and  $\theta$  is a position parameter with value varying in  
 21 between 0 and 1. After three more steps consisting on detrending the signal series to get the  
 22 residual, then dividing the residual series into  $M$  disjoint segment with same size  $n$ , where  
 23  $M = \frac{N}{n} - 1$ , and finally determining the  $q^{th}$  order overall fluctuation function, the power law  
 24 can be determined by varying the segment size  $n$  for fluctuation function as:

$$25 \quad F_q(n) = n^{h(q)} \quad Eq. 12$$

26 The multifractal scaling exponent is given as:

$$27 \quad \tau_{(q)} = qh(q) - D \quad Eq. 13$$

1 where  $D$  is the fractal dimension of geometric support of multifractal measure [85]. The  
 2 singularity strength function and multifractal spectrum are obtained using Legendre transform  
 3 [86] and represented as respectively followed:

$$4 \quad \alpha(q) = \frac{d\tau(q)}{dq} \quad \text{Eq. 14}$$

$$5 \quad f(q) = q\alpha - \tau(q) \quad \text{Eq. 15}$$

6 Finally, the degree of multifractality is measured as the distance between maximum exponent  
 7 and minimum exponent in multifractal spectrum:

$$8 \quad DOM = \alpha_{max} - \alpha_{min} \quad \text{Eq. 16}$$

9 For *MFDF* computation, the MF DFA1 MATLAB function was used with a scale  $q$  varying  
 10 between -10 and 10 with increments of 0.1, and  $m$  varying between  $2^2$  and  $2^{12}$  with  
 11 increments of  $2^{0.1}$  as input parameters [40,47].

#### 12 **2.4.2.2 Entropy**

13 *Approximate entropy* was computed as follow:

$$14 \quad ApEn(m, r, N) = \frac{1}{N-m} \sum_{i=1}^{N-m} \ln \left( \frac{C_i^m(r)}{C_i^{m+1}(r)} \right) \quad \text{Eq. 17}$$

15 where the embedding dimension  $m = 2$ , the distance threshold  $r = 0.25$  [58],  $N$  the number of  
 16 sample in the time series, and  $C_i^m(r)$  the number of vector  $u(i)$  within the distance  $r$  from the  
 17 template vector  $u(i)$  computed as:

$$18 \quad C_i^m(r) = (N - m + 1)^{-1} \sum_{i=1}^{N-m+1} H(r - |d(u(i), u(j))|) \quad \text{Eq. 18}$$

19 with  $H()$  being the Heaviside step function where  $H$  is 1 if  $(r - |d(u(i), u(j))|) \geq 0$  and 0  
 20 otherwise. For the computation, the ApEn Matlab function [87] was used with the mentioned  
 21 above parameters as input.

22 *Sample entropy* can be defined mathematically by:

$$23 \quad SampEn(m, r, N) = -\ln \left( \frac{B_{m+1}^m(r)}{B_m(r)} \right) \quad \text{Eq. 19}$$

24 with  $B_m(r)$  defined as:

$$25 \quad B_m(r) = \frac{1}{N-m} \sum_{i=1}^{N-m} C_i^m(r) \quad \text{Eq. 20}$$

26 where  $B_m(r)$  is the number of matches of length  $m$  and  $B_{m+1}^m(r)$  as the subset of  $B_m(r)$  that  
 27 also matches for length  $m+1$ . Here the embedding dimension  $m$  is equal to 2 and the tolerance

1  $r = 0.25$  [55,56] and  $N$  the number of sample in the time series. For the computation, the  
 2 SampEn Matlab function [88] was used with the mentioned above parameters as input.

3 *Fuzzy Entropy* was computed as follow [28,54,55]:

$$4 \quad \text{FuzzyEn}(m, n, r, N) = -\ln\left(\frac{C^{m+1}(r)}{C^m(r)}\right) \quad \text{Eq. 21}$$

5 where  $N$  is the number of samples in the time series,  $C^m(r)$  is the average of  $C_i^m(r)$   
 6 calculated as:

$$7 \quad C_i^m(r) = (N - m + 1)^{-1} \sum_{j=1, j \neq i}^{N-m+1} \Omega(d_{ij}^m, r) \quad \text{Eq. 22}$$

8 with

$$9 \quad \Omega(d_{ij}^m, n, r) = \exp(-(d_{ij}^m)^n / r) \quad \text{Eq. 23}$$

10 using an embedding dimension  $m = 2$ , a power factor  $n = 2$  and a tolerance  $r = 0.25$   
 11 [54,55,58]. For the computation, the FuzzyEn Matlab function [89] was used with the  
 12 mentioned above parameters as input.

13 *Multiscale Sample Entropy* was calculated using the rapid refined composite multiscale  
 14 sample entropy algorithm (R2CMSE) [53].

$$15 \quad R2CMSE(x, m, r, \tau) = -\ln\left(\frac{\bar{n}_{m+1}^{(\tau)}}{\bar{n}_m^{(\tau)}}\right) \quad \text{Eq. 24}$$

16 with  $\bar{n}_{k,i,m}^{(\tau)}$  the number of vector-matching pairs defined as:

$$17 \quad \bar{n}_{k,i,m}^{(\tau)} = \frac{1}{N-m} \bar{n}_{k,i,m}^{(\tau)} \quad \text{Eq. 25}$$

18 where  $N$  is the number of sample in the time series, the embedding dimension  $m = 2$ , a  
 19 tolerance  $r = 0.25$ , and a time scale factor  $\tau = 20$  [53,90]. For the computation, the R2CMSE  
 20 Matlab function [53] was used with the mentioned above parameters as input.

21

### 22 **2.4.2.3 Correlation**

23 *Recurrence Quantification Analysis (RQA)* was performed using the percent of determinism  
 24 method (%DET) which quantifies the amount of rule-obeying structures present within any  
 25 physiological signal, and the percent of recurrence (%REC) which quantifies signal  
 26 correlations in higher dimensional space [28,91].

$$27 \quad RQA(\%DET) = \frac{\sum_{l=\text{min}}^N l.P(l)}{\sum_{i,j}^N R_{i,j}} \quad \text{Eq. 26}$$

$$1 \quad \%REC(\varepsilon) = \frac{1}{N^2} \sum_{i,j=1}^N R_{i,j}(\varepsilon) \quad Eq. 27$$

2 where  $P(l)$  is the frequency distribution of diagonal lines, with length  $l$  an integer number, and  
 3  $R_{i,j}$  the Euclidian distance matrix created from the phase space and transformed into a  
 4 recurrence plot, using a time delay  $\tau = 4ms$  [33,51], an embedding dimension  $d = 15$  [51], and  
 5 a threshold value  $r = 2$  [92]. For the  $RQA$  computation, the `RPplot` Matlab function [92] was  
 6 first used with the mentioned above parameters as input, before using the `recu_RQA` Matlab  
 7 function with  $I = 1$ .

