14 **Abstract**

15 SARS-CoV-2 in infected patient mainly display pulmonary and oronasal tropism however,
16 the presence of the virus has also been demonstrated in stools of patients and consequently in
17 wastewater treatment plant effluents, questioning the potential risk of environmental
18 contamination (such as seawater contamination) through inadequately treated wastewater
19 spill-over into surface or coastal waters. The environmental detection of RNA alone does not
20 substantiate risk of infection, and evidence of an effective transmission is not clear where
21 empirical observations are lacking.

22 Therefore, here, we decided to experimentally evaluate the persistence and infectious capacity
23 of the Porcine epidemic diarrhea virus (PEDv), considered as a coronavirus representative

24 model and SARS-CoV-2 surrogate, in the coastal environment of France. Coastal seawater
25 was collected, sterile-filtered, and inoculated with PEDv before incubation for 0–4 weeks at
26 four temperatures representative of those measured along the French coasts throughout the
27 year (4, 8, 15, and 24°C). The decay rate of PEDv was determined using mathematical
28 modeling and was used to determine the half-life of the virus along the French coast in
29 accordance with temperatures from 2000 to 2021.

30 We experimentally observed an inverse correlation between seawater temperature and the
31 persistence of infectious viruses in seawater and confirm that the risk of transmission of
32 infectious viruses from contaminated stool in wastewater to seawater during recreational
33 practices is very limited. The present work represents a good model to assess the risk of
34 transmission of not only SARS-CoV-2 but may also be used to model the risk of other
35 coronaviruses, specifically enteric coronaviruses.

36 **Importance**

37 This present work is a follow up addressing the question of the persistence of coronavirus in
38 marine environment owing to the fact that SARS-CoV-2 is regularly detected in wastewater
39 treating plant and the coastal environment is particularly at risk since it is subjected to
40 increasing anthropogenic pressure and is the final receiver of surface waters and treated or
41 sometimes insufficiently depurated waste waters. Our findings are of interest to researchers
42 and authorities seeking to monitor SARS-CoV-2 and also enteric coronaviruses in the
43 environment, either in tourist areas or in regions of the world, where centralized systems for
44 wastewater treatment are not implemented, and more broadly, to the scientific community
45 involved in “One Health” approaches.

48 **Introduction**

49 The emergence of the human coronavirus, SARS-CoV-2, accompanied by its worldwide
50 spread leading to the COVID pandemic (671 million cases and 6.85 million deaths on
51 February 2023) (WHO (World Health Organization), reminds us, if needed, the health hazard
52 posed by coronaviruses.

53 Human coronaviruses (HCoVs) are respiratory viruses that are primarily transmitted by
54 exposure to droplets generated by coughing, sneezing or breathing, either directly in the
55 respiratory tract or indirectly through contact with surfaces contaminated by these droplets
56 (Marques and Domingo, 2021; Zhang et al., 2020a). Interestingly, SARS-CoV-2 RNA has
57 been repeatedly detected in stool samples of infected patients (Xiao et al., 2020; Zhang et al.,
58 2020b), for review (Jones et al., 2020), for long periods (Wu et al., 2020) even in the absence
59 of gastrointestinal symptoms (Han and He, 2021; Tang et al., 2020), questioning in the early
60 time of the pandemic the potential risk of fecal-oral or fecal-respiratory transmission
61 (Ahmed et al., 2020a; Arslan et al., 2020; Dona et al., 2020; Gu et al., 2020; Heller et al.,
62 2020; Hindson, 2020; Shutler et al., 2021). The SARS-CoV-2 genome was detected in raw
63 wastewater from different metropolitan areas including Paris (Wurtzer et al., 2020), with
64 concentrations correlating with the estimated numbers of Covid-19 cases. The genome has
65 also been detected in treated effluents from sewage treatment plants, but to a lesser extent,
66 suggesting that SARS-CoV-2 may contaminate the environment through accidental
67 wastewater discharge or direct discharge (Patel et al., 2021; Polo et al., 2020; Rimoldi et al.,
68 2020).

69 The transmission of enteric viruses through recreational use of sewage-contaminated water
70 being possible ((Lanrewaju et al., 2022; Wyn-Jones et al., 2011), the possibility and potential
71 consequences of environmental contamination with SARS-CoV2 or other coronaviruses was
72 raised early on.

73 Reports on the isolation of infectious SARS-CoV-2 from the feces and urine of COVID-19
74 patients have been documented but remain rare (reviewed in(Ahmed et al., 2021)). SARS-
75 CoV-2 RNA was found to be significantly more persistent than infectious SARS-CoV-2,
76 indicating that environmental detection of RNA alone does not substantiate the risk of
77 infection and evidence of effective transmission is not clear (Bivins et al., 2020). SARS-
78 CoV-2 transmission through wastewater and wastewater-contaminated waters is theoretically
79 possible, but the actual risk is considered very low (Ahmed et al., 2021). Currently, an
80 accurate risk assessment of viral exposure and transmission requires additional experimental
81 evidence of CoV persistence in seawater.

82 Indeed, the resistance of virions to harsh conditions is highly variable and coronaviruses are
83 considered fairly resistant in the environment, for review see (Adelodun et al., 2021;
84 Silverman and Boehm, 2021). Indeed, SARS-CoV-2 virions, remained infectious for up to 3 h
85 in aerosols and for 3 days on artificial surfaces respectively. SARS-CoV-2 virions are also
86 stable over a wide range of pH values at room temperature (pH 3-10) (Anand et al., 2021;
87 Chan et al., 2020; Chin et al., 2020; Kampf et al., 2020; Kwon et al., 2021; La Rosa et al.,
88 2020a; La Rosa et al., 2020b; Nunez-Delgado, 2020). Previous studies on other CoVs (such as
89 SARS-CoV, TGEV, and MHV) have shown them to be detectable in sewage for 2-4 days, in
90 tap water for up to 10 days at 23– 25°C, and up to 100 days at 4°C, for review see (Giacobbo
91 et al., 2021) but studies on the presence and persistence of CoVs in seawater remain scarce.
92 One study showed that SARS-CoV-2 lost its infectivity within two days in seawater at 23°C
93 (Lee et al., 2020), but half-lives were not calculated and this temperature is higher than those
94 encountered in North-Western European countries like France. Another study calculated a
95 T90 of 1.1 day in filtered seawater at 20°C for the porcine respiratory coronavirus (PRCV)
96 (De Rijcke et al., 2021) and finally, a study showed a high impact of the temperature on the
97 decay of SARS-CoV-2 in seawater by comparing conditions at 20°C and 4°C, with T90 of 7

98 to 10 days (Sala-Comorera et al., 2021). Intermediate temperatures were not tested. The
99 possible long survival in water systems raises concerns about the persistence of SARS-CoV-2
100 or other CoV in the coastal environment.

