46 Abstract

47 Background

Leptospirosis is a zoonosis caused by pathogenic species of bacteria belonging to the genus *Leptospira*. Most studies infer the epidemiological patterns of a single serogroup or aggregate all serogroups to estimate overall seropositivity, thus not exploring the risks of exposure to distinct serogroups. The present study aims to delineate the demographic, socioeconomic and environmental factors associated with seropositivity of *Leptospira* serogroup Icterohaemorraghiae and serogroup Cynopteri in an urban high transmission setting for leptospirosis in Brazil.

55 Methods/Principal Findings

56 We performed a cross-sectional serological study in five urban informal communities in 57 the city of Salvador, Brazil. During the years 2018, 2020 2021, we recruited 2.808 58 residents and collected blood samples for serological analysis using microagglutination 59 assays. We used a mixed-effect multinomial logistic regression model to identify risk 60 factors associated with seropositivity for each serogroup. Seropositivity to Cynopteri 61 increased with age in years (OR 1.03; 95% CI 1.01-1.06) and was higher in those living 62 in houses with unplaster walls (exposed brick) (OR 1.68; 95% CI 1.09-2.59) and where 63 cats were present near the household (OR 2.00; 95% CI 1.03-3.88). Seropositivity to 64 Icterohaemorrhagiae also increased with age in years (OR 1.02; 95% CI 1.01-1.03) but 65 was higher in males (OR 1.51; 95% CI 1.09-2.10), in those with work-related exposures 66 (OR 1.71; 95% CI 1.10-2.66) or who had contact with sewage (OR 1.42; 95% CI 1.00-67 2.03). Spatial analysis showed differences in distribution of seropositivity to serogroups 68 Icterohaemorrhagiae and Cynopteri within the five districts where study communities 69 were situated.

70 Conclusions/Significance

4

71 Our data suggests distinct epidemiological patterns associated with serogroups 72 Icterohaemorrhagiae and Cynopteri within the high-risk urban environment for 73 leptospirosis and with differences of spatial niches. Future studies must identify the 74 different pathogenic serogroups circulating in low-income areas, and further evaluate 75 the potential role of cats in the transmission of the serogroup Cynopteri in urban 76 settings.

78 Introduction

79 Leptospirosis is a potentially severe infectious disease that affects animals (both 80 domestic and wild) and humans [1]. The disease is caused by pathogenic species of the 81 genus Leptospira that causes a wide array of clinical manifestations in humans [2]. 82 Symptoms can range from asymptomatic infection and light fever to severe 83 manifestations with risk of death [3]. Over a million cases occur globally every year, 84 causing over 60 thousand deaths [4]. The majority of the disease burden occurs in 85 developing nations that lack adequate infrastructure and health services [5]. Human 86 infection occurs through direct contact with urine or contaminated secretions from 87 infected animals, or indirectly through contact with contaminated soil and water [1,6].

88 The genus Leptospira comprises 69 species and over 300 serovars, classified in 89 more than 20 serogroups [7–9]. The microscopic agglutination test (MAT) is the golden 90 standard serodiagnosis for leptospirosis and can indicate the presumptive infecting 91 serogroup [10]. However, isolation or specific laboratory techniques like DNA sequence 92 analysis are needed for definitive serotyping [11]. Some serovars can infect multiple 93 animal species while others are more adapted to specific animal hosts [2]. This host 94 preference might explain why some serovars/serogroups are more frequent in certain 95 geographic areas. The diversity of reservoirs, serovars and serogroups, together with 96 and socio-behavioral determinants, pose a challenge to environmental the 97 characterization of the epidemiologic patterns of leptospirosis. These factors can 98 influence the risk of transmission, and consequently, increase incidence and cause 99 outbreaks [12].

