53

Key Points

54

55 **Question** Can a deep learning model (DL)^o based on high resolution images of the distal

56 forearm predict fragility fractures?

57

58 **Findings** In the setting of 3 pooled population-based cohorts, the DL model predicted

59 fractures substantially better than areal bone mineral density and FRAX, especially in women

60 ≥ 65 years.

61

62 **Meaning** Our DL model may become an easy to use way to identify postmenopausal women

63 at risk for fracture to improve fracture prevention.

64

65

66

67

Abstract

68

69 **Importance** Fragility fractures are a public health problem. Over 70% of women having

70 fractures have osteopenia or normal BMD, but they remain unidentified and untreated

71 because the definition of ‘osteoporosis’, a bone mineral density (BMD) T-Score $\leq -2.5SD$, is

72 often used to signal bone fragility.

73

74 **Objective** As deep learning facilitates investigation of bone’s multi-level hierarchical

75 structure and soft tissue, we tested whether this approach might better identify women at risk

76 of fracture before fracture.

77

78 **Design** We pooled data from three French and Swiss prospective population-based cohorts

79 (OFELY, QUALYOR, GERICO) that collected clinical risk factors for fracture, areal BMD

80 and distal radius measurements with high resolution peripheral quantitative tomography

81 (HRpQCT). Using only three-dimensional images of the distal radius, ulna and soft tissue

82 acquired by HRpQCT, an algorithm, a Structural Fragility Score-Artificial Intelligence (SFS-

83 AI), was trained to distinguish 277 women having fractures from 1401 remaining fracture-free
84 during 5 years and then was tested in a validation cohort of 422 women.

85

86 **Setting** European postmenopausal women

87

88 **Participants** We have studied postmenopausal women considered as representative of the
89 general population, who were followed for a median 9.4 years in OFELY, 5.4 years in
90 QUALYOR and 5.7 years in GERICO.

91

92 **Main outcome and measure** All types of incident fragility fractures

93

94 **Results** We used data from 2666 postmenopausal women, with age range of 42-94. In women
95 ≥ 65 years having ‘All Fragility Fractures’ or ‘Major Fragility Fractures’, SFS-AI generated
96 an AUC of 66-70%, sensitivities of 60-68% and specificity of 71%. Sensitivities were greater
97 than achieved by the fracture risk assessment (FRAX) with BMD or BMD (6.7-26.7%) with
98 lower specificities than these diagnostics (~95%).

99

100 **Conclusion and relevance** The SFS-AI is a holistic surrogate of fracture risk that pre-
101 emptively identifies most women needing prompt treatment to avert a first fracture.

107

108

109 **Introduction**

110

111 Fragility fractures are a public health problem because fractures impose high morbidity,
112 mortality and cost to the community.¹ To identify women with fragile bones before fracture, a
113 W.H.O group designated women as having ‘osteoporosis’ if femoral neck bone mineral
114 density (BMD) T-Score was ≤ -2.5 standardized deviations (SD) below the premenopausal
115 mean.² Epidemiological studies confirmed that fracture risk increases as BMD decreases, but
116 the frequency distribution around the age-related decline in mean BMD remains normal.

117

118 Because of this normal frequency distribution, most postmenopausal women in the
119 community have osteopenia (T-score -2.5 to -1.0 SD) or normal BMD (T-score > -1.0 SD).
120 These women form the source of 75% of all fragility in the community, only 25% arise
121 among the smaller subset of women in the community with osteoporosis as defined by
122 BMD.³⁻⁹ The women with osteopenia or normal BMD having fragility fractures remain
123 unidentified and untreated using the definition of osteoporosis, a BMD T-Score ≤ -2.5 SD, to
124 signal bone fragility. Treatment is not offered, even in the presence of a prevalent or incident
125 fracture, because the absence of osteoporosis is incorrectly interpreted as being evidence of
126 absence of bone fragility.¹⁰

