

# Anti-SARS-CoV-2 IgG profile of protein subunit, adenovector and mRNA vaccines

*Sebastian Reinig, Kou-Chin, Chia-Chun Wu, Sheng-Yu Huang, Jau-Song Yu, Shin-ru Shih*

## Abstract

Different vaccine platforms were developed in 2019 and 2020 to provide immunization for protection against the SARS-CoV-2-caused disease COVID-19. The majority of vaccinated individuals will develop antibodies against SARS-CoV-2. The isotype (subclass) and Fc-glycosylation of IgG antibodies determine their affinity for secondary effector functions. For protein subunit vaccines in COVID-19, the IgG profile of the subclass and glycosylation are unknown. Therefore, we measured the IgG subclass and N-297 Fc glycosylation by ELISA and LC-MS/MS of anti-spike IgG from individuals vaccinated with the Taiwanese protein subunit vaccine Medigen, the mRNA vaccines (BNT, Moderna), and the adenovector Astrazeneca. Samples were taken after the first and second doses. For all vaccine types, the main IgG response was dominated by IgG1 and IgG3 as subclasses. For glycosylation, mRNA vaccines presented with an afucosylation after the first dose and a constant significant higher galactosylation and sialylation than non-mRNA vaccines.

## Introduction

The COVID-19 pandemic epidemic in 2019 with SARS-CoV-2 as the primary causal agent has sped up the development of numerous coronavirus vaccines (1). The majority of vaccinated individuals will develop neutralizing antibodies against SARS-CoV-2 (2). Studies have revealed that immunizations offer comparable protection against infection or serious disease as natural infection (3). Anti-SARS-CoV-2 antibody function cannot be fully explained by neutralizing antibodies alone. For instance, substantially lower antibody titers are needed in vaccines to provide the same level of protection as natural infection (4). Immunoglobulin (IgG), the most prevalent antibody in the blood, can activate a variety of secondary effector processes, such as complement activation, macrophage-mediated antibody dependent cellular phagocytosis (ADCP), and antibody-dependent cellular cytotoxicity (ADCC) (5). The Fc-domain's structure and affinity for Fc-receptors affect how these secondary activities are activated. The IgG subclass and the conserved n-297 glycosylation site of the Fc-domain determine the structure of the Fc-domain (6). A proinflammatory pattern with higher IgG3 levels and non-fucosylated IgG levels is present in severe COVID-19 disease and may contribute to the progression of the condition. (7–9). According to one study, protein subunit vaccinations induce significant production of fucosylated non-inflammatory antibodies (7). The IgG profile of protein subunit vaccinations in COVID-19 is mostly unknown in people. Our study is the first to examine the IgG profile of the Taiwan-made Medigen protein subunit vaccination (10). We compared the distribution of

anti-spike IgG subclasses, IgG glycosylation, and Medigen adenovector vaccine recipients with Moderna mRNA vaccine recipients. In fact, we were able to confirm that, in contrast to severe COVID-19 disease or mRNA vaccination, no temporary afucosylation took place in Medigen vaccinated individuals. In addition, we discovered a distinctive IgG glycosylation pattern in mRNA vaccine recipients compared to non-mRNA vaccine recipients, with mRNA vaccine recipients having higher levels of galactosylated and sialylated anti-spike IgG.