8 *Correlation dimension* is a measure of the amount of correlation contained in a signal  
 9 connected to the fractal dimension. Its estimation requires the calculation of the correlation  
 10 integral  $C(r)$ , which is the mean probability that the states of the dynamical systems at two  
 11 different times are close, i.e., within a sphere of radius  $r$  in the space of the phases [28]. Given  
 12 a time series  $g(k)$ , the phase space is reconstructed by the vectors:

$$13 \quad G(k) = [h(k), g(k + \tau), \dots, g(k + m - 1)\tau)]^T \quad Eq. 28$$

14 with  $m$  the embedding dimension and  $\tau$  a delay. The correlation integral is then estimated by  
 15 the sum:

$$16 \quad C(r) = \frac{1}{N^2} \sum_{\substack{i,j=1 \\ i \neq j}}^N H(r - |G(i) - G(j)|) \quad Eq. 29$$

17 where  $N$  is the number of states, and  $H()$  the Heaviside function. If  $g(k)$  is the output of a  
 18 complex system, when  $N$  increases and  $r$  decreases,  $C(r)$  tends to increase as a power of  $r$ ,  
 19  $C(r) \sim r^{CD}$ . The correlation dimension of the system can then be estimated as the slope of the  
 20 straight line of best fit in the linear scaling range region in a plot of  $\ln(r)$  versus  $\ln C(r)$  [28]. For  
 21 the *correlation dimension* computation, the `correlationDimension` Matlab function was used.

#### 22 **2.4.2.4 Chaos**

23 *Largest Lyapunov exponent* can be calculated using the Rosenstein's method as follow  
 24 (Rosenstein, Collins, et De Luca 1993; Chakraborty et Parbat 2017; Rampichini et al. 2020):

$$25 \quad d(t) = C e^{\lambda_1 \Delta t} \quad Eq. 30$$

$$26 \quad d_j(i) \approx C_j e^{\lambda_1(i\Delta t)} \quad Eq. 31$$

27 where  $d(t)$  is the average divergence at time  $t$ , and  $C$  is a constant that normalizes the initial  
 28 separation. By taking logarithm of both sides of the equation above, we obtain:

$$29 \quad \ln d_j(i) \approx \ln C_j + \lambda_1(i\Delta t) \quad Eq. 32$$

1 It represents a set of approximately parallel lines (for  $j=1, 2, \dots, M$ ), each with a slope roughly  
2 proportional to  $\lambda_1$ . The largest Lyapunov exponent is easily and accurately calculated using a  
3 least-squares fit to the “average” line defined by:

$$4 \quad y(i) = \frac{1}{\Delta t} \langle \ln d_j(i) \rangle \quad \text{Eq. 33}$$

5 Where  $\langle \rangle$  denotes the average over all values of  $j$ . For the *largest Lyapunov exponent*  
6 computation, the lyaprosen Matlab function [93] was used with  $dt = 0.1$  as input parameter.

### 7 **2.4.3 Statistical analyses**

8 Firstly, a paired t-test was conducted on the maximum voluntary isometric force to assess the  
9 effect of RPT on maximum force.

10 Then, partial least square regression (PLSR) analyses were performed using z-score values of  
11 MMF indicators as predictors and z-score values of RPE as response variable. PLSR is  
12 particularly suited when the number of predictors is larger than the observations, and when  
13 there is multicollinearity among predictors [94,95], which is the case for predicting RPE  
14 scores from the combination of 135 input variable (9 muscles \* 15 MMF indicators) in this  
15 study. To avoid overfitting of the data, the number of latent variables was determined when  
16 the absolute error of RPE prediction was minimal [94]. In order to calculate the performance  
17 of our approach, the whole data was divided into training and testing sets, and 5-folds cross-  
18 validation was used subsequently to reduce the bias due to random sampling of the training  
19 and test sets [97,98]. To do so, the whole data set was randomly split into 5 mutually  
20 exclusive subsets (folds) i.e., 4-folds included 17 participants used as the training set and 1-  
21 fold included 4 participants used as the testing set after excluding three participants because  
22 of missing data. For each model, the absolute error of prediction was calculated on  
23 denormalized values. The cross-validation accuracy was calculated as the average of the  
24 5 individual accuracy measures [99,100]. The variable importance in projection (VIP) was  
25 calculated for each model to determine the most relevant MMF indicators to explain variation  
26 of RPE. This whole PLSR procedure was repeated 100 times in order to have one hundred  
27 partitions of cross-validation, reducing the bias due to random sampling of the training and  
28 testing sets [101,102]. Then model performance (i.e., absolute error of prediction) was  
29 averaged over the 500 data (100 repetitions \* 5-folds). Finally, an unpaired t-test was  
30 performed between the VIP values of the median frequency and the activation level and the  
31 VIP values of each MMF indicator of each muscle and the to assess the efficiency of the other  
32 indicators compared to the JASA indicators.

1 The effect of the RPT for each MMF indicator and muscle was assessed on a participant-  
2 specific basis using an unpaired t-tests between the 10 first cycles (RPT initiation) and the last  
3 10 cycles (RPT termination) followed by Cohen's *d* effect size computation. We then  
4 determined the percentage of participants for which there was a significant change, namely, a  
5 significant decrease for the median frequency, mobility, Higuchi fractal dimension,  
6 correlation dimension, largest Lyapunov exponent, and spectral, approximate, sample,  
7 multiscale, and fuzzy entropy indicators [17,18,56,103–105], and a significant increase for the  
8 activation level, activity, degree of multifractality, percent of determinism, and percent of  
9 recurrence [5,33,56,84].

## 10 3 Results

### 11 3.1 Maximum voluntary isometric force

12 The paired t-test revealed a significant RPT effect ( $p < 0.001$ ) on maximum voluntary  
13 isometric force. The MVIC performed immediately after the RPT termination was  
14 significantly smaller than the MVIC performed before the RPT initiation (Figure 2).