Historically, tropical and subtropical nations have seasonal leptospirosis incidence peaks associated with heavy rainfall and flooding events during the rainy season [12–15]. The informal accelerated expansion of large urban centers, coupled

6

103 with inadequate housing and sanitation, has resulted in environmental and social 104 conditions highly favorable to disease hosts and pathogen transmission [16]. Over 33% 105 of the world population live in urban poor communities [17], a figure around 28% in 106 Brazil [18], where, because of the deep social inequalities, there is a direct correlation 107 between vulnerable environments, disaster risks and public health problems [19,20]. 108 Historically, in the city of Salvador, where most of the population is of black and mixed 109 races, people with lower income to live in the peripheral areas of cities without access to 110 basic rights, and where the prevalence of health problems such as leptospirosis is greater 111 than in other areas of the city.

112 Studies performed in the past two decades in Salvador, Brazil, reported 113 Leptospira interrogans serogroup Icterohaemorrhagiae serovar Copenhageni (strain 114 Fiorruz L1-130) as the serogroup responsible for over 95% of the clinical cases 115 recorded throughout the city [12], as well as asymptomatic infections in residents of the 116 urban community of Pau da Lima within Salvador [21,22]. The animal reservoir of the 117 serovar Copenhageni and serogroup Icterohaemorrhagiae is the brown rat (Rattus 118 norvegicus), as shown by previous studies in the same community [23,24]. These 119 studies identified the seroincidence of Leptospira kirschneri serogroup Cynopteri (strain 120 3522C) as the second highest in residents of urban communities [25]. However, the 121 animal reservoir of this serogroups and the determinants of its transmission, remain 122 unknown.

123 Thus, investigating the *Leptospira* serologic profile of the residents in urban 124 communities, accounting for serogroup-specific risk factors, will contribute to a better 125 understanding of the risk determinants of urban infection and inform the development 126 of more specific control measures. The present study aims to identify demographic, 127 socioeconomic, and environmental factors associated with seropositivity of *Leptospira*

7

interrogans Icterohaemorrhagiae (strain Fiocruz L1-130) and *Leptospira kirschneri*Cynopteri (strain 3522C) in residents of five urban low-income communities in
Salvador, Brazil.

139

140 Study design

141 We performed a cross-sectional study in five urban poor communities (Pau da 142 Lima (PL), Alto do Cabrito (AdC), Marechal Rondon (MR), Nova Constituinte (NC) 143 and Rio Sena (RS) in the city of Salvador, Bahia, Brazil (Figure 1). In PL, we collected 144 samples during the period of November 2020 to February 2021. Previous studies in the 145 area indicated an annual leptospiral incidence of 37.8 infections per thousand [21]. In 146 the four other communities, namely: AdC, MR, NC and RS, sampling occurred from 147 April to September 2018. The communities are considered low-income, with precarious 148 sanitation and infrastructure.

Eligible individuals were recruited, and those willing to participate signed a free consent form and had a small blood sample drawn by a field professional. We applied a structured questionnaire to provide information on individual characteristics of the participant, domestic and peri-domestic environmental characteristics, exposure to

8

sources of environmental contamination, and the presence of potential animalreservoirs.

Serological analysis was performed using the Microscopic Agglutination Test (MAT), the gold standard for human leptospirosis detection, as previously described [16]. MAT is based on dark-field microscopy detection of serum agglutination samples from an individual (antibodies) with live *Leptospira* antibodies. We performed association analysis only for serogroups Icterohaemorrhagiae strain Fiocruz L1-130 and Cynopteri strain 3522C, which were the most prevalent strains in the regions, according to our analyses.

162

163 Outcomes, exposures, and covariates

The outcome of seropositive for leptospirosis was defined as seropositivity against serogroups Cynopteri and/or Icterohaemorrhagiae. A result was considered positive if 50% or more leptospires were agglutinated by MAT with a titer of $\geq 1:50$. When agglutination was observed at a dilution of 1:100, the sample was titrated in serial two-fold dilutions to determine the highest positive titer [25].