127

128 Osteoporosis and bone fragility are used interchangeably even though they are not
129 synonymous terms.¹¹⁻¹³ Absence of osteoporosis does not exclude bone fragility. Bone
130 fragility is not binary, present in women with osteoporosis (T-Score ≤ -2.5 SD) and absent in
131 women without osteoporosis (T-Score > -2.5 SD). Even when bone loss only reduces BMD
132 into the low normal or osteopenia range, the bone is unlikely to be ‘normal’. Bone mass is
133 reduced relative to premenopausal women and many qualities of bone responsible for its
134 strength may be compromised.¹⁴⁻¹⁸

135

136 For example, advancing age deteriorates the composition of the mineralized matrix.^{19,20} Bone
137 loss disrupts the spatial configuration of bone's three-dimensional architecture.^{15,21} These
138 changes produce a non-linear increase in bone fragility, disproportionate to both the bone loss
139 causing the deterioration and the reduction in BMD.^{20,22} Resistance to bending is a 7th power
140 function of bone's cortical porosity and a 3rd power function of its trabecular density.²²

141

142 Consequently, even modest disruption of the spatial configuration of bone at nano-, and
143 micro-levels of resolution compromise bone strength independent of BMD. In addition, soft
144 tissue changes like loss of muscle mass (sarcopenia) impair mobility and balance predisposing
145 to falls, fractures and mortality.²³ Thus, reducing the population burden of fractures requires a
146 diagnostic that complements BMD by identifying women at risk of fracture due to bone
147 fragility caused by compromised bone morphology not captured by $BMD \leq -2.5$ SD, by an
148 increased risk of falls due to deteriorated soft tissues such as muscle mass, or both. Non-
149 invasive evaluation of bone microarchitecture improves fracture prediction compared with
150 FRAX plus BMD or BMD alone.^{8,9}

151

152 A promising area of innovation in the promotion of human health is the use of Artificial
153 Intelligence (AI). Application of Deep Learning to medical imaging²⁴ facilitates the
154 investigation of bone's multilayered qualities and has been reported to identify patients with
155 prevalent fractures or osteoporosis in cross sectional studies.²⁵⁻²⁷ However, no prospective
156 studies have applied deep learning using only the high resolution 3-dimensional images of
157 bone and soft tissue to determine whether an algorithm, a Structural Fragility Score derived
158 by Artificial Intelligence (SFS-AI), might capture deteriorated bone qualities and soft tissue.
159 If so, this holistic surrogate of fracture risk is likely to serve as a diagnostic that pre-emptively

160 identifies women at risk of a first or subsequent fracture needing prompt treatment and would
161 do so better than the fracture risk assessment (FRAX) score with BMD or BMD alone.

181

182

183

184

185

186 **Methods**

187

188 **Participants** We studied (i) 568 postmenopausal women, median age 68.2 years, range 42-
189 94 of Os des Femmes de LYon, OFELY, France followed for a median [interquartile range]
190 of 9.4 [1.0] years,^{9,28,29} (ii) 1427 women of the Qualité Osseuse Lyon Orléans, QUALYOR
191 cohort (1042 recruited in Lyon, 497 in Orléans), median age 65.9 (range 50-87) years
192 followed for 5 years³⁰ and (iii) 671 women of the Geneva Retirees Cohort, GERICO, in
193 Switzerland median age 65 (range 63-68) years followed 5.7 years (range 2-8).³¹ The studies
194 were approved by the institutional review boards. Participants provided informed consent.
195 Fractures (excluding head, toes and fingers) were confirmed using radiographs.

196

197 **Bone microarchitecture, bone densitometry, FRAX with BMD** HRpQCT (voxel size of
198 82 μm^3) was used to scan the non-dominant forearm (Scanco Medical AG, Switzerland).³²
199 Radiation exposure was ~3 microsievert. Quality control was monitored by daily scans of
200 hydroxyapatite rods (QRM, Moehrendorf, Germany). Femoral neck BMD was quantified
201 using Hologic DXA scanners in the French cohorts and Hologic QDR Discovery in the Swiss
202 cohort. T-scores were calculated using NHANES III. FRAX with femoral neck BMD
203 provides a 10-year risk for Major Fragility Fractures (proximal humerus, wrist, distal forearm,
204 clinical spine, or hip).³³