101 Coronaviruses (order: Nidovirales, suborder: Cornidovirinae, family: Coronaviridae,
102 subfamily: Orthocoronavirinae) show very strong genetic diversity and a high prevalence in
103 nature (Ding and Liang, 2020). This family of viruses primarily infects a wide host spectrum
104 of mammals and birds (Su et al., 2016). Based on the variety of non-structural accessory
105 proteins, antigenic properties and host ranges, four genera of CoV have been described
106 (Alpha-, Beta-, Delta-, and Gamma-CoV among which Alpha- and Beta-CoV include viruses
107 infecting humans (HCoV). The emerged pandemic SARS-CoV-2 belongs to Beta-CoV, along
108 with SARS-CoV-1 and MERS-CoV, two previously emerging HCoVs. Alpha and
109 Betacoronaviruses are known to infect a variety of vertebrate mammalian hosts including
110 swine, bats, minks or rodents. Until recently, deltacoronaviruses were known to infect a
111 variety of hosts such as birds and non-human mammals, but two cases of human infection
112 with porcine deltacoroanaviruses were reported in 2021 (Lednicky et al., 2021).
113 Gammacoronaviruses infect essentially birds. Although coronaviruses are divided into four
114 distinct genera, they all share similar physicochemical properties with an enveloped spherical
115 viral particle of 120 nm diameter and the same genomic organization with a single-stranded
116 RNA genome of positive polarity (25 - 30kb) coding for conserved ORFs that are the
117 replicase complex, structural proteins (envelope, membrane, spike and nucleoprotein) and a
118 variable number of non-structural accessory proteins. SARS-CoV-2, like some other
119 coronaviruses (SARS-CoV, MERS) is zoonotic, leading to its classification as a BSL3-like
120 pathogen with a commitment to need for an L3 laboratory facility for its manipulation. The
121 number of BSL3 laboratory is much more limited than that of BSL2 laboratories and non-

122 zoonotic coronaviruses have been largely and successfully used as surrogate of SARS-CoV-2
123 for studies in BSL2 facilities.

124 For this reason, we previously used porcine epidemic diarrhea virus (PEDV) and infectious
125 bronchitis virus (IBV), both without any zoonotic potential, as viral substitutes for SARS-
126 CoV-2 (Bernard louis et al., 2020) and found that treatment in a climate chamber at 70°C for
127 1 h with a 75% humidity rate was adequate for enabling substantial decontamination of both
128 model animal coronaviruses, confirming for these two viruses the overall inactivation
129 properties shared by coronaviruses (Guillier et al., 2020). In the current study, we relied on
130 the CV777 strain of PEDv, a swine alphacoronavirus, as a surrogate for SARS-CoV-2.

131 To evaluate the stability and resistance of CoV and by extension of SARS-CoV-2 in the
132 coastal environment, the genomic and infectious titers, the latter directly correlated to the
133 infection risk of the CoV model and the SARS-CoV-2 surrogate, PEDv, were measured in
134 natural coastal seawater for 28 days, and the results were used to build a mathematical model
135 of coronavirus decay in seawater at a range of temperatures (8°C, 15°C, and 24°C)
136 representative of the annual variation of the French coastal waters. A fourth temperature of
137 4°C was also investigated as a reference temperature, allowing for comparisons with other
138 studies addressing decay in different types of water. The decay rate of PEDv was then used to
139 determine the half-life of the virus in French coastal waters, using the temperatures reported
140 for each trimester (year quarters) from 2000 to 2021.

141 **Materials and methods**

142

143 *Cells and Virus*

144 Vero cells (ATCC® CCL-81) are maintained in EMEM (ThermoFisher Scientific, France)
145 supplemented with 10% fetal calf serum (reference 702774, Corning) and 1% Penicillin /
146 Streptomycin (reference 11548876, GIBCO).

147 CV777 viral strain (genbank: AF353511) of porcine epidemic diarrhea virus (PEDV) was
148 used as a surrogate of the SARS-CoV-2. Briefly, the virus is amplified on Vero cells, in an
149 infection medium, composed of EMEM supplemented with 0.3% tryptone phosphate broth,
150 0.02% yeast extract, 1% Penicillin / Streptomycin and 10 µg / ml trypsin. (reference 215240,
151 DIFCO). After 16 hours of infection, the cells are lysed by three successive freezing (-80 ° C),
152 thawing (37 ° C). The culture medium is clarified by rapid centrifugation at 10000g for 10
153 minutes then the virus is pelletized for 4 hours at 20000g, and taken up in 1/100 of PBS of the
154 initial volume of the CV777 inoculum. Viral titer was determined by Immuno Peroxidase
155 Monolayer Assay (Detection limit: 0.5TCID₅₀/ml), and genomic titer by one-step RT-qPCR
156 (Detection limit: 50 copies/5µl of extract) (Bigault et al., 2020). The viral stock was titrated at
157 1.7*10⁸ TCID₅₀ / ml.

158 ***Determination of the TCID₅₀ by Immuno Peroxidase Monolayer Assay (IPMA)***

159 In a 96-well plate, 8.10⁴ Vero cells are seeded per well and allowed to adhere for at least 6
160 hours. The cells are washed 3 times with PBS (sigma, France), then infected with 100 µl of
161 virus diluted in the infection medium. The infection is stopped after 16 hours and the cells
162 fixed with 50 µl of 80% acetone for 20 minutes at -20 ° C. After drying for 30 minutes at
163 room temperature (RT), the endogenous peroxidases are neutralized with 50 µl of a solution
164 of 99% methanol / 1% H₂O₂ for 30 minutes at RT. Wells are washed twice with 200 µl of
165 PBS tween (PBST, sigma # P3563), then blocked for 90 minutes at 37 ° C with a solution of
166 PBST + 5% milk (PBST5, Dutscher # 2516188). The presence of viral proteins is detected by
167 incubation with 100µl of an anti PEDV pig serum diluted to 1/300th in PBST5, 1h at 37 ° C,
168 followed by 3 washes of 200µl PBST, then a 1h incubation at 37 ° C in the presence of 100µL

169 of Goat anti pig IgG- coupled to horseradish peroxidase (HRP) (Sigma, France, #AP166P)
170 diluted to 1/300 in PBST5. After three washes in PBST, the visualization is made by adding
171 50 μ l of AEC/H₂O₂ (Reference AEC: sigma #A6926) as developer for 10 minutes RT. The
172 reaction was stopped by removing the developer followed by a last wash with PBS. The viral
173 titer was determined by the Kärber method (Kärber 1931). For analysis, log of TCID₅₀ for
174 each point were normalized as the ratio against the initial log of TCID₅₀. TCID₅₀ sensibility
175 is as low as 0.5 * 10^{e1} TCID₅₀, which is therefore the low limit of detection.

176 *Viral decay trial*

177 The impact of seawater temperature on the stability and survival of PEDv, chosen as a
178 substitute model for SARS-CoV-2, is evaluated in natural coastal seawater collected and
179 sand-filtered on the October 21st, 2020 at an experimental oyster farm on the French Atlantic
180 coast (PMMB, Ifremer, Bouin, France) where it is used for growing oysters. At sampling, pH
181 was 8.71, salinity 33.9 and turbidity 2.7 NTU. The seawater is then aliquoted and kept frozen
182 at -80°C for 3 to 8 months before being used. The filtered coastal seawater was spiked with
183 the CV777 virus stock to achieve a load of 1.10⁶ TCID₅₀ / ml and 1.10⁸ genome copy / ml.
184 To prevent any temperature variations due to sample manipulation, as well as the risk of
185 contamination, 1 ml aliquots of this spiked water were incubated in water baths at 4 ° C, 8 °
186 C, 15 ° C and 24 ° C, in the dark, throughout the experiments. A preliminary experiment
187 lasted 16 days with aliquots sampled randomly on day 0 to day 3, day 7 to day 10 and day 14
188 to day 16. Then, based on these first results three series of experiments were conducted during
189 28 days with aliquots randomly sampled on day 4 to day 7, day 11 to day 14, day 18 to day 21
190 and day 25 to day 28. For each time/temperature pair studied, aliquots were analyzed by
191 PEDV-specific RT-qPCR, to quantify the viral genome, and by TCID₅₀, to determine the
192 infectious capacity of the virus. In addition, the rest of spiked seawater at day 0 was stored at -
193 80 °C for later genomic load determination (Bigault 2020) and TCID₅₀.

