45 Running Header: Risk for Suicide Attempt in AUD  
46 Word count abstract: 226; Word count text body: 3,517  
47 Figures and Tables: 1 Table, 1 Figure.  
48

49 Key words: suicide, polygenic score, substance use disorder, alcohol use disorder

## 50 Abstract

51 Research has identified clinical, genomic, and neurophysiological markers associated with  
52 suicide attempts (SA) among individuals with psychiatric illness. However, there is limited  
53 research among those with an alcohol use disorder (AUD), despite their disproportionately  
54 higher rates of SA. We examined lifetime SA in 4,068 individuals with DSM-IV alcohol  
55 dependence from the Collaborative Study on the Genetics of Alcoholism (23% lifetime suicide  
56 attempt; 53% female; mean age: 38). Within participants with an AUD diagnosis, we explored  
57 risk across other clinical conditions, polygenic scores (PGS) for comorbid psychiatric problems,  
58 and neurocognitive functioning for lifetime suicide attempt. Participants with an AUD who had  
59 attempted suicide had greater rates of trauma exposure, major depressive disorder, post-  
60 traumatic stress disorder, and other substance use disorders compared to those who had not  
61 attempted suicide. Polygenic scores for suicide attempt, depression, and PTSD were associated  
62 with reporting a suicide attempt (ORs = 1.22 – 1.44). Participants who reported a SA also had  
63 decreased right hemispheric frontal-parietal theta and decreased interhemispheric temporal-  
64 parietal alpha electroencephalogram resting-state coherences relative to those who did not, but  
65 differences were small. Overall, individuals with an AUD who report a lifetime suicide attempt  
66 appear to experience greater levels of trauma, have more severe comorbidities, and carry  
67 polygenic risk for a variety of psychiatric problems. Our results demonstrate the need to further  
68 investigate suicide attempts in the presence of substance use disorders.

## 69 Introduction

70           Approximately 2-5% of U.S. adults report having attempted suicide in their lifetimes  
71 (Baca-Garcia et al., 2010; Kessler et al., 1999; Scheer et al., 2020), with the prevalence  
72 increasing in more recent birth cohorts (Olfson et al., 2017). Additionally, deaths by suicide are  
73 one of the leading causes in the recent decline in U.S. life expectancy, alongside other “deaths  
74 of despair” such as drug and alcohol related deaths (Case & Deaton, 2015; Tilstra et al., 2021).  
75 While the rate of suicide attempts in the general population is alarming, the rate of lifetime  
76 suicide attempts is greater than triple (17.5%) among those with an alcohol use disorder (AUD)  
77 (Potash et al., 2000). Among those seeking treatment for AUD, 40% report at least one suicide  
78 attempt at some point in their lives (Koller et al., 2002; Modesto-Lowe et al., 2006; Sher, 2006;  
79 Whiteford et al., 2013). A history of past suicide attempts is among the most prominent  
80 predictors of subsequent suicide death and contributes significant health care and disability  
81 costs per attempt (Shepard et al., 2016). Research focused on correlates of suicide attempts  
82 can potentially help identify and treat those with non-fatal suicide attempts, with the goal of  
83 reducing suicide deaths and saving lives (Yuodelis-Flores & Ries, 2015). Importantly, alcohol  
84 use is a consistent risk factor for death by suicide (Isaacs et al., 2022), individuals with an AUD  
85 have emerged as a particularly high-risk group (Edwards et al., 2024; Lannoy et al., 2022,  
86 2024).

87           In addition to clinical and phenotypic correlations between substance use disorders  
88 (SUD), and suicidal behaviors there is also consistent evidence for genetic overlap between  
89 these outcomes, with AUD in particular. Evidence from large scale genome-wide association  
90 studies (GWAS) of both AUD/problematic alcohol use (PAU) (Kranzler et al., 2019; Sanchez-  
91 Roige et al., 2019; Walters et al., 2018; Zhou et al., 2023) and suicide attempts (SA) (Docherty  
92 et al., 2023; Mullins et al., 2022), reveal robust genetic correlations across these outcomes. And  
93 while there are very limited GWASs of suicide attempt in the presence of AUD (Peng et al.,

94 2024), two recent efforts using multivariate approaches which harness existing GWAS have  
95 shown that: 1) a shared genetic liability towards all forms of SUD is correlated with suicidal  
96 ideation, attempt, and self-injurious behavior, independent of genetic liability towards depression  
97 (Colbert et al., 2021), and 2) the shared genetic overlap between AUD and suicide attempts is  
98 explained, in part, by underlying liability towards impulsive behaviors (Stephenson et al., 2023).