## Maximum voluntary isometric contractions

1

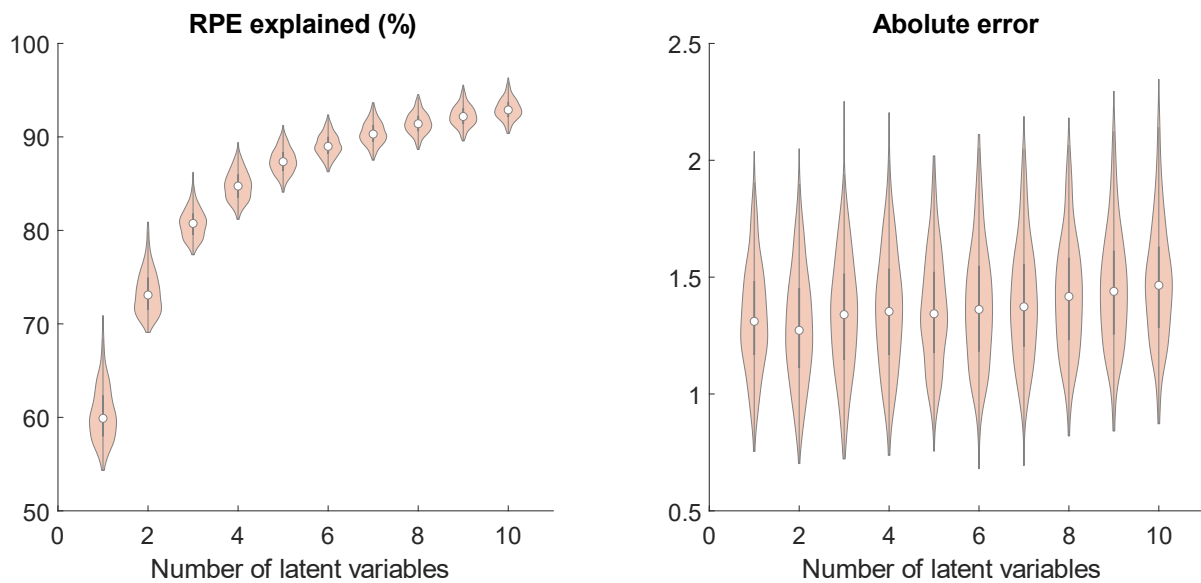

2 Figure 2. Violin plot representation of maximum voluntary isometric force during pre- and  
3 post-RPT. On each violin representation, the white dot represents the median, the thick gray  
4 bar represents the interquartile range, and the pink area violin-shaped represents the data  
5 distribution.

## 1 3.2 Partial least square models

### 2 3.2.1 Performance of the partial least square regression to predict RPE

3 Over the 100 iterations, the PLSR model that generated the smallest mean absolute error of  
4 prediction of RPE values on the testing set included two latent variables ( $1.36 \pm 0.29$ ;  
5 Figure 3, right). This model explained  $73.36 \pm 2.94$  % of the variance of the RPE on the  
6 training set (Figure 3, left). Although models including more latent variables explained a  
7 greater percentage of RPE variance on the training set than the two-latent variable model, the  
8 absolute error of prediction on the testing set was greater than for the two-latent variable  
9 model indicating an overfitting [106]. Consequently, the VIP results in the next section were  
10 computed from the two-latent variable model.