194 ***Viral decay modeling***

195 The objective here is to define a mathematical model representing the decrease in PEDv viral
196 titers over time as a function of temperature. Two models were selected among those recently
197 used for this type of analysis, a bi-exponential model and a Weibull type model (de Oliveira et
198 al., 2021). Data were normalized for TCID₅₀, each point (_nTCID₅₀) treated as the ratio
199 between the value obtained at point t_n and the initial value at point t₀.

200 - The bi-exponential model.

201 This model is expressed as a function of 4 parameters: two threshold values a₁ and a₂ and
202 two decay rates δ₁ and δ₂:

$$V(t) = a_1 \exp(-\delta_1 t) + a_2 \exp(-\delta_2 t).$$

203 Thus, the initial titer is expressed by V(0)=a₁+a₂, to which two successive exponential
204 decreasing phases.

205 - The Weibull model

206 This model is also based on 4 parameters

$$V(t) = 1 - D * \exp(-(\delta t)^{-\alpha}).$$

207 In this model, an asymptotic decrease is represented towards a threshold value $V_{\infty} = 1 - D$.

208 The parameter δ governs the initial phase of decay when the parameter α influences the
209 behavior over longer durations and the speed of convergence towards the value V_{∞} .

210 - Parameter estimation

211 The data used to estimate the parameters are shown in Figure 1 and Table 1. Each panel
212 corresponds to a water temperature (4, 8, 15 and 24°C); for each of them, six kinetics were
213 considered (tree separate experiments analyzed on duplicate). The estimation of the

214 parameters was carried out using a non-linear mixed-effect model for which the kinetics of
215 the repetitions are considered as a longitudinal follow-up in a population. Briefly, for each
216 model, the parameters θ are estimated at the population level. The individual parameters were
217 assumed to be log-normally distributed, thus ensuring their positivity. The parameters of
218 individual i are given by

$$219 \log(\hat{\theta}^i) = \log(\hat{\theta}^{\text{pop}}) + \beta_{\text{Temp}} * \text{Temp} + \eta_{\text{Temp}}(\hat{\theta}^i),$$

220 where $\hat{\theta}_{\text{pop}}$ represents the median parameter independent of temperature at the population
221 level. $\hat{\theta}^{\text{pop}}$ represents the value of the mean parameter in the population. $\eta_{\text{Temp}}(\hat{\theta}^i)$ are random
222 effects vectors assumed to be independent centered Gaussian vectors with variance ω_{Temp}^2 ,
223 representing interindividual variability. The temperature is integrated as a covariate for all the
224 parameters and has an impact when the associated parameter β_{Temp} is significantly different
225 from 0. The quality of adjustment of the models is evaluated according to the Akaike criterion
226 (AIC), the model having the lowest AIC being selected.

227 - Seawater temperature along the French Coast

228 The temperature of the water is regularly monitored on different site of the seashore in
229 France. In this study, data collected in continental French territory were considered. 308
230 sampling points were included for which temperature was recorded between 2000 and 2021 at
231 different depth (REPHY dataset - French Observation and Monitoring program for
232 Phytoplankton and Hydrology in coastal waters. Metropolitan data -
233 <https://doi.org/10.17882/47248>). Here, we focused on surface waters only, with a depth
234 varying between 0 and 1m. The dataset consisted in 54000 temperature records, which where
235 analyzed quarterly from January to December to derive the average quarter temperature for
236 each year. Feeding the decay model with these temperature records allowed for evaluating the
237 virus half-life for each sampling location and each quarter.

238

239 **Results**

240 *Survey of PEDv decay in seawater*

241 The half-life of the coronavirus virion in seawater was poorly characterized when starting
242 these experiments. Therefore, in a preliminary experiment (data not show), we measured the
243 decay of virions at four different temperatures (4, 8, 15, and 24°C) for 16 days. At the two
244 lowest temperatures, we observed only a slight decrease in infection of 5% and 12% at 4°C
245 and 8°C, respectively, by day 16. At day 16, for the 15°C temperature the infectious titer
246 dropped by about 40% (from 6 Log₁₀ TCID₅₀ to 3,6 log₁₀ TCID₅₀) and complete loss of
247 infection was observed after 7 days at 24°C (0.8 log₁₀ TCID₅₀). In parallel with infectivity,
248 a measure of genomic load was performed using RT-qPCR, which revealed the stability of the
249 viral genome throughout the 16 days duration of this preliminary experiment. Therefore, in
250 order to be able to decipher more precisely the viral decay of PEDv in seawater, three
251 independent series of experiments were performed with the same temperature settings (4, 8,
252 15 and 24°C) but extended to 28 days.

253 TABLE 1 gives the mean TCID₅₀ results of the 3 series of experiments and Figure 1 shows
254 the daily evolution of TCID₅₀, normalized to the initial (D0) TCID₅₀, for 28 days at the four
255 different temperatures.

256 We observed good repeatability for the samples collected at different time points in the
257 experiment, with the same trend for each of the triplicates according to the temperature.
258 However, significant variability between the triplicates on days 20 to 28 at a temperature of
259 15 °C was also observed (day 25: 0.5 Log₁₀ TCID₅₀ for series 1 and 2 and 2.9 Log₁₀
260 TCID₅₀ for series 3), which gives a random and blurred aspect to this region of the curve.
261 The complete experiment, over four weeks, confirmed the trend observed during the first test.

262 At 4°C and 8°C, we observed an overall good stability of the PEDv infectious titer with 82%
263 and 69% of the initial TCID50 value maintained after 28 days of incubation in our coastal
264 water sample, respectively. At 15°C, 88% of the TCID 50 was maintained during the first 7
265 days, and then the infectious titer dropped to 67% of the initial TCID50 during the next seven
266 days followed by a regular decline of the TCID50 value to 23% of the initial TCID50 by day
267 28. In the last part of the experiment, the individual TCID50 values at 15°C were much more
268 dispersed, as reflected by the increase in the standard deviation values for the last points from
269 Day 18 onward. Finally, the complete loss of infectious PEDV after 7 days at 24°C was
270 confirmed. In parallel with the measurement of the infectious titer, the viral genome
271 concentration was measured by RT-qPCR to ascertain the presence of viral particles in the
272 incubation medium used for the infection (Supplemental 1 and Figure 1). Despite day-to-day
273 variations, on the 28 days duration of the experiment, the PEDv genome loads remained
274 stable for the four experimental conditions, confirming that the decrease in infectious titer was
275 not due to the loss of virus when preparing the viral inoculum for TCID50 experiments, but to
276 the time- and temperature-dependent degradation of the viral particles.

277 *Modelling the infectious load decay of coronavirus in coastal water*

278 Two models, a bi-exponential model and a Weibull type model (Camillo de Oliveira 2021)
279 were evaluated to define a mathematical model of the decrease in PEDv viral titers in coastal
280 water over time as a function of temperature. Akaike's information criterion was lower with
281 the Weibull model than with the bi-exponential model (-728 and -634, respectively),
282 indicating a better fit of the data with the Weibull model. The model parameters, representing
283 the average kinetics estimated at the population level are listed in Table 2.