205

206 **Deep Learning network** To avoid bias towards any one of the three cohorts, we
207 combined the three cohorts and then we randomly divided the combined data set into a
208 training and testing data set. No training data was used as testing data. **Figure S2** shows
209 participants were randomly allocated to five groups, four used for training (n=1678), the fifth
210 used for testing (n = 422). Scores were calculated for each testing group with the median
211 forming the SFS-AI (see Supplement **Figure S2**). Deep learning was applied to images of the

212 distal radius and ulna and the surrounding soft tissue acquired using HR-pQCT (see
213 Supplement).³⁴⁻³⁷ Training the algorithm to identify women sustaining fractures faced two
214 challenges: (i) extraction of features within the three-dimensional image captured by a matrix
215 of 110*1560*1560 voxels conferring fracture risk and (ii) limited data for training
216 predisposing to model over-fitting. We used the DenseNet121 as the feature extraction
217 network (**Figure S1**). Features conferring fracture risk were learnt collectively by densely
218 connected layers in the neural network. The input to the feature extraction network was the
219 110 slices acquired by the HR-pQCT at the distal radius (including the ulna and surrounding
220 soft tissues). The output from the feature extraction network is a feature vector of 256
221 numbers.

222

223 To achieve robust feature extraction, a multi-task learning strategy was used to overcome
224 model overfitting. To provide pictorial representation of the fracture risk prediction, extracted
225 features were displayed as a heat map overlaid upon a 2D projection of the images. Red
226 reflects greater relevance of the region's bone or soft tissue to fracture prediction.

227

228 **Statistical Analyses** Analyses were conducted using data in women of any age and those 65
229 years and over. Follow-up was to fracture or freedom from fracture for five years since HR-
230 pQCT scanning. SFS-AI, FRAX with BMD and BMD were not normally distributed and so
231 are presented as median and interquartile range (IQR). Values are adjusted for age and cohort
232 because of cohort differences in age and follow-up duration. (**Tables S1 and S2.**) Comparison
233 of the diagnostics in women having fractures and those remaining fracture-free was carried
234 out using analysis of covariance adjusted for age and cohort and estimated by robust
235 regression. (**Table 1.**)

236

237 The performance of SFS-AI as a continuous trait was assessed using the area under the curve
238 (AUC) and was estimated using a parametric probit model³⁸ and logistic regression to derive
239 Odds Ratios (ORs) for fracture. Both analyses are presented unadjusted and adjusted for age
240 and cohort effect. The sensitivity and specificity of SFS-AI as a binary trait used a threshold
241 of 0.5. (Addressed in **Table 2.**)

242

243 We also assessed the performance of FRAX with BMD and BMD as continuous traits using
244 ROC analysis and computed sensitivity and specificity using thresholds of 20% for FRAX
245 with BMD and – 2.5 SD for BMD denoting high fracture risk. Logistic regression was then
246 used to assess any association of these diagnostics with fracture, separately and combined, for
247 women of any age and women aged 65 years and over. (Addressed in **Figure 1 and Table**
248 **S3.**)

249

250 Linear regression was used to assess the association of SFS-AI with age, separately for
251 women with fractures and women remaining fracture-free. (Addressed in **Figure 2.**) Age,
252 cortical porosity, trabecular density, FRAX with BMD and BMD were used in linear
253 regression to compute an overall R-squared and to determine the proportion of variance in
254 SFS-AI explained by these independent variables. The percentage contribution of each trait
255 to the overall R-squared was computed using the Shapley method.³⁹ (Addressed in **Table S5**
256 **and Figure 3.**)

257

258

259

260

261

262

263 **Results**

264

265 **Table 1** shows SFS-AI was higher in women having ‘All’ or ‘Major Fragility Fractures’ than
266 women remaining fracture-free (both $p < 0.001$). Neither FRAX with BMD nor BMD alone
267 differed in women having fractures versus those remaining fracture-free ($p > 0.15$).