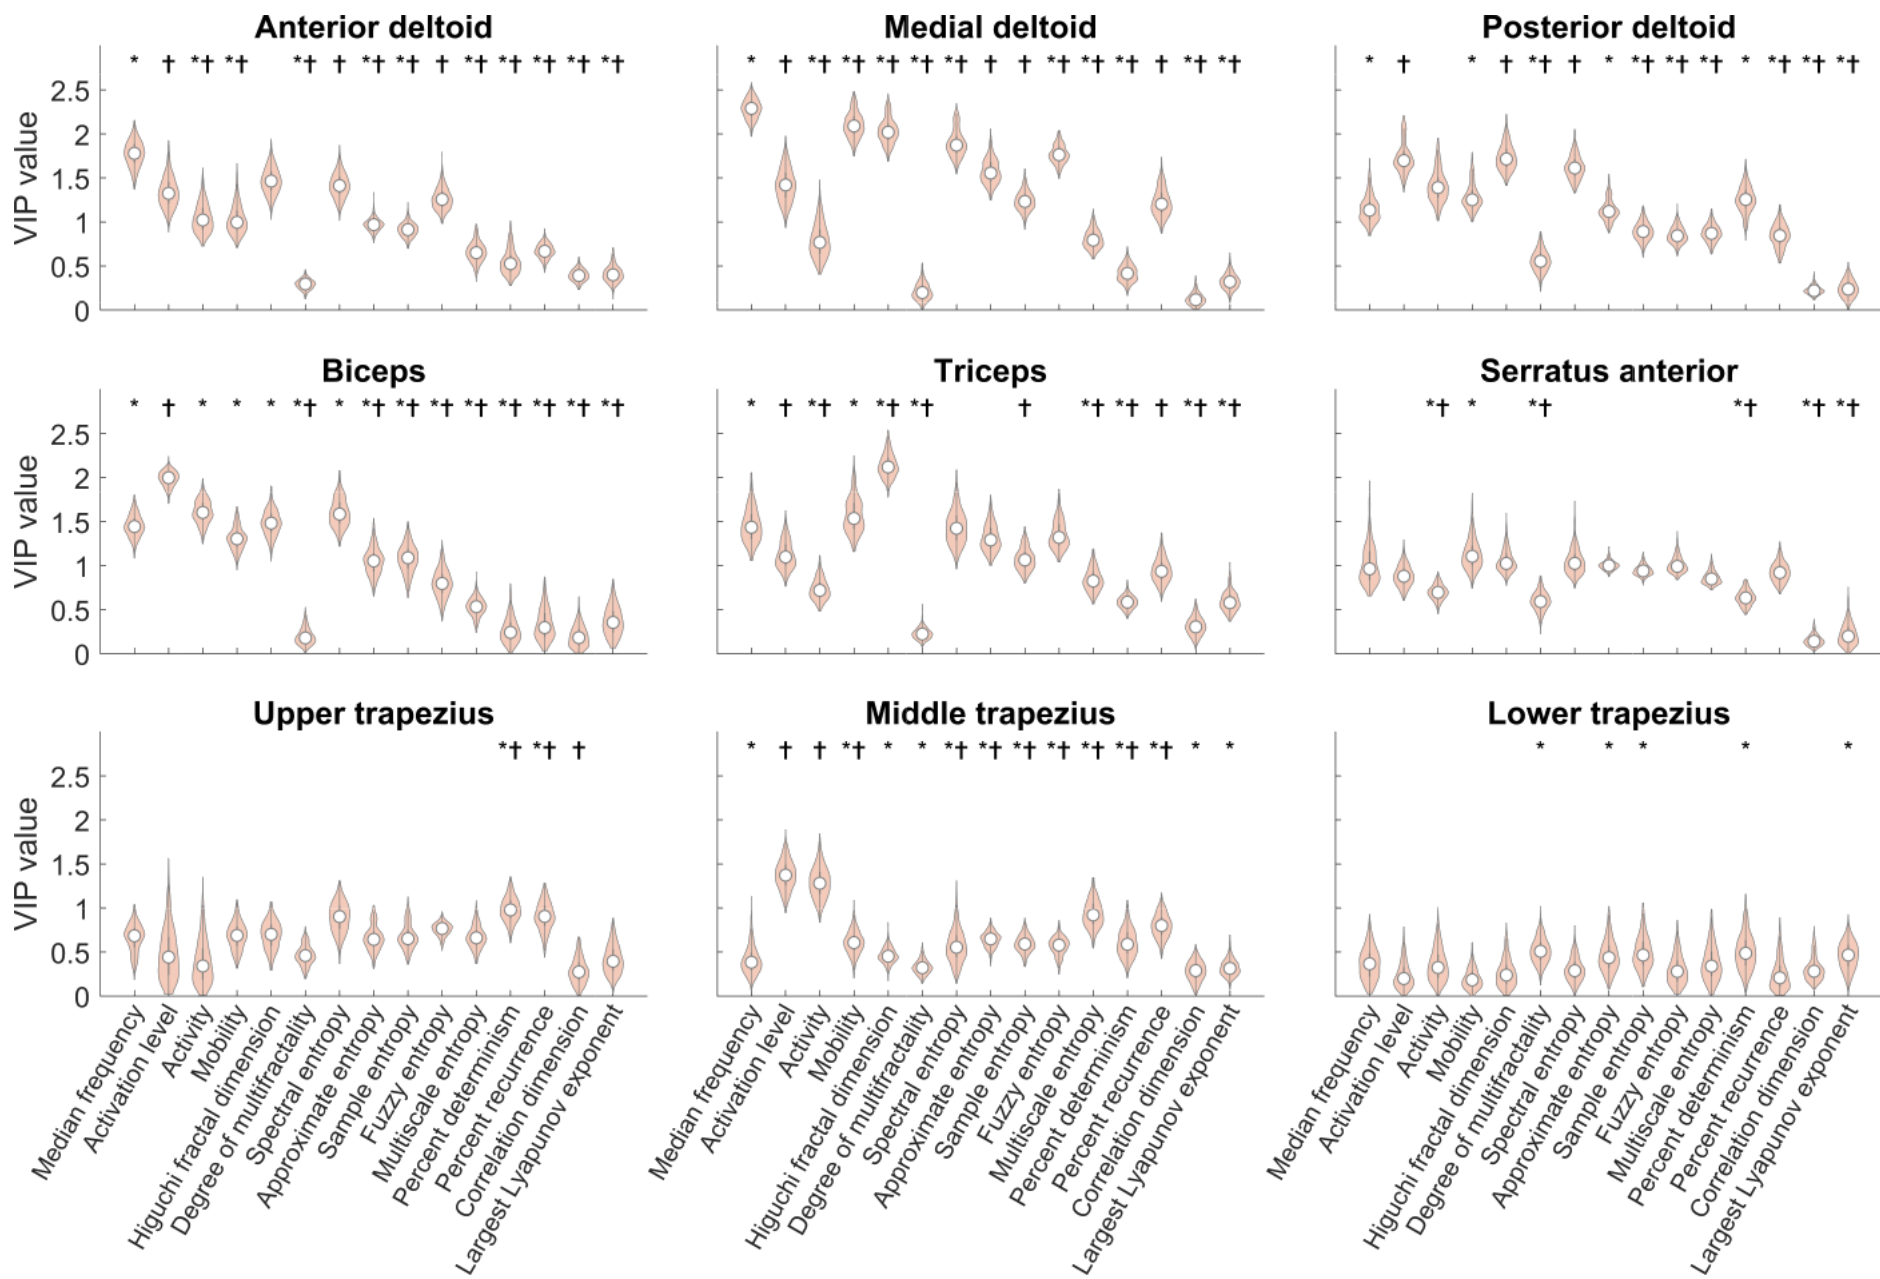

11  
12 Figure 3. Violin plot representation of the percentage of RPE explained obtained on the  
13 training set (left) and absolute error of prediction obtained on the testing set (right) for the  
14 100 iterations of the 5-fold cross-validation of the PLSR analysis. On each violin  
15 representation, the white dot represents the median, the thick gray bar represents the  
16 interquartile range, and the pink area violin-shaped represents the data distribution.

### 17 3.2.2 VIP values for each MMF indicator and muscle

18 The highest VIP value was obtained for the median frequency of the medial deltoid  
19 ( $2.28 \pm 0.11$ ) and was significantly higher than the VIP of any other MMF indicator of this  
20 muscle (Figure 4). The VIP value of the activation level ( $1.41 \pm 0.18$ ) was significantly lower  
21 than the VIP value of the mobility ( $2.10 \pm 0.14$ ), Higuchi fractal dimension ( $2.03 \pm 0.14$ ),  
22 spectral entropy ( $1.89 \pm 0.15$ ), and fuzzy entropy ( $1.77 \pm 0.10$ ). All other MMF indicators had