284 The log-linear regression model revealed a significant effect of temperature on all the
285 individual parameters, accounting for inter-individual variability. Correlation between the

286 parameters estimated for each kinetic and the water temperature is shown in Figure 2. The
287 parameters governing the decrease (δ and α) reflect the persistence observed at 4°C over the
288 duration of the experiment. These parameters showed a strong dependence on the water
289 temperature. A strong exponential increase in δ was observed between 15 °C and 24°C,
290 indicating an impact on the initial decrease. The increase in parameter α , which governs the
291 speed of convergence towards V_{∞} (asymptotic viral load), also showed an exponential trend,
292 varying from 1 to 3 between 4 and 24°C.

293 *Analysis of the persistency of coronaviruses along the French seashore*

294 We applied the coronavirus decay model along the French seashore, considering the
295 variations in temperature occurring within a year.

296 The quarterly average temperature varied seasonally, ranging from 6 °C to 14°C in winter and
297 from 14 to 26°C in summer. The map displayed in figure 3 highlights geographical
298 discrepancies between northern and southern France as well as between the Mediterranean
299 coast and the Atlantic Ocean in the west.

300 The half-life of the virus in the surface water at each sampling point was evaluated based on
301 the quarterly average temperature and is represented as a heat map in figure 4. Reflecting the
302 analysis of the temperature records, a huge seasonal effect was observed, with a half-life of
303 coronavirus infectivity of up to 70-80 days during the coldest period, falling below 20 days at
304 all locations during the summer. The northern area exhibited the highest half-life seasonal
305 variation compared to that of Corsica where water temperatures remained much stable
306 throughout the year.

307

308

309

310 **Discussion**

311 Viral contamination of water or food by human sewage is a long-documented origin of
312 gastroenteritis outbreaks, as exemplified by the contamination of oysters by human norovirus
313 (HuNoV) (Le Guyader et al., 2009; McLeod et al., 2017). At the beginning of the pandemic,
314 the question regarding SARS-CoV-2 risk of exposure and transmission to human during
315 recreational activities was highlighted. Although significant amounts of SARS-CoV-2 RNA
316 are regularly detected in the feces of patients, it has been shown that the infectious capacity of
317 the SARS-CoV-2 virus from feces is very limited. A few studies have concluded that the risk
318 of infection following exposure to SARS-CoV-2 in water is low (Ahmed et al., 2021; Bivins
319 et al., 2020; Silverman and Boehm, 2021). However, the evaluation of CoV survival in water
320 and especially in seawater will be informative for SARS-CoV-2 but also for other CoV,
321 especially enteric CoV.

322 This study aimed to monitor experimentally and concretely the survival/persistence of PEDV,
323 as a representative of CoV and as a surrogate for SARS-CoV-2, in marine waters. This using
324 the modeling of its decay over time and water temperature data taken in France. The potential
325 risk of infection in French coastal waters, in case of contamination by the discharge of
326 wastewater was also evaluated and confirmed to be low or inexistent. As mentioned above,
327 SARS-CoV-2 manipulation requires a level 3 laboratory, which is available in a limited
328 number of facilities and represents more tedious working conditions than level two
329 laboratories. To circumvent this constraint, several surrogate agents of SARS-CoV-2 have
330 been used for decay and environmental persistence experiments. Non-enveloped viruses, such

331 as bacteriophage MS2, pose problems of misinterpretation and accuracy; non enveloped
332 viruses are known to be more resistant than enveloped viruses (La Rosa et al., 2020a; La Rosa
333 et al., 2020b). The use of a coronavirus as a surrogate provides greater reliability as
334 coronaviruses form an organizational unit with similar biophysical properties and genomic
335 structures. Moreover, (Guillier et al., 2020) have shown a similar temperature and relative
336 humidity persistence potential of different coronaviruses infecting human and non-human
337 mammals, on surfaces and in suspension, confirming the potential of animal coronaviruses as
338 surrogates. To study the persistence of coronavirus in seawater, we selected PEDv, a porcine
339 enteric alphacoronavirus we handled in a BSL2-type confined laboratory . Recently, the
340 PEDv has been used several times, as surrogate for HCoV, including SARS-CoV-2, i) to
341 compare analytical methods to detect SARS-CoV-2 in wastewater (Perez-Cataluna et al.,
342 2021), ii) as a process control for the monitoring of the occurrence of SARS-CoV-2 in 2020 in
343 six wastewater treatments plants in Spain (Randazzo et al., 2020), iii) to evaluate the use of
344 viability RT-qPCR for the selective discrimination and surveillance of infectious SARS-CoV-
345 2 in secondary-treated wastewater (Monteiro et al., 2022), iv) to test the temperature
346 sensitivity of different CoV in fomites (Cuevas-Ferrando et al., 2022), v) to evaluate the
347 effects of dry- and moist-air controlled heating treatment on structure and chemical integrity,
348 decontamination yield, and filtration performance of surgical masks and FFP2 respirators
349 (Bernard et al., 2020), vi) and to test inactivation of PEDv on contaminated surgery masks by
350 low-concentrated sodium hypochlorite dispersion (Antas et al., 2020). Furthermore, in a
351 previous study, we demonstrated and quantified the bioaccumulation of PEDv or inactivated
352 SARS-CoV-2 in oysters, and observed a similar tissue distribution and efficacy of
353 bioaccumulation between the two coronaviruses, suggesting that PEDv is an adequate
354 surrogate for SARS-CoV-2 in marine environments (Desdouits et al., 2021).

355 Various studies using surrogate viruses (Sala-Comorera et al., 2021) and addressing the
356 detection and survival of coronaviruses in wastewater, river water, or filtered or sterilized
357 water have been conducted over the past 2 years (Ahmed et al., 2020b; Guillier et al., 2020;
358 Randazzo et al., 2020). Others used both surrogates and the SARS-CoV-2 (de Oliveira et al.,
359 2021; Sala-Comorera et al., 2021) but were conducted either at low temperatures (4°C) or at
360 higher temperatures (20–25°C). Yet, the temperature gradient was not considered in the same
361 model. The synthesis that can be drawn from these studies shows a common trend, in which
362 different viruses remain infectious for several hours to several weeks, depending on the
363 experiment, in different types of water (pure water, surface water, seawater and sterilized
364 wastewater), with infectivity maintained for a longer period of time at the lowest temperatures
365 (Chin et al., 2020; Lee et al., 2020; Ye et al., 2016). Recently, (Sun et al., 2022) showed an
366 inverse correlation between temperature and viral titer for the viability of SARS-CoV-2 in
367 media and artificial seawater. These studies illustrate that intact coronavirus particles present
368 in coastal waters may remain infectious for some time.