169 The main explanatory variables were at the individual-level: age in years (as a 170 quantitative variable), gender, ethnicity, highest education level achieved, receiving the 171 Federal government stimulus program (Bolsa Família), employment status, work 172 involving contact with sewer/garbage/construction materials, use of protective boots, 173 contact with mud in the last 12 months, walking barefoot outside, and cleaning sewer 174 canals in the last 12 months. In addition, environmental explanatory variables included 175 proximity of the household to open sewers, paved access to the household, household 176 with a backyard, plastered walls (proxy for quality of construction), garbage

9

accumulation near the household, and presence of domestic animals (cats, dogs, andchickens).

179

180 Spatial descriptive analysis

181 QGIS version 2.18.20 was used to construct a georeferenced database from 182 satellite image WorldView-3 May 2017, at 31 cm resolution. The study team identified 183 households within the study site and marked their positions onto hard copy 1:1,500 184 scale maps. The image WorldView-3 was acquired by the research project / Institute 185 Gonçalo de Moniz - IGM - Fiocruz Bahia from the company Stamap, with disclosure 186 permitted referencing the Copyrights of DigitalGlobe images. Kernel Density 187 Estimation analysis (KDE) [26], with standard expression for two-dimensional spatial 188 context: fhat(x) = n-1h-2 $\sum k\{(x-xi)/h\}$, where k(u) is the kernel function (a bivariate 189 probability density), x1,...,xn are the data-points and h is the bandwidth, was 190 performed to complementary analyses to evaluated possible territorial difference of 191 niches between serogroups Icterohaemorrhagiae and Cynopteri with no overlapping 192 patters territorial concentration. The study evaluates smoothed spatial distributions of 193 sites with positive human cases of serogroups Icterohaemorrhagiae and Cynopteri, 194 considering as a weight factor in the analysis the total number of cases in the household 195 with distance matrix by 30 meters. The 30-meter distance matrix considered the average 196 distance traveled by rats per day [27] as a possible exposure factor of households to 197 serogroups, aiming to compare patterns of the Kernel analysis suitable for the scale of 198 the maps in the evaluated areas. To determine the smoothed population-adjusted risk 199 distribution we calculated the ratio of the KDE for positive cases of households to all 200 households evaluated with residents tested by leptospirosis cases of serogroups 201 Icterohaemorrhagiae and Cynopteri.

202 Statistical Analysis

203 We performed a descriptive analysis using relative and absolute frequencies for 204 qualitative variables and median and interquartile range for quantitative variables. 205 A mixed-effect multinomial logistic regression model was used to estimate potential 206 factors associated to seropositivity for both Icterohaemorrhagiae and Cynopteri 207 serogroups. Variables included in the multivariate analysis were those with p < 0.15 in 208 the bivariate analysis. The multivariable analyses were performed using the stepwise 209 method based on the purposeful selection of variables, including both statistical and 210 research criteria (biological plausibility) [21,28]. Also, "area" (five urban low-income 211 communities) was include in the final model as a fixed effect. We checked for high 212 levels of correlation among the predictor models that were selected to be included in the 213 final model using Variance Inflation Factor (VIF), but VIF values were <5 and thus no 214 variables were excluded. The best model that explained the outcome was selected 215 according to Akaike's Information Criteria (AIC). The linearity assumption was 216 confirmed before the inclusion of quantitative variables in bivariate and multivariate 217 models. The seroprevalence are presented with their 95% confidence intervals adjusted 218 by random effects (neighborhood). All statistical procedures were performed in R 219 studio, using tidyverse, lme4 and nmet packages [29–32]

220

221 **Results**

222 The study included 2,808 residents of five neighborhoods located in Salvador, Brazil

223 (Fig 1); of which 1,512 were from Pau da Lima, 332 from Marechal Rondon, 367 from

Alto do Cabrito, 304 from Nova Constituinte and 293 from Rio Sena (Table 1). In

general, the population studied was predominantly female (58%; 1,620/2,808) and self-

226 declared black (51%; 1,422/2,808) (Table 1).