1 significantly lower VIP values than the VIP value of the activation level. The VIP values  
2 obtained for the anterior deltoid showed similar pattern for the median frequency  
3 ( $1.77 \pm 0.14$ ) that was significantly higher than the VIP value of any other MMF. Then,  
4 fractal Higuchi ( $1.47 \pm 0.14$ ), spectral entropy ( $1.41 \pm 0.14$ ) and fuzzy entropy ( $1.26 \pm 0.12$ )  
5 had qualitatively higher VIP values than the activation level but did not reach significance.  
6 For the posterior deltoid, activation level ( $1.73 \pm 0.17$ ) had VIP values significantly higher  
7 than the VIP values of all indicators except Higuchi fractal dimension ( $1.74 \pm 0.15$ ). For the  
8 biceps, the VIP value of the median frequency ( $1.46 \pm 0.12$ ) was significantly smaller than the  
9 VIP value of the mobility ( $1.57 \pm 0.13$ ) and the Higuchi fractal dimension ( $2.13 \pm 0.14$ ); the  
10 VIP value of the activation level ( $1.12 \pm 0.09$ ) was significantly smaller than the VIP value of  
11 the mobility ( $1.57 \pm 0.13$ ), Higuchi fractal dimension ( $2.13 \pm 0.14$ ), spectral entropy  
12 ( $1.44 \pm 0.16$ ), approximate entropy ( $1.31 \pm 0.15$ ), and fuzzy entropy ( $1.35 \pm 0.16$ ). For the  
13 triceps, the VIP value of the activation level ( $1.98 \pm 0.19$ ) was significantly greater than the  
14 VIP value of activity ( $1.61 \pm 0.12$ ), mobility ( $1.31 \pm 0.20$ ), Higuchi fractal dimension  
15 ( $1.48 \pm 0.13$ ) and spectral entropy ( $1.60 \pm 0.20$ ). Finally, the MMF indicators of the serratus  
16 anterior, upper, middle, and lower trapezius had the lowest VIP values.

