### 29 Abstract

30 Functional dysregulations in multiple regions are caused by excessive copper deposition in the brain for Wilson 31 disease (WD). While the biological mechanism of these dysregulations was thought to be the absent or reduced 32 expression of the ATP7B protein in the liver, mechanisms for such gene impacting brain function remain 33 unexplored. Here, we used a large cohort of resting-state fMRI data (105 WD patients and 93 healthy controls) to 34 derive the functional connectome gradient, and its WD-related alterations were further evaluated. Then, we used 35 Neurosynth, clinical data, and whole-brain gene expression to examine the meta-analytic cognitive function, 36 clinical phenotypes, and transcriptional specializations related to WD gradient alterations. In parallel, spatial 37 correlation between gradient and gray matter volume was accessed for both WD patients and healthy controls. 38 Compared to controls, WD patients exhibited principal gradient alterations in both global and system levels and 39 regional alterations mainly distributed in the sensorimotor, visual, ventral attention, subcortical, and default mode 40 networks. Meta-analytic terms and clinical characters showed the correlations of these gradient alterations in 41 motor-related processing, higher-order cognition, neurological symptom, and age. Results of spatial correlation 42 revealed structure-function decoupling in multiple networks, especially in subcortical and visual networks. Within 43 the cortex, the gradient alterations derived transcriptional specializations of WD that mainly display properties 44 indicative of ion homeostasis, neural development, and motor controls. Within the subcortical regions, we for the 45 first time characterized the role of the ATP7B gene impacting subcortical function. Transcriptional specializations 46 of WD within both cortex and subcortical regions were also associated with neurological and psychiatric disorders, 47 explaining the mechanism underlying complex clinical symptoms from the biological level for WD. In addition, we 48 further illustrated that structural lesion and gradient perturbation shared similar transcriptional specializations in 49 both cortex and subcortical regions for WD. These findings bridged functional gradient perturbation to structural 50 lesions and transcriptional profiles in WD, possibly promoting our understanding of the neurobiological 51 underpinnings underlying the emergence of complex neurological and psychiatric phenotypes.

#### 53 INTRODUCTION

54 Wilson disease (WD) is an autosomal recessive disorder of copper metabolism caused by the lack of biliary copper 55 excretion<sup>1</sup>. The mutation of the ATP7B gene which is most highly expressed in the liver results in the absent and reduced expression of the ATP7B protein, identifying as causative of copper dysmetabolism<sup>2</sup>. Excessive copper 56 57 accumulation in the liver and brain ultimately leads to neurological and psychiatric phenotypes in WD patients<sup>3</sup>. 58 Animal model of WD, however, has determined that the ATP7B gene is also expressed in neuronal cells of the 59 hippocampus, olfactory bulbs, cerebellum, brainstem, and cerebral cortex. The concurrent high levels of copper in 60 these regions further implicated that dysfunctional ATP7B protein is related to local copper accumulation and the 61 cerebral manifestations of WD<sup>4</sup>.

62 The toxic effect of copper results in damaged astrocytes, neurons, and oligodendrocytes, which gradually build up 63 structural lesions, especially in the subcortical regions, including the basal ganglia, thalamus, and brainstem<sup>5, 6</sup>. Of note, functional MRI studies revealing functional abnormities across the entire brain suggested that a 64 structure-function decoupling may be the leading cause for these abnormities in  $WD^{7,8}$ . Further, the defective 65 cortical function may be due to dysfunction of cortio-subcortical pathways, leading to neurological and psychiatric 66 symptoms in WD<sup>9, 10</sup>. However, the neurobiological mechanisms underlying the brain dysfunction remain to be 67 elucidated. Given that gene has an essential influence on brain function<sup>11</sup>, brain dysfunction of WD may also be 68 69 conceivable to shape by the specific mutated gene, such as ATP7B. Moreover, in consideration of the variability of 70 gene expression profile across the entire brain, such as the cortex and subcortical regions<sup>12</sup>, their relation to the WD 71 topology of dysfunction may provide insights into the neurobiological pathways contributing to the neurological 72 pathogenesis of WD.

73 Brain hierarchical theories uncovered that functional connectome patterns are governed by the graded macroscale 74 axe that spans the primary sensorimotor areas to transmodal regions of the default mode network  $(DMN)^{13}$ . 75 Perturbation in these patterns shapes the clinical phenotypes, such as perception, cognition, and neurological disorder, in multiple neurodegenerative diseases<sup>14, 15</sup>. Furthermore, the macroscale axe of the cortex also is intrinsic 76 77 in gene expression and microstructural topography, indicating that the functional basis strongly depends on the intact gene expression and microstructural profiles<sup>12</sup>. Although many studies revealed alterations in functional 78 connectivity involving basal ganglia, sensorimotor, and DMN regions in patients with WD<sup>7, 8, 16</sup>, no studies reported 79 80 whether and how these alterations are affected by structural and transcriptomic vulnerability. Therefore, if WD 81 patients exhibit perturbation in the functional hierarchy, these abnormalities might be associated with gene 82 expression and structural topography. The illustration of such alterations would provide complementary insights 83 into the structural and molecular genetic underpinnings of dysfunctional hierarchy in WD.