99         Similar to the genetics of AUD and SA, two separate literatures have explored  
100 neurocognitive differences between (a) individuals who have attempted suicide to those who  
101 have not (Keilp et al., 2013; Richard-Devantoy et al., 2012, 2014) and (b) individuals with AUD  
102 (Cabé et al., 2016; Le Berre, 2019; Le Berre et al., 2017) compared to those unaffected with  
103 AUD. Those with AUD exhibit deficits in many domains of brain functioning, including  
104 neuropsychological performance, and neurophysiological indices (Cabé et al., 2016; Le Berre,  
105 2019; Le Berre et al., 2017). Executive functioning is typically the primary focus of such studies,  
106 with a large literature demonstrating that individuals with AUD display poorer executive  
107 functioning and atypical neurophysiological profiles (e.g., EEG connectivity) than individuals  
108 without AUD (Cardenas et al., 2018; Kamarajan et al., 2020; Mumtaz et al., 2017; Park et al.,  
109 2017). Researchers have also examined these areas of brain functioning among individuals  
110 who have exhibited suicidal ideation and related mental health problems, such as depression  
111 (Keilp et al., 2013; Richard-Devantoy et al., 2012, 2014), though research focused on SA is  
112 limited. While no previous studies have examined EEG connectivity and SA, EEG connectivity  
113 in depressed patients exhibited higher alpha and theta coherences in frontal, temporal, and  
114 parietal regions, and higher beta coherence in frontal and temporal regions (Leuchter et al.,  
115 2012a). Further, a recent study found other neurophysiological differences associated with  
116 binge drinking and suicidal behaviors in adolescents (Ehlers et al., 2020). To our knowledge, no  
117 prior study has examined neural connectivity among those with AUD who have attempted  
118 suicide.

119           Given the higher rates of SA observed among those with AUD, we explored whether  
120 there are clinical, genomic, and neurophysiological markers of SA within this population. Among  
121 participants diagnosed with an AUD (DSM-IV alcohol dependence) drawn from the  
122 Collaborative Study on the Genetics of Alcoholism (COGA), we examined whether clinical risk  
123 factors, polygenic scores (PGS) for comorbid psychiatric problems, and neurocognitive  
124 functioning differed between those who have and have not reported a lifetime suicide attempt.

## 125   Methods

### 126   *Sample and Measures*

127           The Collaborative Study on the Genetics of Alcoholism (COGA) is a large, multi-site  
128 study of 2,255 families affected with AUD, designed to identify and understand genetic factors  
129 involved in the predisposition to AUD and related disorders, as previously described (Agrawal et  
130 al., 2023; Begleiter, 1995; Dick et al., 2023). Probands along with all willing first-degree relatives  
131 were assessed; recruitment was extended to include additional relatives in families that  
132 contained 2 or more first degree relatives with alcohol dependence and community ascertained  
133 comparison families (N = 17,878). Participants 18 or older completed the Semi-Structured  
134 Assessment for the Genetics of Alcoholism (SSAGA) which is a poly-diagnostic interview  
135 (Bucholz et al., 1994), and participants ages 12-17 completed an adolescent SSAGA. We  
136 currently have genome wide data on 12,145 individuals. Our final analytic sample consisted of  
137 4,068 COGA participants with an alcohol dependence diagnosis (lifetime) and GWAS data  
138 (including 3,270 individuals of European-like and 798 individuals of African-like genetic  
139 similarity, see following section for discussion on assignment of genetic similarity).