## Results

### **Anti-spike IgG subclass distribution is IgG1/3 dominated and is similar among different vaccines**

All samples came from 41 Taiwanese people who had not been exposed to the disease before receiving the immunization. The participants received vaccine doses from protein subunit vaccine Medigen (MVC-COV1901), adenovector vaccine Astrazeneca (ChAdOx1-S), and both mRNA vaccines Moderna (mRNA-1273) and, BNT (BNT162b2). The only antigen used in all vaccinations is the spike glycoprotein (S) of the SARS-CoV-2 coronavirus. The estimated IgG NT titer increased from the 1<sup>st</sup> to 2<sup>nd</sup> dose and was significant higher in the mRNA vaccines in comparison to non-mRNA vaccines (**Figure 1**). The main IgG subclass during the first and second dose against the spike glycoprotein is in all vaccine groups IgG1 and IgG3 in comparison to the signal for pre-vaccination (**Figure 2 A, C**). Anti-S IgG2 and IgG4 are or only slightly elevated before pre-vaccination level (**Figure 2 B, D**). Elevated anti-S IgG4 level are observed after the second vaccination in accordance to other studies in Moderna vaccinated individuals (**Figure 2 D**). However, this was not statistical significant different from other vaccines. Subtle, but significant differences could be found between Medigen and BNT vaccinated with higher anti-S IgG4 level in BNT vaccinated individuals. There were no significant differences in the IgG between the first and second dose of each vaccine (**Figure 2 E-H**).

### **Anti spike IgG glycosylation showed distinct patterns between mRNA and non-mRNA vaccinated individuals.**

IgG1 glycosylation was measured by LC-MS/MS of anti-S IgG1. Here major differences could be identified between mRNA vaccinated (Moderna, BNT) and non-mRNA (Astrazeneca and Medigen). Galactosylation and sialylation were significant higher in mRNA vaccinated (**Figure 3 B,C**). There was also a significant lower sialylation level in Astrazeneca vaccinated in comparison to Medigen vaccinated (**Figure 3 C**). Fucosylation was lower in mRNA vaccinated, but there was no significant difference between Medigen and mRNA vaccinated (**Figure 3 A**). The fucosylation increased from the

first to second dose in mRNA vaccinated (only significant in Moderna vaccinated, **Figure 3 F1**). For galactosylation and sialylation, the pattern is stable among the majority of individuals from the first to second vaccination (**Figure 3 E-G**).

## Discussion

This is the initial investigation of the IgG profile of COVID-19 protein subunit vaccines. Similar to other adenovector and mRNA vaccines, the IgG subclass distribution of Medigen was dominated by IgG1/3. This is consistent with previous research on the COVID-19 vaccination as well as subunit protein vaccines against other viruses like hepatitis B (11,12). Recent studies found an increase in anti-S IgG4 after the second or third dose of mRNA vaccines (12,13). After the second dose, we noticed a slight increase in anti-S IgG4, although it was not yet statistically significant. Since it takes 50–150 days after the initial injection for the anti-S IgG4 level to rise in mRNA vaccines, the observation period in our current data may be too short. In hepatitis B protein subunit vaccinations, an escalating level of antigen-specific IgG4 is also seen over time (14). Inclusion of samples at later time points especially after the 3. dose will elucidate if there is also a rise in anti-spike IgG4 after prolonged time.

The most significant findings between the vaccine groups were found in the n-glycosylation level of IgG1 as the main subclass. In agreement to prior studies mRNA vaccines showed lower levels of anti-S IgG1 fucosylation that increase over time and this is in agreement with prior studies (12,15). Medigen and Astrazeneca vaccine recipients did not show early afucosylation and maintained a high anti-S IgG1 fucosylation level in the first and second doses. Since the afucosylation was strongest either in the mRNA vaccinated or infection shortly after seroconversion 7-8 days after vaccination, it cannot be excluded in our study that some afucosylation occurs earlier since all our samples were taken at least 14 days after the injection. In prior studies, it was claimed that soluble antigens like those present in protein subunit vaccines would induce fucosylated antigenic IgG in comparison to situations in which the antigen is membrane-bound (7,16). This is supported by our findings on Medigen IgG glycosylation, while Astrazeneca vaccinations exhibited the greatest levels of fucosylation of any vaccine groups. As a genetic vaccination, AstraZeneca should cause the appearance of the spike protein by transfecting the membrane with the body's own cells. However, because the Astrazeneca vaccine's spike protein contains the furin cleavage site and has the potential to cleave the S1 subunit. This make it possible that a significant portion of the spike protein is a soluble antigen (17,18). Additionally, it was possible to see vaccine-induced free spike protein in blood plasma together with mRNA (19). For a better understanding of the immunization mechanisms in genetic vaccines, further investigations are needed to ascertain the quantity of spike protein that is membrane bound and is free soluble in the blood between the different genetic vaccines. Non-