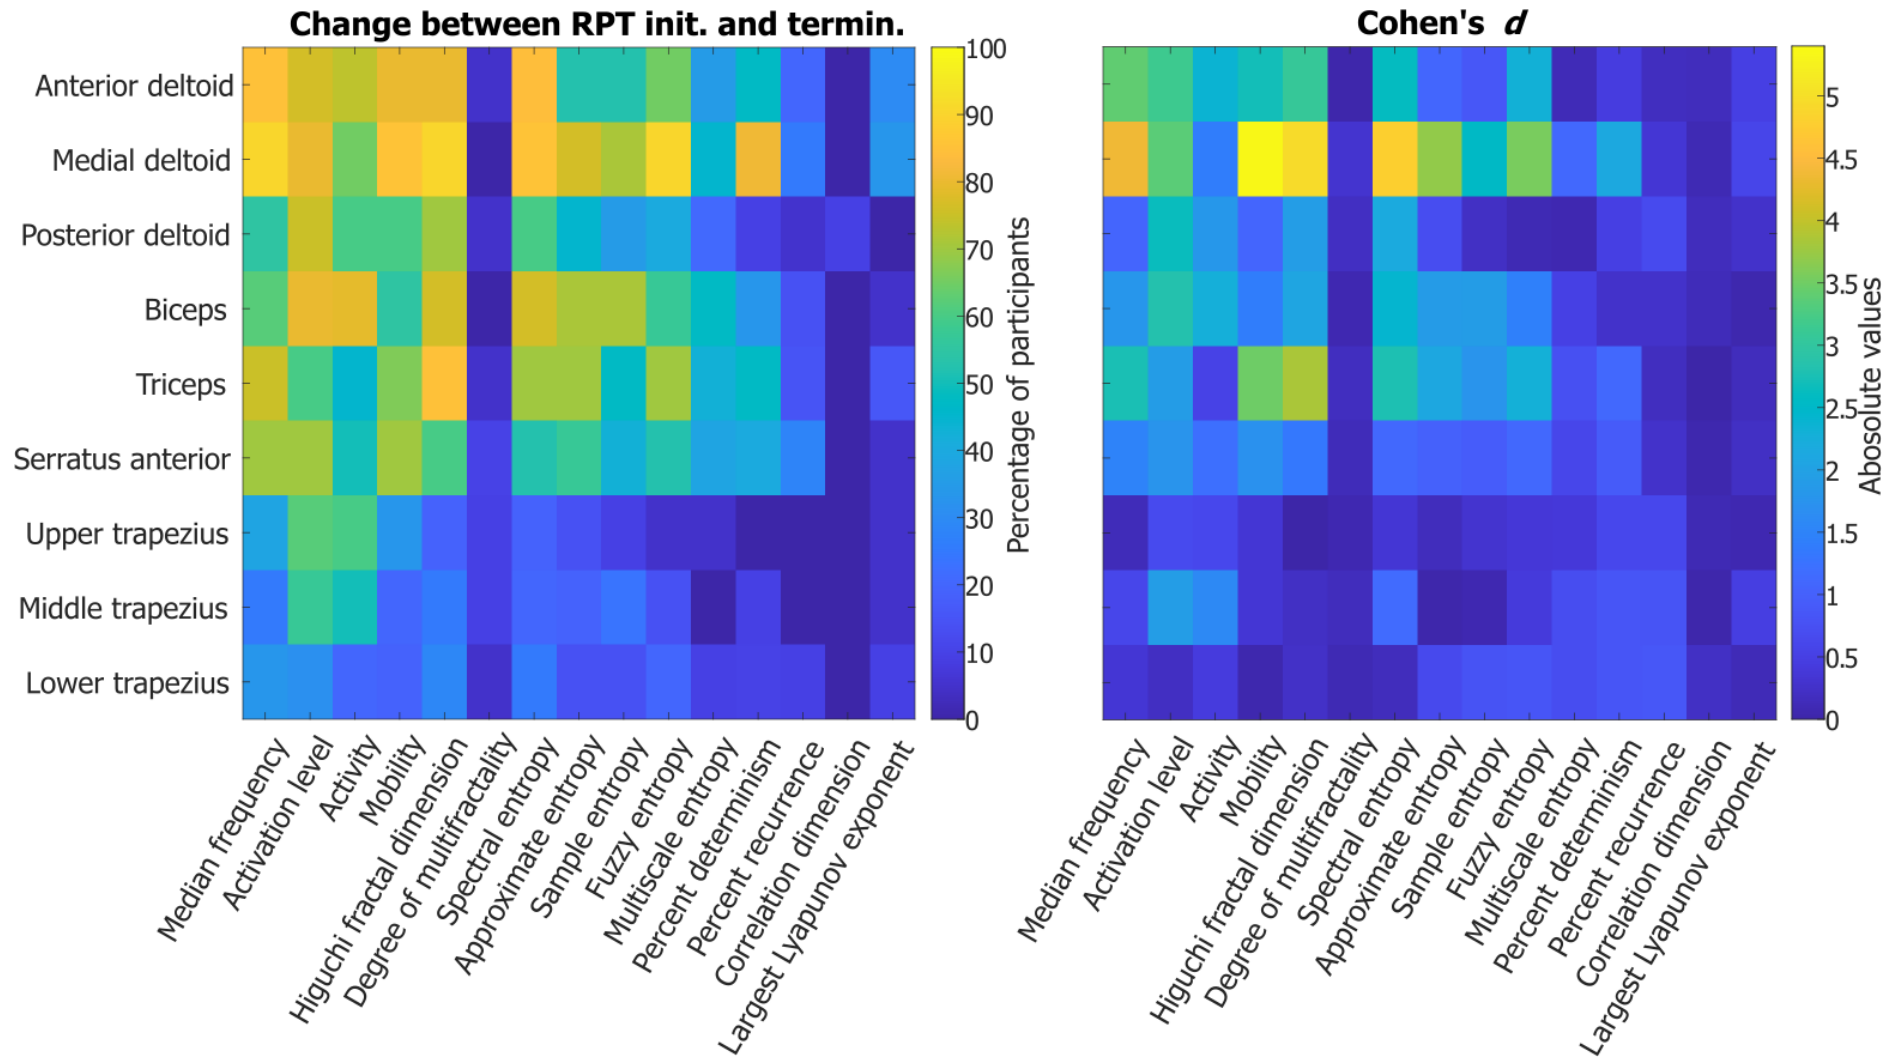

1 Figure 4. Violin plot representation of VIP values for all muscles and MMF indicators. On  
2 each violin representation, the white dot represents the median, the thick gray bar represents  
3 the interquartile range, and the pink area violin-shaped represents the data distribution. An \*  
4 indicates a significant difference between activation level and a MMF indicator and a †  
5 indicates a significant difference between median frequency and a MMF indicator.

### 6 **3.2.3 Proportion of change of MMF indicators among participants**

7 Figures in supplementary material S1-9 (one figure per muscle) show row values of each  
8 MMF indicator for each participant at RPT initiation and termination. Concerning the medial  
9 deltoid, the proportion of the participants for whom there was a change between initiation and  
10 termination for median frequency, mobility, Higuchi fractal dimension, spectral entropy,  
11 fuzzy entropy, and percent of determinism, was 90%, 80%, 90%, 86%, 90% and 81%,  
12 respectively. These indicators also showed the strongest effect sizes (Cohen's *d* ranged  
13 between 3.5-5.35, the percent of determinism excluded, which had a Cohen's *d* value equal to  
14 2.13) (Figure 5). Strong effect sizes were also observed for approximate entropy (Cohen's  
15  $d=4$ ) and activation level (Cohen's  $d=3.6$ ). The degree of multifractality, multiscale entropy,  
16 correlation dimension, and Lyapunov exponent changed for only 0% -45% participants with  
17 Cohen's *d* effect sizes below 1.1. Concerning the anterior deltoid, the median frequency,  
18 activation level, activity, mobility, Higuchi fractal dimension, spectral entropy and fuzzy  
19 entropy were the MMF indicators that also showed significant change between RPT initiation  
20 and termination for a large proportion of the participants, i.e., 85%, 76%, 74%, 80%, 80%,  
21 84%, 65% (Cohens' *d* effect sizes ranged between 2.05-3.16).

22 Other noteworthy results involved median frequency, activation level, mobility, fractal  
23 Higuchi, spectral entropy and fuzzy entropy of the triceps that significantly changed for 75%,  
24 60%, 67%, 85%, 70%, 70% of the participants respectively (Cohens' *d* effect sizes ranged  
25 between 1.9-3.8); the activation level, activity, Higuchi fractal dimension, and spectral  
26 entropy of the biceps changed for 80%, 79%, 76%, 76%, (Cohens' *d* effect sizes ranged  
27 between 2.26-2.83); the activation level and the activity of the upper trapezius that changed  
28 for 62% and 60 of the participants, respectively (Cohens' *d* effect sizes equal to 0.67 and 0.63,  
29 respectively); the median frequency, the activation level and the mobility of the serratus  
30 anterior changed for 70% of the participants for all the three indicators (Cohens' *d* effect sizes  
31 ranged between 1.5-1.8); the activation level and the Higuchi fractal dimension of the  
32 posterior deltoid changed for 75% and 70% of the participants (Cohens' *d* effect sizes equal to  
33 2.64 and 1.9, respectively); the degree of multifractality, multiscale entropy, percent of

1 recurrence, correlation dimension, and largest Lyapunov exponent changed significantly for  
2 less than 45% of participants between RPT initiation and termination with Cohens' *d* effect  
3 sizes lower than 0.7; the middle and lower trapezius showed significant changes for less than  
4 57% of the participants (Cohen's *d* effect sizes lower than 1.9) for all MMF indicators.

1

2 Figure 5. Heat maps representation of the percentage of participants showing significant effect of time between RPT initiation and termination on  
 3 unpaired t-test (left column) and their corresponding Cohen's *d* effect sizes (right column) for each muscle and each MMF indicator.

## 1 4 **Discussion**

2 The aim of this study was to identify the MMF indicators that best assess muscle fatigue  
3 during a repetitive pointing task. To this end, a PLSR method was used to predict the RPE  
4 from 15 linear and non-linear MMF indicators. The trained PLSR model explained 73% of the  
5 RPE variance. Median frequency, mobility, spectral entropy, fuzzy entropy, and fractal  
6 Higuchi had greater VIP values and changed for more than 65% of the participants during the  
7 RPT for both the anterior and medial deltoids. Moreover, the degree of multifractality, the  
8 multiscale entropy, the correlation dimension, the recurrence quantification analysis, and the  
9 largest Lyapunov exponent were the MMF indicators that had the lowest VIP values for the  
10 anterior and medial deltoids and did not change for a large proportion of participants.