268

269 **SFS-AI pre-emptively identifies women at risk of ‘All’ and ‘Major Fragility Fractures’**

270

271 **Table 2** shows that in the testing cohort of 422 women of any age and the 236 women ≥ 65
272 years of age, the SFS-AI as a continuous trait generated AUCs of 73-74% for ‘All Fragility
273 Fractures’ and ‘Major Fragility fractures’ with adjusted ORs ranging from 2.53 to 2.67 per
274 standard deviation. The SFS-AI as a categorical trait (using a threshold of 0.5), had
275 sensitivities ranging from 58.1% to 74.0% and specificities ranging from 71.0% to 77.3% (all
276 significant, $p < 0.001$ for OR and AUC).

277

278 **Comparing SFS-AI with FRAX with BMD and BMD**

279

280 **Women of any age** Comparisons of the diagnostics was confined to participants having all
281 three measurements. **Figure 1** shows the diagnostics as continuous traits. For ‘All Fragility
282 Fractures’ and ‘Major Fragility Fractures’, the AUCs for SFS-AI were 72% and 69%
283 respectively ($p < 0.05$). **Table S3** shows unadjusted and adjusted SFS-AI predicted women
284 having either category of fractures (ORs ranged from 2.07 to 2.41, all $p < 0.001$). Neither of
285 the other two diagnostics predicted either category of fracture. **Figure 1** also shows the
286 diagnostics as categorical traits. For SFS-AI, sensitivities were 59.3% and 50.0% for
287 detecting women having ‘All Fragility Fractures’ or ‘Major Fragility Fractures’ respectively,
288 values that were significantly greater than sensitivities of FRAX with BMD or BMD (which

289 ranged 4.2 to 16.7%). Specificities of SFS-AI were 77.1%, significantly lower than
290 specificities of the other two diagnostics (which ranged 94.6 to 96.6%).

291

292 **Women aged ≥ 65 years** Supplementary **Figure S3** shows the performance of the
293 diagnostics as continuous traits. For ‘All Fragility Fractures’ and ‘Major Fragility Fractures’,
294 the AUCs for SFS-AI were 70% and 66% respectively. **Table S4** shows unadjusted and
295 adjusted SFS-AI predicted both categories of fractures (OR 1.68 to 2.15, all $p < 0.05$).
296 Neither of the other two diagnostics predicted either category of fracture. **Figure S3** also
297 shows the performance of the diagnostics as categorical traits. For SFS-AI, sensitivities were
298 67.6% and 60.0% for detecting women having ‘All Fragility Fractures’ or ‘Major Fragility
299 Fractures’ respectively, values significantly greater than the sensitivities of FRAX with BMD
300 or BMD (ranging 6.67 to 26.7%). Specificities of SFS-AI were 70.7%, significantly lower
301 than specificity of 94.6% for the other two diagnostics.

302

303 **The morphological basis of the SFS-AI** **Figure 2** shows that SFS-AI increased across
304 age in women having fragility fractures and in women remaining fracture-free. Red regions
305 of the heat map overlying bone and soft tissue identify regions of high relevance to risk of
306 incident fractures compared to the blue regions. **Figure 3** shows that SFS-AI correlated with
307 microarchitecture; directly with cortical porosity and FRAX with BMD, and negatively with
308 trabecular density and BMD. **Figure 3** and Supplementary **Table S5** show that 46% of the
309 variance in SFS-AI was explained by variance in age ($p = 0.002$), cortical porosity and
310 trabecular density (both $p < 0.001$) but not with BMD or FRAX with BMD; 54% of the
311 variance remained unexplained.

312

313

314

315 **Discussion**

316

317 A deep learning algorithm was trained to identify women having fragility fractures using only
318 the high-resolution three-dimensional images of bone and soft tissue. No other information
319 was used. When training no longer improved predictive strength, the algorithm was tested in
320 a cohort without knowledge of their fracture status during the ensuing 5 years. This algorithm
321 served as a surrogate of fracture risk, predicting the incidence of ‘All Fragility Fractures’ and
322 ‘Major Fragility Fractures’ and did so in women 65 years and older with a sensitivity and
323 specificity of 60-70%, out-performing BMD and FRAX with BMD, neither of which
324 predicted fractures.