fucosylated IgG have a larger affinity for the FcγIIIa receptor, which can increase the activation of NK cells and the release of cytokines by spike-protein IgG complexes in macrophages. Low IgG fucosylation can be harmful for COVID-19 and Dengue, but it can be helpful for HIV and malaria infections (16). An initial vaccination with either the subunit protein vaccine or the adenovector vaccine can be used, depending on whether or not high levels of transiently fucosylated IgG are needed. This is because transient fucosylation can be inhibited by preceding immunization with a non-mRNA vaccine (15).

There was a significant trend between non-mRNA and mRNA vaccines for IgG glycosylation, with larger galactosylation and sialylation in mRNA vaccinated individuals. This is consistent with a previous study that found decreased galactosylation and sialylation in Astranzeneca vaccine recipients than in mRNA vaccine recipients (12). Sialylation can promote the expression of inhibitory FcγIIb receptors, while galactosylation should increase the affinity of IgG to the complement system and NK cells (20). The overall impact of these changes may be determined by conducting more functional investigations specifically on PBMCs.

The spike glycoprotein is the only antigen used in all of the vaccinations used in the study. This study offers a novel perspective on the impact of several vaccination platforms on the IgG profile. Additionally, because all of the samples used in this investigation were collected before to Taiwan's first significant COVID-19 outbreak in April 2022 (21), a significant influence from earlier SARS-CoV-2 infection memory may be ruled out. This situation is also unusual since when the mass vaccination program began, the virus had already infected a sizable fraction of the population in most parts of the world (22). There is a considerable chance that previously infected people were included in research on the IgG profile of vaccine recipients since many asymptomatic and mildly infected people might not have been screened or have not developed antibodies against SARS-CoV-2 to confirm a past infection. Therefore this represent a unique study comparing four different vaccine platforms in immune naive individuals with the same antigen.

## Methods

### Sample collection

Serum and Plasma samples were collected from 41 COVID-19 vaccinated individuals at the Chang Gung University or the Chang Gung Memorial hospital between 14 and 157 days after the injection (median: 27 days). The sample collection period was from June 9<sup>th</sup> 2021 to January 25<sup>th</sup> 2022. For the pre-vaccine serum as baseline serum was collected from 10 individuals before vaccination. The age of the from the donors ranged from 21 to 60 years (median: 33 years). 73.75% of the donors were

female. The samples were collected as per protocol SDP-003, Human Biological Specimens Collection, data September 22, 2017 and qualifications of the principal investigator (Robert Pyrtle, M.D.) were reviewed and approved by the Diagnostic Investigations Investigational Review Board (Cummerbund, MA, USA).

### **IgG NT titer determination**

For Each serum sample the NT titer was estimated by MeDiPro SARS-CoV-2 antibody ELISA according to the manufacturer's instructions and calculated according to following study (2).

### **IgG subclass ELISA**

To estimate the composition of Spike protein S1 binding IgG subclasses in the serum, Spike protein was immobilized at a concentration of 2 mg/ml per well using PBS conjugate on the plate overnight. A blocking solution consisting of 5% Bovine serum albumin (BSA) in PBST. All samples were diluted 1:10 with 2.5% BSA in PBST under the same condition. The following mouse anti-human IgG secondary antibodies were utilized: IgG1 at a dilution of 1:2000 (Southern Biotech), IgG3 at a dilution of 1:500 (Southern Biotech), IgG2 at a dilution of 1:500 (Southern Biotech), and IgG4 at a dilution of 1:500 (Southern Biotech). To determine the fold change for IgG subclass the baseline for each subclass was determined by the mean signal of pre-vaccine sera of seronegative individuals.

### **Anti-spike IgG purification**

BcMag™ Tosyl Activated Magnetic Beads (bioclone) were utilized to purify antigen-specific IgG (Spike protein) from serum. For coupling the Spike protein, 100 µg of Spike protein (Sino Biological) was bound to 30 mg of Tosyl magnetic beads. For each sample the beads were then divided equally, with coupling beads containing 2.5 µg of spike protein used for the serum. Elution of antibodies was done by 0.1% Trifluoroacetic acid (TFA). The spike protein-specific IgGs obtained were subsequently analyzed using mass spectrometry.