140           *Lifetime suicide attempt.* All participants were queried about whether they had “ever tried  
141 to kill” themselves (*suicide attempt*), regardless of a history of suicidal ideation (i.e., thoughts  
142 about killing yourself). For the current analyses, we included individuals reporting any suicide

143 attempt, including those reporting drug-related suicide attempt (14% of all attempts).  
144 Importantly, suicide attempt items were not exclusively nested within the diagnostic section for  
145 major depressive disorder (MDD), although individuals who reported suicide attempts in that  
146 section were coded accordingly as having reported the behavior.

147 *Clinical Risk Factors and Comorbidities.* We created lifetime diagnoses of other  
148 substance use disorders (SUD), psychiatric disorders, suicidal thoughts and behaviors, and  
149 trauma exposure based upon DSM-IV criteria using the child and adult versions of the SSAGA  
150 (Dick et al., 2023). We assessed nicotine dependence using the Fagerström Test for Nicotine  
151 Dependence (FTND) scores (Heatherton et al., 1991). Additionally, we included measures of  
152 extended family histories of AUD, and other alcohol-related problems (Pandey et al., 2020).

### 153 *Polygenic scores (PGS)*

154 Genotyping, imputation and quality control have been described previously (Johnson et  
155 al., 2023; Lai et al., 2021). Briefly, in order to limit the impact of population structure, genetic  
156 data were used to assign individuals into genetically similar groupings (National Academies of  
157 Sciences and Medicine, 2023) based on the first two principal components and the 1000  
158 genomes reference panel (Phase 3, version 5) (Johnson et al., 2023). Families were classified  
159 as primarily European-like (EUR-like) or African-like (AFR-like) according to the genetic  
160 similarity of the greatest proportion of family members (Lai et al., 2021). Genotyping of  
161 individuals in the analytic sample was performed using the Illumina 2.5M array (Illumina, San  
162 Diego, CA, USA), the Illumina OmniExpress (Wang et al., 2013), or the Illumina 1M array, or the  
163 Affymetrix Smokescreen array (Baurley et al., 2016). SNPs with a genotyping rate <98%,  
164 Hardy-Weinberg equilibrium violations ( $p < 10^{-6}$ ), or with minor allele frequency (MAF) less than  
165 3% were excluded from analyses. Data were imputed to 1000 genomes (Phase 3) using  
166 SHAPEIT (Delaneau et al., 2013) and IMPUTE2 (Das et al., 2016). Following imputation,

167 dosage probabilities  $\geq 0.90$  were converted to hard calls. SNPs with an imputation information  
168 score  $< 0.30$  or MAF  $< 0.03$  were excluded from subsequent analysis.

169 We estimated polygenic scores (PGS), which are aggregate measures of the number of  
170 risk alleles individuals carry weighted by effect sizes from GWAS summary statistics, for a  
171 variety of psychiatric and substance use phenotypes. We included PGS derived from recent  
172 GWAS of (1) alcohol use disorders (AUD) (Zhou et al., 2020), (2) depression (DEP, 23andMe  
173 excluded) (Levey et al., 2021), (3) post-traumatic stress disorder (PTSD) (Nievergelt et al.,  
174 2019), (4) bipolar disorders (BIP) (Bigdeli et al., 2020; Mullins et al., 2021), (5) schizophrenia  
175 (SCZ) (Bigdeli et al., 2020; Trubetsky et al., 2022) (6) smoking initiation (SMOK, as a proxy for  
176 externalizing risk) (Karlsson Linnér et al., 2021; Saunders et al., 2022) and (7) suicide attempt  
177 (SUI) (Docherty et al., 2023). For AUD and BIP, we meta-analyzed published GWAS results  
178 with corresponding results from FinnGen (release 9) (Kurki et al., 2023). We focus on these  
179 PGS specifically because: 1) these disorders are phenotypically correlated with suicide attempt,  
180 and 2) they contain GWAS results for both European-like and African-like groupings. For GWAS  
181 that originally included COGA in the discovery sample, we obtained summary statistics with  
182 COGA removed.