369 Our results present a follow-up of the decay of the virus over a long period with a wide
370 temperature gradient (from 4°C to 24°C), similar to the temperature gradient observed in
371 French coastal waters throughout the year, associated with a mathematical model used for
372 evaluating the virus half-life along the French shore throughout the year. This experiment
373 clearly shows that seawater temperature has a dramatic effect on the duration of the infectious
374 capacity of PEDv and, by homology, on coronaviruses including SARS-CoV-2. The parallel
375 evaluation of the genomic load of the samples throughout the experiment precludes the
376 possible bias of a reduction in the viral load due to artifacts such as adsorption on the tube
377 walls or other phenomena. Under summer conditions representative of Mediterranean
378 conditions (24°C), we observed a rapid loss of the infectious capacity of the virus in seawater,
379 with a loss of almost two log TCID₅₀ at 3-4 days and a total loss at day 7. Under conditions

380 mimicking the spring Atlantic coast (~15°C), the effect was more gradual, with a loss of one
381 log in one week and almost total loss at 3 weeks. In winter conditions (4°C and 8°C), the
382 infectious virus is more stable, with survival extending beyond four weeks

383 In another study assessing SARS-CoV-2 survival in cell culture medium, with a similar range
384 of temperatures as ours (4°C, 13°C, 21°C and 25°C), the best virus survival was also
385 observed with the coolest conditions; the virus was relatively stable for all the temperature
386 conditions with the maximum log reduction of 1.17 virus titer at 4 days post-contamination at
387 25°C (5.104 TCID₅₀ starting dose) (Kwon et al., 2021). Coronaviruses are sensitive to
388 extremely acidic and basic pH. Therefore, the faster inactivation of PEDv in seawater can be
389 explained by the high salinity concentration in combination with alkaline conditions (pH>8)
390 in seawater compared to that in culture medium (Kwon et al., 2021), wastewater and pure
391 water (Chan et al., 2020).

392 Using the experimental kinetics of the viral decay of PEDv as a function of real temperature
393 data along the French coast during the year (considering the mean temperatures reported from
394 2000 to 2021) allowed us to evaluate the half-life of the virus according to seasons. The risk
395 of viral transmission is correlated with a longer half-life of the virus and a higher
396 frequentation of human populations in coastal environments. Fortunately, these two
397 parameters are inversely correlated with a peak of human population in coastal areas during
398 summer, when the half-life of the virus is the shortest, owing to the higher water temperature
399 which is deleterious to the virus. Conversely, the better survival conditions for the virus in
400 winter is balanced by a lower population size and frequentation in the recreational usage of
401 coastal areas. The situation is somewhat different concerning workers, such as for oyster
402 farmers or fisherman, in contact with water all the year around even at the coldest
403 temperature when virus half-life is the longest. In our previous study, we showed a low
404 bioaccumulation efficiency of SARS-CoV-2 in oysters, as well as the absence of detection of

405 this virus in seawater and shellfish samples collected on the French coast from April to
406 August 2020 (Desdouits et al., 2021), confirming that the actual risk of contamination in food
407 such as shellfish by the SARS-CoV-2 is low. Furthermore, if we consider the effect of tides,
408 bringing an additional physical dispersion and dilution effect on the virus, all of these
409 parameters favor a low risk of coronavirus contamination during seashore activities.

410 It is important to mention that these results could be refined by considering additional
411 parameters of seawater as the variation in salinity (this study used only one salinity
412 representative of the Brittany coast) and by estimating the effect of solar radiation, a known
413 driver of viral decay, with summer exhibiting higher UV radiation exposure than winter.

414 Given the low survival of SARS-CoV-2 in sewage (Silverman and Boehm, 2021), the main
415 risk of SARS-CoV-2 contamination through coastal water exposure likely lies in the direct
416 release of raw sewage, places without connection to wastewater collection systems, ports, and
417 in the event of a sanitation accident or human feces in seawater. The question also arises of
418 soils contamination during spreading by slurry potentially contaminated by coronaviruses
419 from livestock (ex: PEDv) and therefore by runoff and water contamination. This work could
420 thus be used for the identification of areas that are the most at risk for humans in the case of
421 spillover before treatment, as well as for the identification of maritime areas at risk of reverse
422 zoonotic transmission to the marine animal population and, therefore, to be monitored as a
423 priority. Indeed, cases of SARS-CoV-2 contamination have been reported essentially in
424 various terrestrial animal species (Andersen et al., 2020; Hale et al., 2021; Prince et al., 2021;
425 Sharun et al., 2021) it might also infect marine mammals (Audino et al., 2021). Alpha, and
426 gammacoronavirus infections are already known to cause respiratory diseases in aquatic
427 mammals and recent studies have shown that several species of marine mammals possessed
428 the SARS-CoV-2 receptor, ACE2 (Luan et al., 2020; Nabi and Khan, 2020), with amino acids

429 sequences highly conserved between human and marine mammal species. The binding of
430 SARS-CoV-2 to ACE2 is an essential step in the infection of SARS-CoV-2, which can
431 therefore make these animals susceptible to SARS-CoV-2 infection (Mathavarajah et al.,
432 2021; Mordecai and Hewson, 2020). Thus, contamination of seawater from sewage,
433 wastewater effluent, or urban and agricultural runoff, and the survival of SARS-CoV-2 are
434 potentially a risk for marine mammals. Guo et al. modeled this risk by analyzing the possible
435 dispersion of the virus following contamination in seawater and confirmed that this risk of
436 infection is directly linked to viral concentrations, but also suggested a critical role of the
437 temperature of the water (Guo et al., 2021).

438 **Funding**

439 This work is supported by the Agence Nationale de la Recherche and the Fondation de France
440 (ANR RA-Covid wave 5, n°00109676), the Région Pays de la Loire (order n°2020-12887), by
441 an internal funding from Ifremer General Direction (SARS-CoV-2 action plan) and the
442 European project VEO (H2020, SC1-2019-874735).