### 11 **4.1 Effect of RPT on muscle fatigue**

12 As a decrease in MVIC and an increase in RPE is often used to emphasize muscle fatigue [1-  
13 4], the results of this study confirm the presence of muscular fatigue at RPT termination.  
14 Indeed, the t-test analysis revealed a significant decrease of the MVIC performed immediately  
15 after the completion of the RPT compared to the MVIC performed before the RPT. Also, all  
16 participants reached 8 or higher out of 10 at RPE scale at the completion of the RPT, 7  
17 corresponding to “very strong” and 10 to “extremely strong (almost max)” perceived exertion  
18 [69] to perform the RPT at task termination. Since the task remained the same across the RPT,  
19 the increasing perceived exertion, in combination with the decreasing maximum voluntary  
20 isometric force indicated that the RPT caused muscle fatigue [107].

### 21 **4.2 PLSR algorithm to predict RPE**

22 For the first time, the present study used PLSR to predict muscle fatigue through the evolution  
23 of RPE and using MMF indicators as predictors during multi-joint movement of the shoulder.  
24 This approach allowed to explain 73% of the RPE variance on the training set, with an  
25 absolute error of prediction of 1.36 on the testing set. This explained variance is greater than  
26 that observed by Goubault et al., [24], Ni et al., [68] and Troiano [43] that used bivariate of  
27 multivariate regression models. Indeed, Goubault et al., [24] performed multivariate  
28 regression analyses between various MMF indicators and RPE scores during a working task.  
29 Their R-square values ranged between 11% and 39%. In the study of Troiano [43], the EMG  
30 fractal dimension and the EMG normalized mean frequency explained the RPE changes by  
31 52% and 50%, respectively, during isometric contractions of the upper trapezius. In Ni et al.,  
32 [68], EMG indicators explained 49% of the RPE variance during dynamic contractions. In the

1 present study, the greater percentage of RPE variance explained can be due to the  
2 combination of several MMF indicators together in the PLSR model. In addition, various  
3 complex indicators identified as good predictors of muscle fatigue [28], such as fuzzy entropy  
4 and Higuchi fractal dimension, were used for the first time in such a model. Interestingly, our  
5 PLSR approach not only provided better prediction of RPE, but also physiologically  
6 meaningful results. Indeed, the highest VIP values were observed for the anterior and medial  
7 deltoids that are the muscles known to fatigue the most during the RPT used in the present  
8 study [72,73] and for the median frequency, a commonly well recognized indicator of muscle  
9 fatigue [108–113].

#### 10 **4.3 Median frequency, mobility, spectral entropy, fuzzy entropy, and fractal Higuchi** 11 **MMF indicators to assess muscle fatigue**

12 Median frequency was the MMF indicator that had the highest VIP value (2.28) and changed  
13 for a very large proportion of the participants (>85%) between RPT initiation and termination  
14 in the muscles known to fatigue the most during the RPT used in the present study, i.e.,  
15 anterior and medial deltoids [72,73]. This result agrees with Goubault et al., [24], that also  
16 found that when correlating six MMF indicators to RPE, mobility and spectral entropy were  
17 among the MMF indicators that showed the highest R-square values. Our results are  
18 consistent with this recent study as mobility and spectral entropy also showed high VIP values  
19 (1.26-1.41) and significantly changed for a large proportion of the participants (80%-86%)  
20 between RPT initiation and termination for the anterior and medial deltoids, which reaffirms  
21 that these MMF indicators may be relevant to assess muscle fatigue. Concerning chaos,  
22 correlation, entropy, and fractals MMF indicators, Higuchi fractal dimension and fuzzy  
23 entropy were the only indicators that had high VIP values (1.26-2.03) and changed  
24 significantly for a large proportion of the participants (65%-90%) for the anterior and medial  
25 deltoids. Higuchi fractal dimension therefore confirms that the fractal dimension is sensitive  
26 to intrinsic changes of EMG signals occurring with muscle fatigue [18,49]. As to fuzzy  
27 entropy, our results are in line with Xie et al., [54] which stated that it provides an improved  
28 evaluation of time series complexity. Considering that median frequency is sensitive to both  
29 muscle fiber conduction velocity and motor unit synchronization [17,114], mobility is  
30 sensitive to conduction velocity [56], spectral entropy is sensitive to muscle fiber conduction  
31 velocity and motor units firing rate [56], and fuzzy entropy and Higuchi fractal dimension are  
32 sensitive to the increase of motor unit synchronization [90,104] occurring with muscle  
33 fatigue, our results emphasize the need to consider and combine a variety of MMF indicators

1 that are sensitive to all parameters of motor unit behavior affected by fatigue in order to  
2 improve its assessment. Noteworthy, median frequency, mobility, spectral entropy, fuzzy  
3 entropy, and Higuchi fractal dimension were the only indicators that both showed low VIP  
4 values and changed for a moderate proportion of the participants (14%-38%) during RPT  
5 initiation and termination for the trapezius muscles, which did not show signs of fatigue  
6 during the RPT used in the present study [72–74]. These five indicators may therefore have  
7 good specificity to assess muscle fatigue, and future investigations should focus on their  
8 combination into a single MMF indicator to maximize the sensitivity and specificity of  
9 muscle fatigue assessment.

#### 10 **4.4 Activation level, activity, approximate, sample, and multiscale entropy, recurrence** 11 **quantification analysis, correlation dimension, and chaos MMF indicators to assess** 12 **muscle fatigue**

13 The activation level was shown to be a part of the two MMF indicators required to assess  
14 muscle fatigue according to the JASA method [14]. Firstly, our results showed that the VIP  
15 value of activation level of the medial deltoid was 1.41, which was significantly lower than  
16 the VIP value of the median frequency, mobility, Higuchi fractal dimension, spectral entropy,  
17 and fuzzy entropy for this muscle. Secondly, although the activation level of both the anterior  
18 and medial deltoid increased significantly for a large proportion of the participants (76%-  
19 80%), which can be interpreted as a MMF [14], the activation level of the posterior deltoid  
20 and upper trapezius also increased for a comparable proportion of the participants (75%-76%)  
21 between the RPT initiation and termination while they the latter muscles did not show sign of  
22 fatigue in previous studies [72,73]. Supporting these results on activation level, muscles act in  
23 synergy so that many postural and movement adaptations are induced by muscle fatigue  
24 during a RPT [72]. Therefore, the upper trapezius and the posterior deltoid changes in  
25 amplitude-based MMF indicators may reflect compensatory mechanisms in response to  
26 fatigue in prime mover muscles rather than local fatigue [115,116]. Consequently, a change of  
27 activation level may reflect local muscle fatigue for prime mover muscles or compensatory  
28 mechanisms in response to fatigue of prime mover muscles for synergistic muscles [72,73].  
29 These observations suggest that activation level, and therefore the JASA method, should be  
30 used with caution for the assessment of muscle fatigue [6] as it may increase the risk of false  
31 positive. Another MMF indicator related to the amplitude of EMG signals is the activity. The  
32 VIP value of the activity of the median and anterior deltoids ranged between 0.73-1.61, which  
33 is qualitatively smaller than the VIP value of median frequency, mobility, Higuchi fractal