183 To date, GWAS have been overwhelmingly limited to individuals of primarily European  
184 descent (Mills & Rahal, 2019). Because of variation in allele frequencies and linkage  
185 disequilibrium (LD) patterns, PGS often lose predictive accuracy when there is mismatch  
186 between the genetic similarity of the discovery GWAS and target sample (Ding et al., 2023).  
187 COGA includes participants of both African-like and European-like groupings, thus we used  
188 PRS-CSx (Ruan et al., 2022), a method that integrates GWAS summary statistics from well-  
189 powered GWAS (typically of European-like individuals) with those from other populations to  
190 improve the predictive power of PGS in the participants of African-like groupings in COGA.  
191 PRS-CSx employs a Bayesian approach to correct GWAS summary statistics for the non-  
192 independence of SNPs in LD. We converted PGS into Z-scores for ease of interpretation

## 193 *Electroencephalogram (EEG) data*

194 EEG recording and processing have been detailed previously (Meyers et al., 2023).  
195 Briefly, resting (eyes-closed) EEG was recorded for 4.25 min; a continuous interval of 256  
196 seconds was analyzed. Each subject wore a fitted electrode cap using the 61-channel montage  
197 as specified according to the extended 10–20 International system. The nose served as  
198 reference and the ground electrode was placed on the forehead. Electrode impedances were  
199 always maintained below 5 k $\Omega$ . EEG was recorded with subjects seated comfortably in a dimly  
200 lit sound-attenuated temperature-regulated booth. They were instructed to keep their eyes  
201 closed and remain relaxed, but not to fall asleep. Electrical activity was amplified 10,000 times  
202 by Neuroscan and Masscomp amplifiers, with a bandpass between 0.02 Hz to 100 Hz and  
203 recorded using the Neuroscan system (Compumedics Limited; El Paso, TX). EEG procedures  
204 were identical at all COGA collection sites. Bipolar electrode pairs were derived to reduce  
205 volume conduction effects, and 27 representative coherence pairs were selected based on  
206 previous EEG coherence work in COGA (Meyers et al., 2023). Magnitude squared coherence  
207 was calculated from power spectral values derived from Fourier Conventional Fourier transform  
208 methods (Nunez et al., 1997). Coherence measures were generated between bipolar pairs at  
209 the following frequency bands: theta (3-7 Hz), alpha (7-12 Hz), beta (12-28 Hz).

## 210 *Statistical analyses*

211 We compared those with an AUD who reported a suicide attempt and those with an AUD  
212 who did not report a suicide attempt across a range of sociodemographic, psychiatric  
213 comorbidities, experiences of trauma, and other measures related to alcohol misuse. We use  
214 multiple-group, multi-level regression models in Mplus (Rattana Wannisa & Rattana Narunart,  
215 2558) and adjusted for sex, age (at time of psychiatric assessment), genetic similarity (AFR-like  
216 vs. EUR-like), family history of AUD, and family relatedness. We ran all models simultaneously  
217 (i.e., correlation among all variables accounted for) to limit multiple testing.

218 For polygenic scores, we first compared those with AUD who had reported a suicide  
219 attempt to those with AUD who had not reported a suicide attempt across all PGSs,  
220 independently, using logistic regression in R (version 4.2.1). Second, to ensure that results  
221 within those with AUD were not biased by conditioning on AUD (Akimova et al., 2021), we also  
222 compared: 1) those with AUD who had a reported suicide attempt, 2) those with AUD who had  
223 not reported a suicide attempt, and 3) those without AUD who had a reported suicide attempt to  
224 those who neither reported a suicide attempt nor meet criteria for AUD (see Supplemental Table  
225 1 for sample description) using a multinomial logistic regression model in the *nnet* package in R  
226 (Ripley & Venables, 2022). In both analyses, we included sex, age, the first six genetic principal  
227 components (PCs), genotype array, and birth cohort as covariates. To adjust for familial  
228 clustering, we used cluster robust standard errors (Colin Cameron et al., 2011; Davenport et al.,  
229 2011). We stratified analyses by genetic similarity and then meta-analyzed results (by PGS)  
230 within each of the analyses above. All analyses were corrected for multiple testing. We also  
231 performed a GWAS of SA, but lacked the power to identify any individual variants associated  
232 with SA (see supplementary information)

233 Lastly, we compared those with AUD who reported a suicide attempt and those with  
234 AUD who did not report a suicide attempt across neurophysiological measures (resting state  
235 EEG coherence), again using multiple-group, multi-level regression models adjusted for sex,  
236 age (at time of psychiatric assessment), genetic similarity, family history of AUD, and family  
237 relatedness. We ran all models simultaneously to limit multiple testing. ). We also performed a  
238 series of exploratory analyses within a subset of individuals who had available neurocognitive  
239 measures (see supplemental information for full description).