325

326 This surrogate of fracture risk, a Structural Fragility Score derived by deep learning artificial
327 intelligence, increased across advancing age, was higher in women having incident fractures
328 than those remaining fracture-free, and correlated directly with cortical porosity and
329 negatively with trabecular density. Deterioration of these two traits produces a nonlinear
330 increase in bone fragility,²² predicts incident fractures,^{8,9} prevalent fractures⁴⁰ and predicts
331 estimated bone strength independent of BMD.⁴¹ Deterioration of these two traits accounted
332 for most of the 48% explained variance in SFS-AI. BMD was not an independent predictor of
333 SFS-AI.

334

335 Many qualities of bone not captured by BMD but not yet quantifiable non-invasively, may
336 contribute to the 54% of the unexplained variance in this surrogate of fracture risk.¹⁴⁻¹⁹ For
337 example, heterogeneity in bone’s material composition forms discontinuities, edges, that
338 defend against fracture by increasing the energy required to initiate and propagate a crack.⁴²
339 Small changes in the degree of mineralization increase matrix stiffness but reduce its ductility
340 (ability to absorb energy by deforming).⁴³ Heterogeneity in the size and number of osteons,⁴⁴

341 the cement line around each osteon,^{45,46} the differing orientation of mineralized collagen
342 fibres of adjacent concentric osteonal lamellae,⁴⁷⁻⁴⁹ the extent glycation,⁵⁰ hydration⁵¹ and
343 other factors^{52,53} influence the mechanical properties of bone. The heat map implicated
344 deterioration of soft tissue as well as bone. The nature of soft tissue deterioration is not
345 known but if it is sarcopenia then the SFS-AI algorithm might capture a component of risk for
346 falls.²³

347

348 Most studies using machine learning are cross sectional and examine the ability to identify
349 persons with prevalent fractures or osteoporosis (BMD T-Score \leq - 2.5 SD).²⁴⁻²⁷ This is the
350 first prospective study using deep learning to derive an algorithm that identifies women
351 having incident fractures during five years. The algorithm was developed by interrogating the
352 three-dimensional images of bone and soft tissue, no other information was used. This
353 Structural Fragility Score serves as a surrogate of fracture risk that is likely to assist in
354 reducing the population burden of fragility fractures. It provides a diagnostic able to identify
355 most women at risk of fracture and provides fast processing, easy access to risk assessment
356 allowing prompt initiation and monitoring of preventative treatment at the community level.

357

358 High resolution peripheral quantitative computed tomography (HRpQCT) technology is no-
359 longer confined to the research domain. Commercial devices are now CE marked and FDA
360 cleared for multiple clinical settings. Analysis requires only the acquisition of the three-
361 dimensional image of the distal radius, ulna and soft tissue and cloud-based computer
362 technology provides prompt diagnosis allowing initiation or monitoring of therapy.

363

364 This study has several limitations. Further studies are needed to determine whether including
365 factors predisposing to falls such as muscle mass and function, age, height, weight and other

366 covariates improves the performance of the diagnostic. The sample sizes were insufficient to
367 evaluate performance of the diagnostic in predicting individual types of fracture.

368

369 Advancing age is accompanied by deterioration in bone mass, its material composition,
370 architecture and muscle mass - factors contributing to fragility fractures, a public health
371 problem. High-resolution quantitative computed tomography and deep learning provide a
372 Structural Fragility Score that serves as a holistic surrogate of fracture risk. This diagnostic is
373 an accurate, safe, rapid and easily accessible tool that captures the deterioration of bone
374 qualities contributing to bone fragility independent of BMD and perhaps deterioration of
375 muscle predisposing falls. This surrogate identifies women at high risk of fracture needing
376 prompt treatment to avert fracture and may allow monitoring the success or failure of
377 treatment.

393

394 **Figure 1. Left two panels:** Receiver Operator Characteristic (ROC) curves for Structural
395 Fragility Score Artificial Intelligence (SFS-AI), Fracture Risk Assessment Score (FRAX) with
396 bone mineral density (BMD) and BMD as a continuous trait predicting for ‘All Fragility
397 Fractures’ and ‘Majority Fragility Fractures’ for women of any age. Area under the Curves
398 (AUCs) with 95% Confidence Intervals (CI) were significant ($*p < 0.05$) for SFS-AI only.

399 **Right two panels:** Sensitivity and specificity of SFS-AI, FRAX with BMD and BMD as
400 categorical traits.