1 dimension, spectral entropy, and fuzzy entropy (1.26-2.28) for these muscles. Similarly to  
2 activation level, there were changes in activity for a large proportion of the participants in the  
3 upper trapezius (90%), although this muscle is not supposed to fatigue [72,73]. Thus, our  
4 results further confirm that amplitude related MMF indicators are not relevant for assessing  
5 muscle fatigue.

6 Approximate and sample entropy had moderate VIP values (0.91-1.57), in the anterior and  
7 median deltoids and changed for a moderate to large proportion of the participants (52%-  
8 76%) between the RPT initiation and termination. To support this latter result, the lack of  
9 consistency and monotonicity of approximate entropy causes difficulty in interpreting the  
10 signal's complexity and reduced its efficiency to dichotomize fatigue and non-fatigue states  
11 [54,88]. Although sample entropy addresses the drawbacks of approximate entropy  
12 calculation to assess muscle fatigue [88], our results revealed that this MMF indicator had  
13 moderate efficiency to assess muscle fatigue, which may be caused by its high variability to  
14 precise parameter selection [117]. Multiscale entropy was therefore introduced to better detect  
15 the presence of complexity in time series and overcome the limitations of approximate and  
16 sample entropy [57]. Although multiscale entropy was shown more sensitive to muscle  
17 fatigue than median frequency [118], our results evidenced that multiscale entropy had  
18 significantly smaller VIP values than median frequency and changed for a moderate  
19 proportion of the participants (35%-45%) for the anterior and medial deltoids between RPT  
20 initiation and termination. Consequently, fuzzy entropy, as previously discussed, is the only  
21 entropy-based indicator that may be efficient to assess MMF. Concerning the degree of  
22 multifractality, it had very low VIP values ( $<0.5$ ) and marginally changed ( $<10\%$ ) between  
23 the RPT initiation and termination. This result contradicts previous studies that found that this  
24 multifractal MMF indicator is more efficient than the median frequency and Higuchi fractal  
25 dimension to assess muscle fatigue in dynamic and static conditions [40,46,47,49]. More  
26 investigations are therefore required to determine the effectiveness of the degree of  
27 multifractality for assessing MMF. As to correlation dimension, percent determinism, and  
28 percent of recurrence, they had very low VIP values (0.4-1.2), which agrees with previous  
29 evidences that correlation dimension is not sensitive to changes in EMG signal properties  
30 caused by fatigue [28]. Although previous studies have shown an effect of muscle fatigue on  
31 recurrence quantification analyses, our results are in agreement with the lower performance of  
32 this MMF indicator compared to frequency-based and fuzzy entropy indicators [75]. Finally,  
33 the largest Lyapunov exponent also had very low VIP values for all muscles ( $<0.6$ ) and did  
34 not change during the RPT for more than 38% of the participants between RPT initiation and

1 termination in median and anterior deltoid. To support this result, Chakraborty et al., [36]  
2 found that the largest Lyapunov exponent did not change with fatigue during dynamic  
3 contractions of the biceps brachii. Thus, our results confirm that the potential of approximate,  
4 sample, and multiscale entropy, degree of multifractality, correlation dimension, and the  
5 largest Lyapunov exponent is limited to assess muscle fatigue during low-load repetitive  
6 tasks, which question their sensitivity to changes in muscle fiber conduction velocity  
7 [5,84,104] and motor unit firing rate [35,56,103] and synchronization [35,104] caused by  
8 fatigue.

#### 9 **4.5 Limitations**

10 The first limitation of this study was that, considering the nature of the task which is a multi-  
11 joint task performed with the whole dominant upper limb in a standing position, several  
12 muscles act as prime mover and stabilizer muscles so that changes of MMF indicators may be  
13 caused either by their function or muscle fatigue that make interpretation of amplitude related  
14 indicators difficult [115,119]. Another limitation is that the RPE was used as a measure of  
15 fatigue, while its evolution can be multifactorial during a fatiguing task. Finally, even though  
16 the previous literature has suggested the presence of sex differences in some EMG patterns of  
17 fatigue during the performance of the RPT [120], our sample size was too small to develop a  
18 sex-specific model.

#### 19 **5 Conclusion**

20 The present study confirmed that median frequency, mobility, and spectral entropy are  
21 efficient EMG-based indicators to assess muscle fatigue. Interestingly, our analyses also  
22 showed that fuzzy entropy and Higuchi fractal dimension may also be efficient MMF  
23 indicators. Therefore, a combination of median frequency, mobility, spectral entropy, fuzzy  
24 entropy, and Higuchi fractal dimension should be further considered to assess muscle fatigue  
25 compared to the exclusive use of median frequency and activation level. Alternatively,  
26 although other MMF indicators such as the multiscale entropy, the degree of multifractality,  
27 correlation dimension, the percent of determinism, the percent of recurrence, and the largest  
28 Lyapunov exponent were previously used to assess muscle fatigue, they should no further be  
29 considered as our analyses showed that they poorly contributed to the prediction of RPE and  
30 did not change significantly for a large proportion of the participants during a fatiguing RPT.  
31 These results may help to improve the identification of MMF indicators to accurately assess  
32 muscle fatigue. In the long term, more accurate methods to identify fatigue-related changes in  
33 EMG, combined with other advances such as in workplace wearable sensors, could contribute

1 to the real-time, early detection of injury risk factors, and ultimately, prevention of  
2 musculoskeletal disorders caused by muscle fatigue.

### 3 6 **Acknowledgments**

4 We would like to thank our industrial partner, David's TEA, with a special mention to our  
5 contact, R. Butman, for his help in the recruitment.

### 6 7 **Funding**

7 This study was supported by the Institut Robert-Sauvé en Santé et Sécurité du Travail  
8 (IRSST) (2017\_0016).