235 The overall unadjusted seroprevalence was 9% (253/2,808) (95% CI 8.0% -236 10.1%). Of the 253 infected, 18% (45/253) were seropositive to serogroup Cynopteri 237 and 82% (208/253) were seropositive to serogroup Icterohaemorrhagiae. Regarding the 238 distribution of titers, 190/208 (91%) of the samples had titers of 50 to 400, followed by 239 18/208 (9%) of the samples reacted to titers of 800 and 1600 for serogroup 240 Icterohaemorrhagiae. For the Cynopteri serogroup, 43/45 (96%) of the samples had 241 titers of 50 to 400 followed by 2/45 (4%) of the samples reacted to titers of 800 and 242 Stratifying seroprevalence per area, the seropositivity to serogroup 6400. 243 Icterohaemorrhagiae was lowest in AdC (6.5%) and was highest in RS (7.8%). 244 Seroprevalence of Cynopteri ranged between 1.0% in NC and 2.1% in MR (Table 1). 245 Seroprevalence of Icterohaemorrhagiae increased with age group (Fig 2), and females

15

showed less chance to be infected than males (OR 0.69; 95% CI 0.52 - 0.91). This pattern was not observed for serogroup Cynopteri, which presented higher seroprevalence in the age group >45 years (Fig 2).

249

265

266 The final multivariable multinomial analysis (Table 2) which includes data for 267 residents > 18 years of age to investigate work-related exposures (n=2,009), identified 268 the following variables as significantly associated with the serogroup Cynopteri: age in 269 years (as a quantitative variable) (OR 1.03; 95% CI 1.01-1.06), lives in house with 270 unplaster walls (exposed brick) (OR 1.68; 95% CI 1.09-2.59) and presence of cats near 271 the household (OR 2.00; 95% CI 1.03-3.88). In addition, gender (males>females (OR 272 1.51; 95% CI 1.09-2.10), age in years (OR 1.02; 95% CI 1.01-1.03), work-related 273 exposures (OR 1.71; 95% CI 1.10-2.66) and contact with sewage (OR 1.42; 95% CI 274 1.00-2.03) were factors associated to seropositivity against Icterohaemorrhagiae.

16

Table 2. Multivariate multinomial regression of seropositivity for *Leptospira kirschneri* Cynopteri (3522C) and *Leptospira interrogans* Icterohaemorrhagiae (Fiocruz L1-130), n=

278 2,009). Note that there were no differences in seropositivity among neighborhoods.

281

282 Figure 3 shows differences in spatial patterns of seropositivity between

283 serogroups Icterohaemorrhagiae and Cynopteri (yellow rectangle indicate Non-284 overlapping Kernel ratio concentration areas between serogroups). The objective of this 285 complementary analysis was to verify possible overlaps in the occurrence of spatial 286 patterns between serogroups in the territory.

287 288

Figure 3. Spatial patterns of seropositivity to serogroups' Icterohaemorrhagiae and Cynopteri 289 (yellow rectangle) on five neighborhoods of Salvador, Bahia, Brazil. The light red-to- hard red 290 gradient represents increasing density in smoothing analyses which used 30 meters as the 291 bandwidth.

294 **Discussion**

Here, we found that of *L. interrogans* serogroup Icterohaemorrhagiae was the main serogroup responsible for leptospirosis cases in Salvador [12,33]. However, we also found evidence of local exposure to *L. kirschneri* serogroup Cynopteri in residents of all communities studied. Prevalence of *L. kirschneri* serogroup Cynopteri, a serogroup considered pathogenic and for which the reservoir in an urban environment is not known, was lower than that of *L. interrogans* serogroup Icterohaemorrhagiae.

301 We identified differences in the demographic and socioenvironmental factors 302 that affect seropositivity for each serogroup. Residents exposed to serogroup Cynopteri 303 had a distinct demographic profile compared to that of serogroup Icterohaemorrhagiae. 304 We observed higher seroprevalence for serogroup Cynopteri in ages >45 years for both 305 genders, suggesting that behavioral differences between men and women do not affect 306 exposure. However, for serogroup Icterohaemorrhagiae, we found that seropositivity 307 increased with age, and males were more likely to be seropositive. This relationship 308 between age and exposure to Icterohaemorrhagiae is similar to that observed in previous 309 studies [16].