## 240 Results

### 241 *Clinical Risk Factors Associated with Suicide Attempt in Participants with AUD*

242 The main analytic sample was limited to the 4,068 participants with a DSM-IV diagnoses  
243 of alcohol dependence. We compared 3,138 COGA participants who met criteria for AUD and  
244 did not attempt suicide in their lifetime with 930 participants with AUD who attempted suicide.  
245 Table 1 presents the demographic characteristics. Overall, those with AUD who attempted  
246 suicide were more likely to be female (53% vs. 32%). Rates of suicide attempt and the age  
247 distribution of participants were similar across EUR-like and AFR-like groups (see Table S2 for  
248 stratified results). The majority (58.4%) of the analytic sample endorsed suicidal ideation at  
249 some point in their lifetime; of those who attempted suicide, 97.6% endorsed prior suicidal  
250 ideation compared to 46.8% of those who did not attempt suicide.

251 Figure 1 presents the means and rates for clinical and psychiatric comorbidities cross  
252 those with and without a history of SA. Participants with AUD who had attempted suicide were  
253 significantly more likely to have been exposed to traumatic events in their life, regardless of the  
254 type of trauma (sexual, assaultive and non-assaultive). Additionally, those who reported suicide  
255 attempt also had significantly higher lifetime rates of major depressive disorder and post-  
256 traumatic stress disorder relative to those who had not attempted suicide. In terms of comorbid  
257 substance use addition, participants that reported attempting suicide had higher family history  
258 densities of AUD (Pandey et al., 2020), started drinking at an earlier age, had more severe  
259 indicators of alcohol-related problems, and had higher rates of meeting lifetime criteria for other  
260 SUDs (cocaine, nicotine, sedative, and stimulant). In total, those with AUD who report suicide  
261 attempt seem to be more severely affected for other psychiatric and substance use disorders.

## 262 *Polygenic Scores*

263 Figure 2, Panel A presents the meta-analyzed results for associations between each of  
264 the corresponding PGSs and lifetime suicide attempt within those meeting criteria for AUD.  
265 PGSs for DEP ( $OR_{META} = 1.34$ , 95% CI = 1.18, 1.53), PTSD ( $OR_{META} = 1.23$ , 95% CI = 1.03,  
266 1.45), and SUI ( $OR_{META} = 1.44$ , 95% CI = 1.22, 1.70) were associated with increased odds of  
267 reporting suicide attempt. However, the AUD, BIP, SCZ, and SMOK PGSs were not associated  
268 with suicide attempt (stratified results in Table S3).

269 Figure 2 (Panel B) shows conditional PGS results from the multinomial logistic models  
270 comparing those with AUD who had attempted suicide (AUD+/SA+) and those with AUD who  
271 had not attempted suicide (AUD+/SA-), to those without an AUD diagnosis and who had not  
272 attempted suicide (AUD-/SA+ omitted for clarity, full results in Table S4). Relative to the AUD-  
273 /SA- group, the AUD ( $OR_{META} = 1.16$ , 95% CI = 1.05, 1.28), DEP ( $OR_{META} = 1.29$ , 95% CI =  
274 1.16, 1.44), SMOK ( $OR_{META} = 1.30$ , 95% CI = 1.17, 1.44), and SUI ( $OR_{META} = 1.40$ , 95% CI =  
275 1.22, 1.60) PGSs were all associated with increased odds of being in the AUD+/SA+ group. By  
276 contrast, only the AUD ( $OR_{META} = 1.15$ , 95% CI = 1.08, 1.22) and SMOK ( $OR_{META} = 1.30$ , 95%  
277 CI = 1.21, 1.39) PGSs were associated with increased odds of being in the AUD+/SA- group  
278 relative to the reference group (AUD-/SA-).