### **Preparation for LC-MS/MS**

100 mM Tris-HCl was added to 5mg of each anti-spike IgG sample. The samples were reduced with 5 mM TCEP (Sigma) for 30 min at 60 °C and alkylated with 10 mM iodoacetamide (Sigma) in the dark for 35 min at 37 °C. Samples were then digested with trypsin 0.2 mg/ml in 0.1% FA/10% ACN for 16 hours at 37°C. Samples were acidified with 0.5% FA and 0.2% TFA, and each sample was desalted with C18 dissolved in 50 µl (50% ACN/DDW). Taking 5 ml into the insert and Speed Vac, it was dissolving by 6 ml (0.1% FA).

### **Accurate inclusion mass screening (AIMS)**

The tryptic peptide samples were reconstituted in High-performance liquid chromatography (HPLC) buffer A (0.1% formic acid), loaded across a trap column (Zorbax 300SB-C18, 0.3 × 5 mm; Agilent Technologies, Wilmington, DE, USA) at a flow rate of 15 µL/min in HPLC buffer A. The peptides were eluted by a linear gradient of HPLC buffer B (100% acetonitrile/0.1% formic acid) at a flow rate of 0.18 µL/min, and separated on an analytical column (nanoACQUITY UPLC C18 1.7 µm, 0.15 x 10 mm, Waters, Milford, MA, USA) coupled with in-line dilution at a flow rate of 0.1 µL/min HPLC buffer C (0.1% formic acid) for refocusing peptides. Eluted peptides were analyzed with a two-dimensional linear ion trap mass spectrometer LTQ-Orbitrap, which was controlled by Xcalibur 2.2 software (Thermo Fisher, San Jose, CA, USA). Intact peptides were detected in the full-scan MS, performed in the Orbitrap over a range of 400 to 2,000 Da and a resolution of 60,000 at m/z 400. Internal calibration was performed using the ion signal of (Si (CH<sub>3</sub>)<sub>2</sub>O)<sub>6</sub>H<sup>+</sup> at m/z 536.165365 as a lock mass. Accurate m/z values were first entered as input into the inclusion list, and MS/MS analysis was performed on the LTQ–Orbitrap MS with a 10-ppm tolerance on the parent mass in to verify that the given peptides can be detected. Twenty MS/MS scan events (20 HCD) of 20 target precursor ions with most abundancy were followed by one preview MS scan. The m/z values selected for MS/MS were dynamically excluded for 15 seconds with a relative mass window of 15 ppm. The electrospray voltage was set to 2 kV, and the temperature of the capillary was set to 200°C. MS and MS/MS automatic gain control were set to 1,000 ms (full scan), 300 ms (HCD) or 3 x 10<sup>6</sup> ions (full scan) and 3 x 10<sup>4</sup> ions (HCD) for maximum accumulated time or ions, respectively.

### **Processing of LC-MS/MS data**

The signals of the peptides were obtained by analyzing the RAW files with Maxquant 2.0.3.1 software. The intensity of the signal of the precursor was used as signals. The RAW files were converted into .mgf files. Based on mass, charge and retention time the precursor ions were selected initially by manual annotation and literature reports. This was then automated with a custom written python script, which used additionally to mass, charge, retention time and a scoring system for the fragments of the precursor ion to determine, if the precursor has a glycan change. The scoring system was based on the GlyxtoolMS software. The fucosylation, galactosylation and sialylation was estimated by normalizing the through the sum of the signal of all IgG1 N-297 glycopeptides as done in prior studies (7,15).

### **Statistical analysis**

Statistical analysis was performed with R software using the dplyr package. Mann-Whitney-U test was used to compare between 2 samples. Kruskal-Wallis test to compare between multiple groups. P values < 0.05 were considered as statistical significant.