401

402 **Figure 2. Left panels:** Advancing age is associated with a higher Structural Fragility Score-
403 Artificial Intelligence (SFS-AI) in women having ‘All Fragility Fractures’ or Major Fragility
404 Fractures (closed circles) and in women remaining fracture-free (open circles). The images of
405 the distal radius and ulna with the heat map illustrate regions commonly encountered in
406 women having fractures.

407

408 **Figure 3. Left panels.** The Structural Fragility Score-Artificial Intelligence (SFS-AI) was
409 associated directly with cortical porosity, FRAX with BMD and negatively with trabecular
410 density and BMD. **Right diagram.** Of the 47% of explained variance in the SFS-AI, most
411 was attributed to trabecular density, cortical porosity, age and the FRAX with BMD. The
412 contribution of BMD was not significant. The remaining 53 percent remained unexplained.

413

414 **Legends for Figures in supplementary material**

415

416 **Figure S1.** Structure of the deep learning model used to predict fracture. The input is the 110
417 slices of a wrist scan used to acquire the three-dimensional image of the distal radius, distal

418 ulna and adjacent soft tissue. DenseNet121 is used as the neural network backbone. The
419 output feature after the global average pool is a 256-dimension feature. A multi-task (age
420 prediction, fracture prediction and non-fracture years prediction) learning strategy was used to
421 achieve robust extraction of relevant features.

422

423 **Figure S2.** We studied women from OFELY (n = 568), Qalyor (n = 1427) and Gerico (n =
424 671). (A) There were 526, 1187 and 387 images remaining from the respective cohorts for
425 analysis after excluding images from women remaining fracture-free followed for under 5
426 years and images from women having traumatic (non-fragility). (B) Women having a
427 fragility fracture during 5 years were denoted as (+), women remaining fracture-free as (-).
428 (C) Participants from each cohort were randomly allotted into five groups with approximately
429 equal numbers of (+) and (-) subjects. See Methods section.

430

431 **Figure S3. Left two panels.** Receiver Operator Characteristic (ROC) curves for Structural
432 Fragility Score Artificial Intelligence (SFS-AI), Fracture Risk Assessment Score (FRAX) with
433 bone mineral density (BMD) and BMD as continuous traits predicting ‘All Fragility
434 Fractures’ and ‘Major Fragility Fractures’ in women 65 years of age and over. Area under the
435 Curves (AUCs) with 95% Confidence Intervals (CI) were significantly different from 0.5 (*p
436 < 0.05) for SFS-AI only. **Right two panels.** Sensitivity and specificity of the SFS-AI, FRAX
437 with BMD and BMD as categorical traits predicting women having ‘All Fragility Fractures’
438 or ‘Major Fragility Fractures’.

Supplementary AI methods

Deep Learning Network, training and the heat map DenseNet used dense connection between layers and achieved efficacy in feature extraction. The first layer had a 110-dimension input instead of 3-dimension input in the original DenseNet.³⁴ We added a transition layer using 1*1 convolution after the last denseblock of DenseNet to reduce the feature dimension from 1024 to 256 to extract a compact feature. A multi-task learning strategy was used to achieve more robust features. Extracted features were used to predict fractures during the ensuing 5-years, to predict the patient's age at the time of scanning and the duration of the fracture-free years of follow-up since scanning. The latter two tasks are included in the training to produce generalized feature representations powerful enough to be shared across different tasks.

We used a pretrained model as the initial model and 0.5 as the classification threshold for the training and validation. During training, cross-entropy loss was used as the fracture situation prediction loss, and used the mean squared error loss as the loss of age prediction and non-fracture year prediction. L1 regularization is performed on the weights of the classification layer to reduce overfitting. The model is optimized by ADAM optimizer using the four losses with weight 1 on the first three losses and weight 0.01 on the L1 regularization loss.³⁵ The learning rate is set as 5e-6 for the DenseNet backbone and 5e-5 for the other layers, including the transition layer and the three multi-learning branches. Pytorch is chosen to implement the model training and testing.³⁶ The Grad-CAM is utilized to generate the heatmap to represent the features that are extracted by the deep learning model.³⁷