## 279 *Neurophysiological Findings*

280 We observed nominal differences in resting state EEG coherence patterns in those with  
281 AUD that had attempted suicide compared to those who had not attempted suicide. However,  
282 only two findings withstood multiple test correction: decreased right hemispheric frontal-parietal  
283 theta (3-7Hz @ F8-F4--P8-P4) and decreased interhemispheric temporal-parietal alpha (7-12  
284 Hz @ T8-P8--T7-P7) EEG resting-state coherences ( $p < 0.001$ , Figure 3). Our exploratory  
285 analyses within a subset of individuals who had available neurocognitive measures did not  
286 produce any significant results (available in the supplementary information).

## 287 Discussion

288 Researchers have begun to identify clinical, genomic, and neurophysiological correlates  
289 of suicide attempts among individuals with and without psychiatric illnesses (i.e., schizophrenia,  
290 bipolar disorder, depression) [13,14,15,16]. However, few have examined these risk factors in  
291 tandem among those with AUD, despite the higher rates of suicide attempts of this group. The  
292 current study identified distinct clinical, genomic, and neurophysiological associations with  
293 lifetime suicide attempt among individuals who meet criteria for DSM-IV alcohol dependence.

294 All participants with an AUD in COGA reported elevated rates of suicidal ideation, other  
295 substance use disorders, and trauma exposure compared to the general population (Baca-  
296 Garcia et al., 2010; Grant et al., 2016). However, those who met criteria for an AUD and  
297 reported a lifetime suicide attempt had even greater levels of lifetime trauma (sexual, assaultive,  
298 and non-assaultive), other substance related problems, suicidal ideation, and comorbid  
299 psychiatric conditions (PTSD and major depressive disorder) relative to those who had not  
300 attempted suicide. These results confirm that those with AUD who report a lifetime suicide  
301 attempt represent clinically high-risk group. Given the strong role early trauma plays in risk for  
302 suicide attempt (Zatti et al., 2017), the elevated levels of exposure to trauma in this group, and  
303 the higher rates of PTSD, trauma exposure may play an even more important role for SA risk in  
304 those with AUD. Future work should utilize prospective information to determine whether early  
305 trauma exposure and psychiatric problems predate the onset of AUD and eventual SA in  
306 COGA.

307 In terms of genetic risk, the polygenic scores for suicide attempt, depression, and PTSD  
308 were associated with a lifetime suicide attempt in persons with an AUD in the meta-analyzed  
309 results. Exploration of the stratified results demonstrate these were primarily driven by the  
310 associations in the EUR-like participants. The lack of associations of PGSs in the AFR-like  
311 grouping likely stems from the relatively small sample sizes of the discovery GWASs

312 (Dudbridge, 2013). Importantly, in the multinomial logistic regression models, those with AUD  
313 did not differ in mean levels of AUD PGS regardless of whether they had reported a lifetime  
314 suicide attempt. Similar to the logistic regression models limited to persons with AUD, those  
315 who had attempted suicide had higher suicide and depression PGSs.

316 We also observed significant decreases in right hemispheric frontal-parietal theta (3-7  
317 Hz @ F8-F4--P8-P4) and interhemispheric temporal-parietal alpha (7-12 Hz @ T8-P8--T7-P7)  
318 EEG resting-state coherences in the resting state among AUD individuals who had  
319 attempted suicide. While there are no prior studies of suicide attempt that examined EEG  
320 coherence, differences in alpha and theta coherences in frontal, temporal, and parietal regions,  
321 and higher beta coherence in frontal and temporal regions were found previously in depressed  
322 patients (Leuchter et al., 2012b). Together, these data suggest that while both decreased theta  
323 and alpha resting state connectivity are likely among AUD individuals with depression and  
324 suicide attempts, but more data are needed to make definitive any conclusions.