310 Occupation-related factors were associated with exposure to serogroup 311 Icterohaemorrhagiae. Individuals who engaged in activities involving solid waste 312 management, or contact with mud, floodwaters and/or sewage, were more likely to be 313 seropositive. This is in line with previous results from these and similar communities, 314 where leptospirosis is associated to work-related exposures, including occupations like 315 subsistence farming [3]. Further, inhabitants of low-income communities are commonly 316 enrolled in informal employment, often close to their households, highlighting the role 317 of the environment as an important source for transmission. Interestingly, we did not 318 detect any independent associations between work-related risk exposures and serogroup

19

319 Cynopteri, maybe because have a lower number of individuals seropositive for320 Cynopteri.

Little is known about the animal and environmental reservoirs for serogroup Cynopteri. In our final model, we detected a positive association of individuals between anti-Cynopteri antibodies and the presence of cats in the household. Although there is a report on the occurrence of this serogroup in wild animals such as bats [34], there are also indications that cats can be exposed to *Leptospira* and higher seroprevalence of serogroup Cynopteri has been found in cats from Spain compared to other serogroups studied [35].

328 Among the domestic and peri-domiciliary variables, the presence of open 329 sewage near the home was associated with greater seropositivity for serogroup 330 Icterohaemorrhagiae. This result is consistent with a previous study [19] in which "living near an open sewer" was a factor associated with seropositivity. This further 331 332 suggests that environmental exposure is an important route of indirect transmission, and 333 it should be noted that animals other than rats can release leptospires through urine into 334 the environment. This association has also been reported in other epidemiological 335 studies [31,32]. In a previous study, in the same study area, it was identified that, in 336 addition to sewage, the presence of pond water on the ground, from rainwater 337 accumulations, can be a source of pathogenic *Leptospira* [36].

Infrastructure deficiencies in homes, for example, living in a house with unplaster walls (exposed brick), has also been considered a source of transmission for repeated exposures to *Leptospira* [19]. This may mean that risk factors for peridomiciliary exposure may also be important for infection by serogroup Cynopteri. We believe that the structural precariousness in the household could be an indicator of low socioeconomic status, as suggested in another study [24].

20

344 It is possible that different spatial niches of reservoirs occur for serogroups 345 Icterohaemorrhagiae and Cynopteri in urban areas, as a difference in spatial 346 concentration patterns was observed in the analysis of the Kernel ratio (Figure 3) for the 347 occurrence of these serogroups in the five neighborhoods evaluated. There was low 348 overlap in human case concentration patterns for the serogroups, possibly because 349 serogroup Icterohaemorrhagiae is associated with proximity to sewers and Cynopteri 350 with the presence of cats, as demonstrated by statistical analysis. However, these 351 investigations are limited by the fact that MAT is the standard test used in prevalence 352 surveys, but this serological analysis does not actually indicate that the individual has 353 acute disease. Additionally, we had a low prevalence of Cynopteri, which might not be 354 possible to understand the true epidemiological pattern. Future studies may deepen to 355 evaluate spatial correlations between the occurrence of serogroups and the abundance 356 and mobility of rodents or felines and proximity by households.

357

358 Conclusion

359 Our data show different exposure risk for different serogroups, with possible 360 different spatial territorial niches of reservoirs, which can potentially indicate different 361 epidemiology or transmission pathways. Further, our findings indicate cats were 362 associated to seropositivity for serogroup Cynopteri in residents of the communities 363 studied. Our results can serve as base for future studies in One Health approach that can 364 elucidate the role of synanthropic, wild animals, and environment in the transmission of 365 serogroup Cynopteri in urban areas, in addition to contributing to the orientation of 366 public health measures to prevent future infections.

367

368 Acknowledgments

21

369 The authors would like to thank the individuals from the communities who participated

in this study.