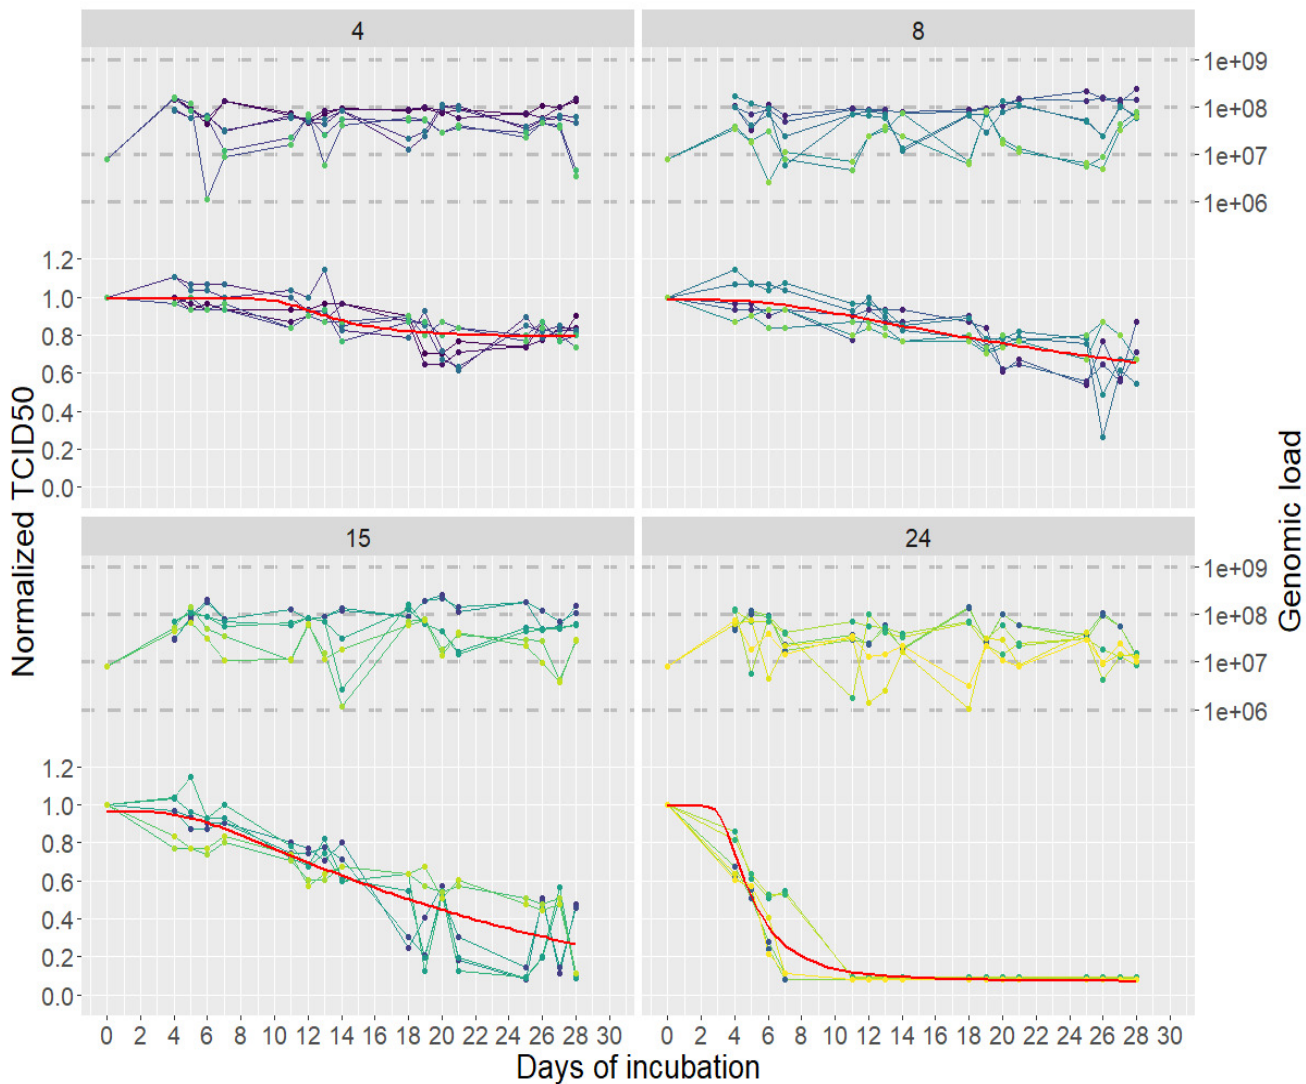

Figure 1: Genomic and infectious titers of PEDv incubated in seawater at four different temperatures for 28 days. 1 ml aliquots of seawater were spiked with the PEDv CV777 virus stock to achieve a load of 1.10^6 TCID₅₀ / ml and 1.10^8 genome copy / ml then incubated in water baths for 28 days at 4 different temperatures : 4°C, upper left panel ; 8°C, upper right panel ; 15°C, lower left panel and 24°C, lower right panel. The genomic load (genome copies, in log scale, right axis, upper part of each panel) and infectious titer (ratio of the TCID₅₀ measured at each time point (days of incubation, horizontal axis) on the one at day 0 for each experiment, left axis, bottom part of each panel) were measured 4 days a week (D4 to D7, D11 to D14, D18 to D21 and D25 to D28), by RT-qPCR and IPMA respectively, in duplicate for each aliquot on the same aliquot, and during three independent experiments. For each condition, the 6 measures are depicted with blue to yellow points and lines. The Weibull models calculated for the infectious titer decay are represented by the red curves.