325 We note several important limitations. First, we focused on lifetime risk for all of the  
326 clinical measures included and cannot speak to the time order between these clinical risk  
327 factors and suicide attempt. Future research can harness the smaller subset of prospective  
328 participants in COGA to examine the longitudinal associations between psychiatric conditions  
329 and future suicide attempt among those with an SUD. Second, we focused exclusively on AUD.  
330 There is also a high rate of suicide attempts among individuals with other SUDs, particularly  
331 cocaine and opioid use disorders. Lastly, we did not have data on those who died by suicide,  
332 which may differ from those who have attempted but not taken their own lives.

333 Understanding the antecedents for suicide attempt remains one of the top goals of  
334 psychiatric epidemiology. Persons with substance use disorders are a particularly at-risk group  
335 for lifetime suicide attempt. In the current analysis, we demonstrated that persons with an AUD  
336 that attempted suicide had particularly higher levels of trauma exposure and psychiatric  
337 comorbidities, elevated polygenic scores for suicide attempt, depression, and PTSD, and lower

338 neurophysiological functioning. Future work with larger and more diverse samples can examine  
339 additional risk factors, such as social and environmental conditions. Identifying robust predictive  
340 markers within an already high risk group may allow for earlier intervention and prevention from  
341 unnecessary loss of human life.

## 342 Acknowledgements

343 Research reported in this publication was supported by the National Institute on Alcohol  
344 Abuse and Alcoholism under award numbers U01AA008401. The content is solely the  
345 responsibility of the authors and does not necessarily represent the official views of the National  
346 Institutes of Health. This research also used summary data from the Psychiatric Genomics  
347 Consortium (PGC), the Million Veterans Program (MVP), and the International Suicide Genetics  
348 Consortium (ISGC, now part of the PGC). We would like to thank the many studies that made  
349 these consortia possible, the researchers involved, and the participants in those studies, without  
350 whom this effort would not be possible.

351 The Collaborative Study on the Genetics of Alcoholism (COGA), Principal Investigators  
352 B. Porjesz, V. Hesselbrock, T. Foroud; Scientific Director, A. Agrawal; Translational Director, D.  
353 Dick, includes ten different centers: University of Connecticut (V. Hesselbrock); Indiana  
354 University (H.J. Edenberg, T. Foroud, Y. Liu, M.H. Plawecki); University of Iowa Carver College  
355 of Medicine (S. Kuperman, J. Kramer); SUNY Downstate Health Sciences University (B.  
356 Porjesz, J. Meyers, C. Kamarajan, A. Pandey); Washington University in St. Louis (L. Bierut, J.  
357 Rice, K. Bucholz, A. Agrawal); University of California at San Diego (M. Schuckit); Rutgers  
358 University (J. Tischfield, D. Dick, R. Hart, J. Salvatore); The Children's Hospital of Philadelphia,  
359 University of Pennsylvania (L. Almasy); Icahn School of Medicine at Mount Sinai (A. Goate, P.  
360 Slesinger); and Howard University (D. Scott). Other COGA collaborators include: L. Bauer

367 and A. Parsian are the NIAAA Staff Collaborators. We continue to be inspired by our memories  
368 of Henri Begleiter and Theodore Reich, founding PI and Co-PI of COGA, and also owe a debt of  
369 gratitude to other past organizers of COGA, including Ting-Kai Li, P. Michael Conneally,  
370 Raymond Crowe, and Wendy Reich, for their critical contributions. This national collaborative  
371 study is supported by NIH Grant U10AA008401 from the National Institute on Alcohol Abuse  
372 and Alcoholism (NIAAA) and the National Institute on Drug Abuse (NIDA).

### 373 Disclosures

374 The authors do not have any conflicts of interest to report.

### 375 Data availability

376 All data sources are described in the manuscript and supplemental information. No new  
377 data were collected. COGA genetic data available through dbGaP (Study Accession:  
378 phs000763.v1.p1). The process for obtaining the GWAS summary statistics used in these  
379 analyses are described in the corresponding original GWAS publications.

## 693 Figure Captions

694 *Figure 1: Clinical comorbidities across those who have and have not reported a suicide attempt*  
695 Percentages and means for psychiatric and substance use comorbidities for those who have  
696 attempted (SA) and have not attempted (No SA) suicide. Significant differences ( $p < .05$ )  
697 indicated by dashed lines around bars.

698  
699 *Figure 2: Polygenic scores across those who have and have not reported a suicide attempt*  
700 Panel A presents odds ratios (OR) for AUD, DEP, and SUI PGSs from logistic regression  
701 models in persons with AUD who had and had not attempted suicide. Panel B presents OR from  
702 multinomial logistic models (no AUD, no suicide attempt as reference group). All models include  
703 cohort, sex, PC1-PC3, array, and site as covariates. SEs adjusted for familial clustering using  
704 cluster-robust standard errors. AFR = African-like genetic similarity grouping, EUR = European  
705 like genetic similarity grouping, AUD = alcohol use disorder polygenic score, DEP = depression  
706 polygenic score, = SUI suicide attempt polygenic score, SA- = no lifetime suicide attempt, AUD-  
707 = does not meet criteria for alcohol use disorder, SA+ = lifetime suicide attempt, AUD+ = meets  
708 criteria for alcohol use disorder.

709  
710 *Figure 3. Neurophysiological measures across those with and without a reported suicide*  
711 *attempt.*

712 Decreased right hemispheric frontal-parietal theta (3-7 Hz @ F8-F4--P8-P4) and decreased  
713 interhemispheric temporal-parietal (7-12 Hz @ T8-P8--T7-P7) alpha EEG resting-state  
714 coherences. A) Decreased right hemispheric frontal-parietal theta (3-7 Hz @ F8-F4--P8-P4)  
715 resting-state EEG coherence. B) Decreased interhemispheric temporal-parietal alpha (7-12 Hz  
716 @ T8-P8--T7-P7) resting-state EEG coherence

Table 1. Sociodemographic Characteristics in COGA Participants with an Alcohol Use Disorder (N = 4,068)

	No Suicide Attempt (N = 3,138)	Suicide Attempt (N = 930)
Female (%)	31.8%	53.1%*
Black or African American (%)	20.5%	16.7%
Hispanic (%)	6.2%	8.5%
Mean age at last interview (SD)	39.9 (11.9)	38.2 (10.5)
Suicidal Ideation (%)	46.8%	97.6%*

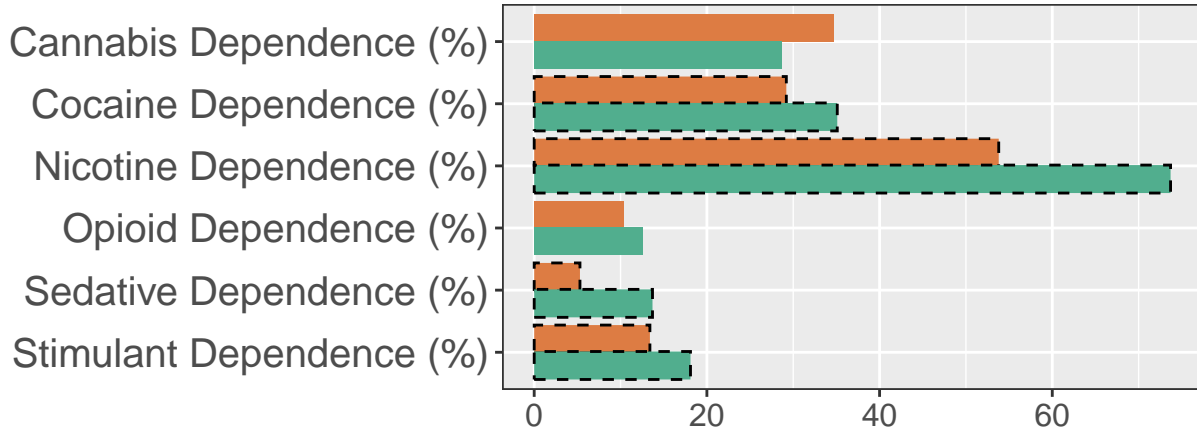

\*  $p < .05$