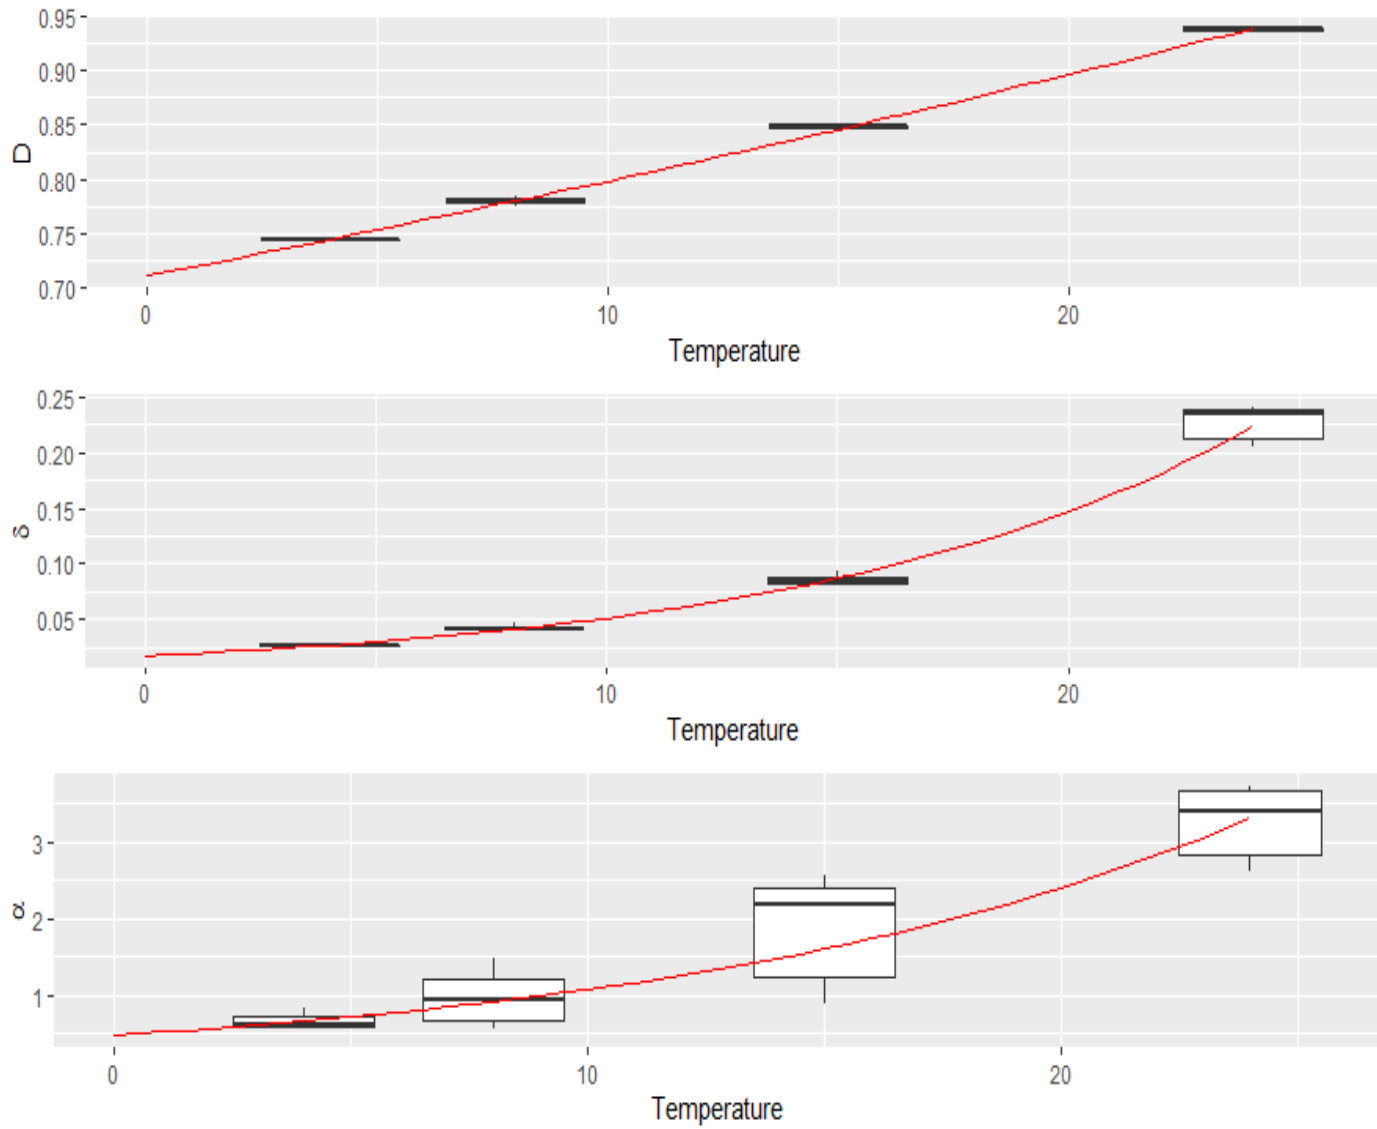

Figure 2: Correlation between the parameters estimated for each kinetic and the water temperature.

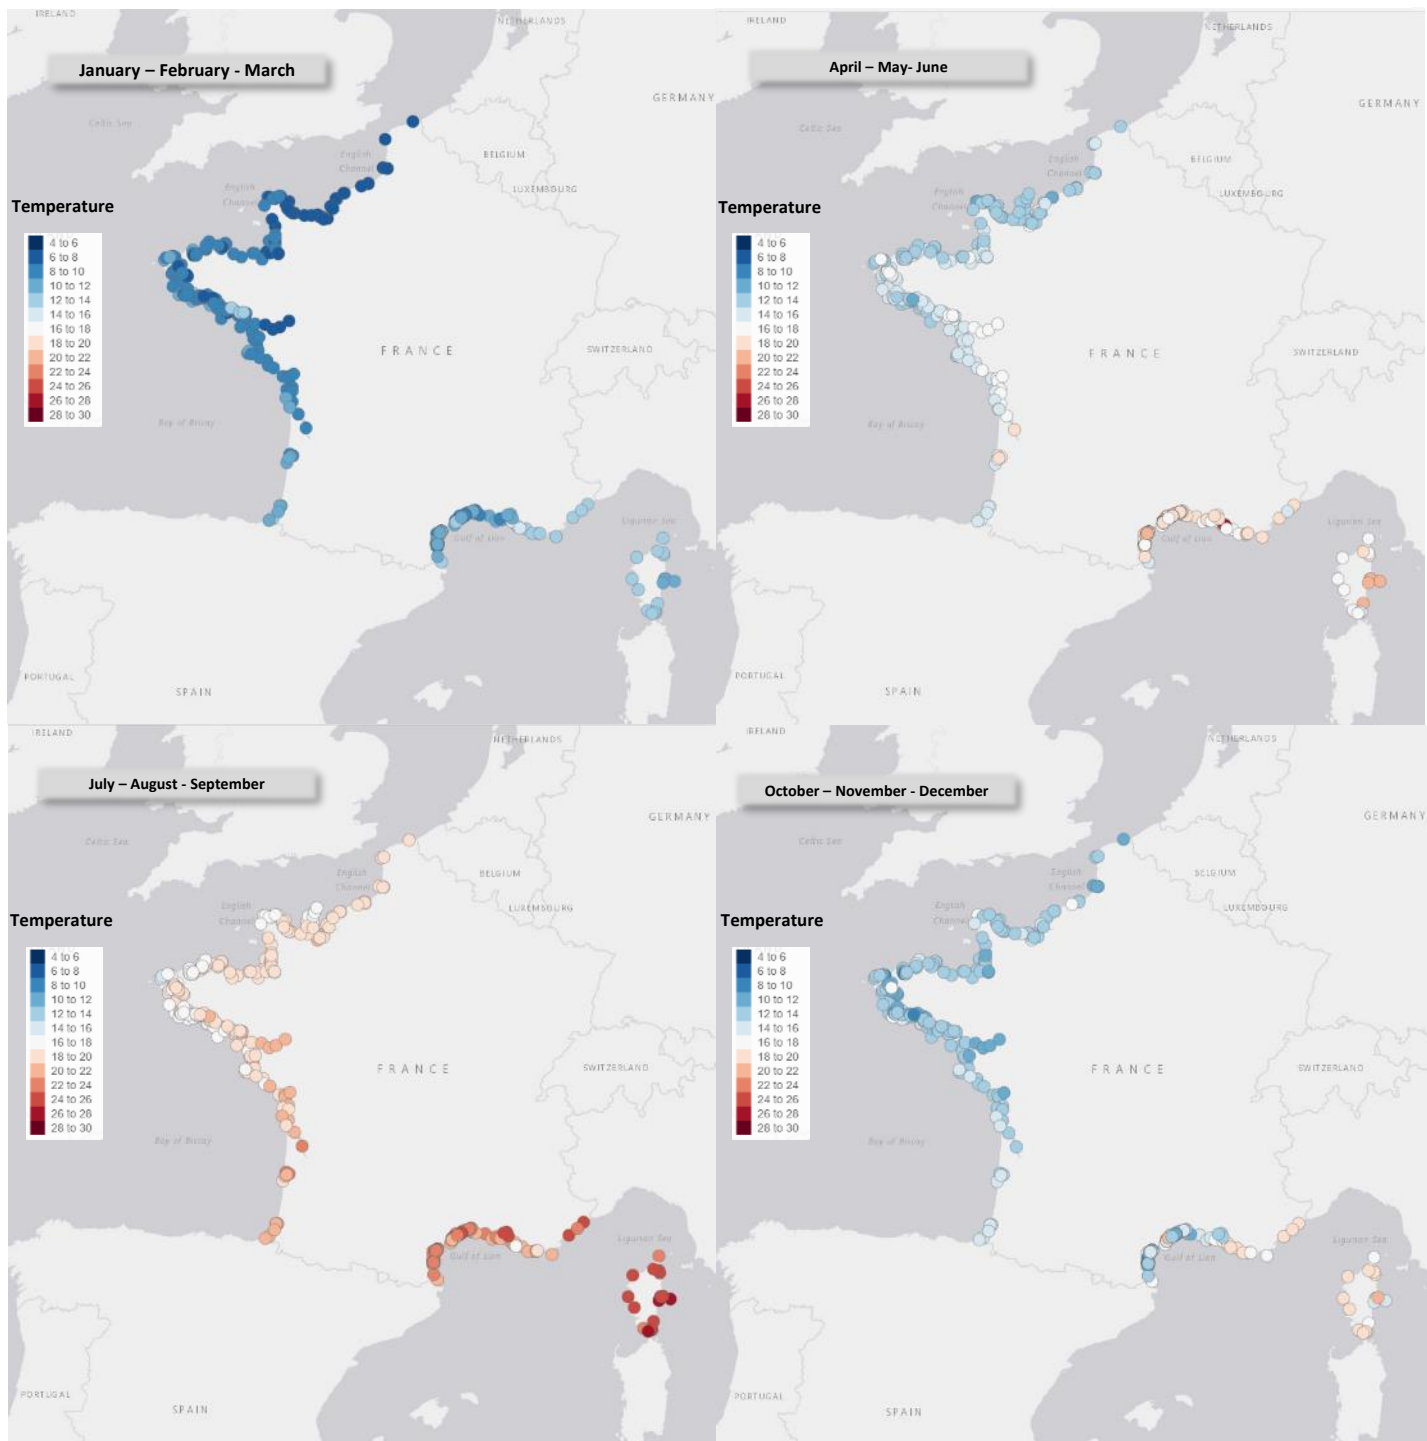

Figure 3: Mean quarterly temperatures of surface waters on the French coast from 2000 to 2021.

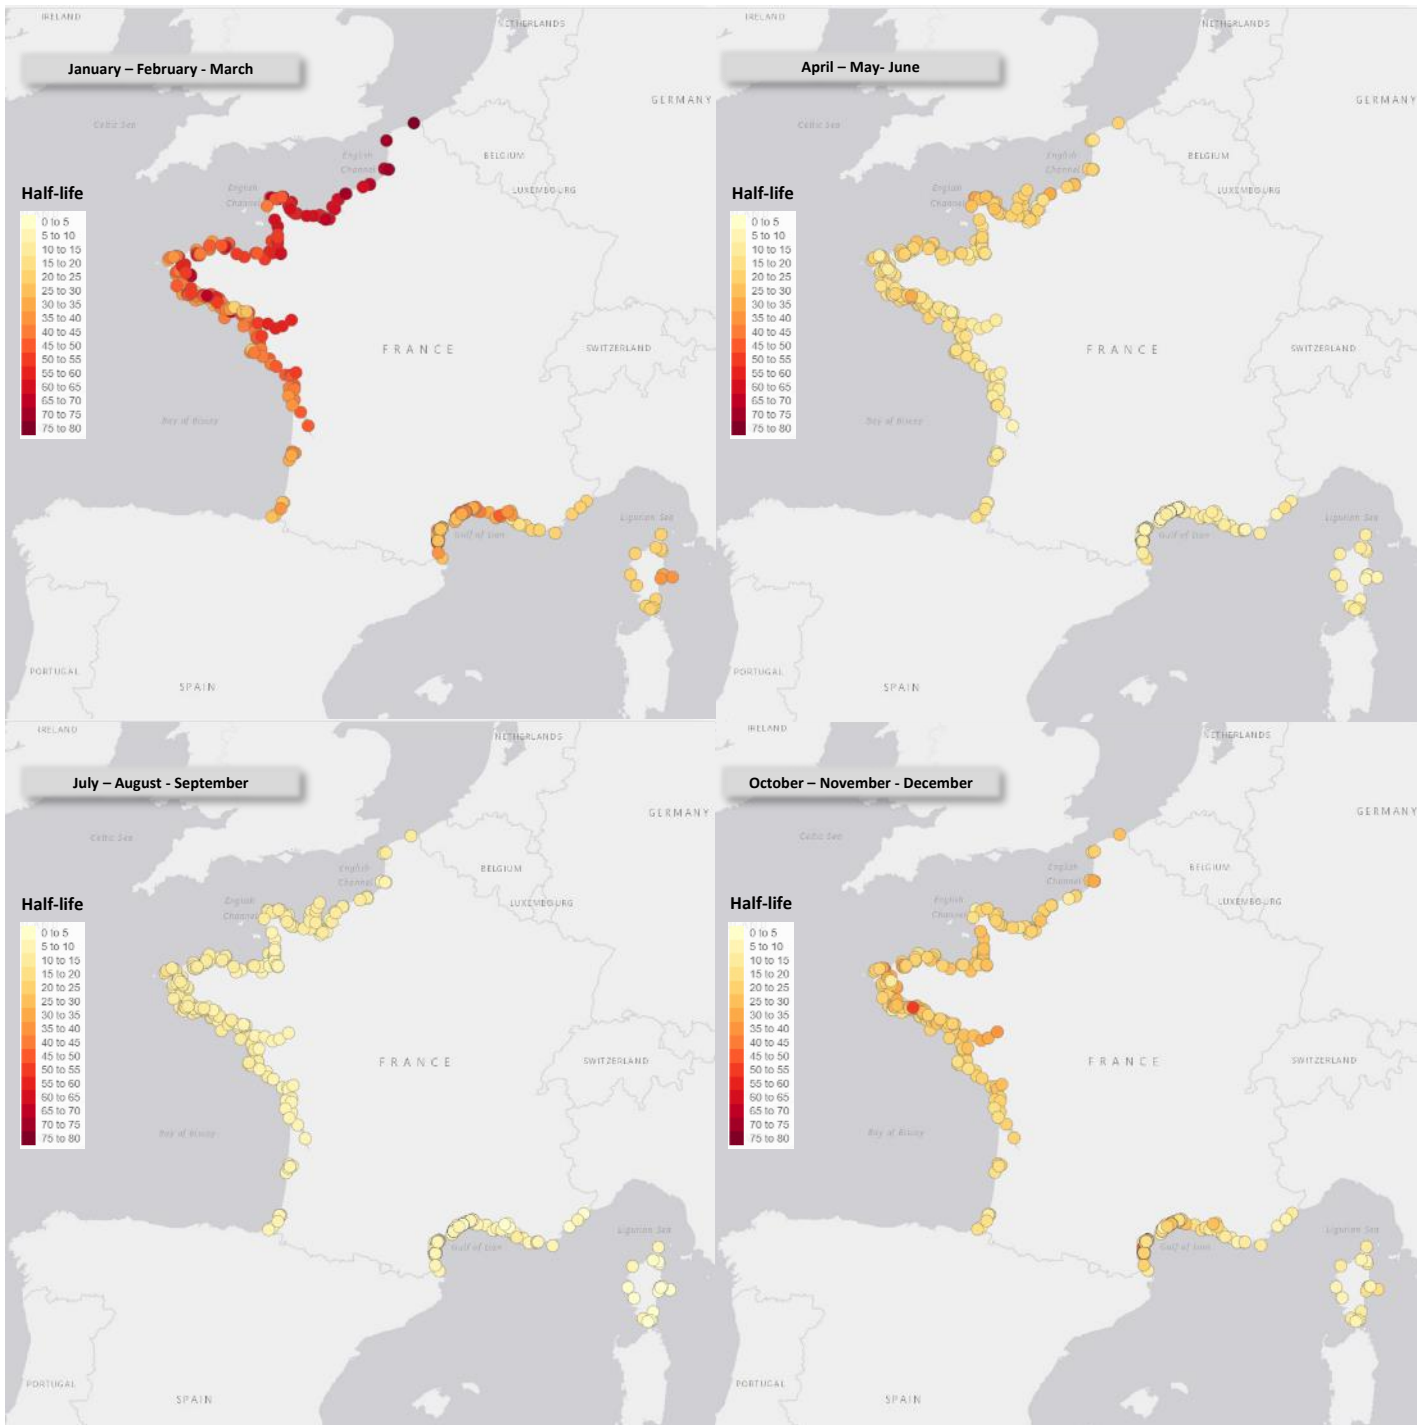

Figure 4: Estimated half life (in days) of coronavirus in surface water, based on quarterly average temperature for each collection location.