84 Functional connectome patterns are facilitated by decomposing the functional connectivity data into different gradients to capture the topography of the connectome<sup>17</sup>. Such a principal functional gradient is presented in the 85 macroscale organization of functional brain networks, reflecting the hierarchical macroscale axe<sup>13</sup>. This study 86 87 aimed to investigate the structural and genetic underpinnings of functional hierarchical perturbation in WD. For this 88 purpose, we mapped the functional gradient using functional MRI and determined the perturbation in the 89 hierarchical macroscale axe for WD. Then, the gray volume was mapped based on 3D high-resolution MRI to 90 apply to a function-structure coupling analysis, revealing whether function-structure is decoupled in WD. 91 Meanwhile, we calculated the spatial correlation of connectome gradient perturbation with whole-brain gene 92 expression data from the Allen Human Brain Atlas<sup>18</sup> (AHBA) and further examined whether structural lesions and 93 gradient perturbation shared similar transcriptional specializations. Gene enrichment analysis was finally used to 94 probe transcriptomic associations for known pathogenic WD variants, as well as other neurological and psychiatric 95 disorders.

### 96 MATERIALS AND METHODS

#### 97 **Participants**

98 We studied a larger cohort of 105 WD patients (65 males, mean  $\pm$  SD age = 27.29  $\pm$  4.02 years) and 93 healthy 99 controls (60 males, mean  $\pm$  SD age = 24.48  $\pm$  2.26 years) collected from the First Affiliated Hospital of Anhui 100 University of Chinese Medicine. All patients met the diagnostic criteria, with a ceruloplasmin concentration < 0.1101 g/L, a 24-h urinary copper excretion >100 µg, and the presence of a K-F ring on slit-lamp examination. Unified 102 Wilson's Disease Rating Scale neurological examination (UWDRS-N) subscores were recorded as a measure of neurological disorder severity<sup>19</sup>. Exclusion criterium for WD patients was diagnosed with other diseases. Normal 103 104 individuals with a history of mental health problems or other serious diseases were excluded from this study. Ethics 105 committee of the First Affiliated Hospital of Anhui University of Chinese Medicine gave ethical approval for this 106 work, and written informed consent was obtained from all participants. Demographic and clinical information are 107 described in Table 1.

# 108 Data acquisition and preprocessing

Data were obtained at the First Affiliated Hospital of AUCM using a GE MR750 scanner. Resting-state functional MRI (R-fMRI) was acquired using a gradient-echo single-shot echo-planar imaging sequence, with the following parameter settings: repetition time (TR), 2000 ms; echo time, 30 ms; flip angle,  $90^{\circ}$ ; matrix size,  $64 \times 64$ ; field of view, 220 mm × 220 mm; resolution of the axial slice,  $3.4375 \times 3.4375$  mm<sup>2</sup>; slice thickness, 3 mm. A total of 185 volumes were acquired from each individual with 36 slices per volume. T1-weighted images were collected using a

114 T1-3D BRAVO sequence: TR, 8.16 ms; echo time, 3.18 ms; flip angle,  $12^{\circ}$ ; matrix size,  $256 \times 256$ ; field of view,

115 256 mm  $\times$  256 mm; voxel size, 1 mm<sup>3</sup>; slice thickness, 1 mm. R-fMRI data were preprocessed using a standard

pipeline, including slice timing, head motion correction, normalization, and bandpass, described in Supplementary

117 Materials.

### 118 Gray matter volume estimation

119 Gray matter (GM) volume measurements were performed using a voxel-based morphometric (VBM) approach<sup>20</sup> 120 that is embedded in the FSL-VBM toolbox. Briefly, the gray matter was first segmented from the T1-weighted 121 images, followed by normalized to MNI152 standard space. The normalized images were further applied to create a 122 study-specific GM template. All native GM images were subsequently registered to the template and modulated for 123 contraction. The modulated GM images were finally smoothed using an isotropic Gaussian kernel with a sigma of 3 124 mm. GM volume differences between WD and HCs were evaluated using permutation-based non-parametric 125 testing with random permutations. The statistical significance was set as P < 0.001, using a threshold-free cluster enhancement (TFCE) approach with family wise-error (FWE) correction for multiple comparisons<sup>21</sup>. 126

### 127 Preprocessing gene expression data

The microarray gene expression data from six donors (mean age: 42.5 years, 5 males and 1 female) were 128 downloaded from the Allen Human Brain Atlas (AHBA, http://human.brain-map.org/)<sup>22</sup>. The six post-mortem 129 130 brains were segmented into 3702 spatially distinct tissue samples, with each tissue sample normalized to Montreal 131 Neurological Institute (MNI) coordinate space, and indexed with expression levels for more than 20,000 genes from at least two probes<sup>22</sup>. We respectively conducted gene expression analysis within the cortical and subcortical 132 regions due to the large transcriptional differences between the two main regions<sup>23</sup>. The standard preprocessed 133 134 pipeline of the gene expression microarray data was performed in the current study, including mapping the tissue samples onto a cortical parcellation with 360 parcels<sup>24</sup> and a subcortical parcellation with 54 parcels<sup>25</sup>, probe 135 reannotation and selection, and normalization across donors<sup>18</sup>. 136

#### 137 **Functional connectome gradient analysis**

We constructed individual functional connectomes at the voxel level. To reduce the computational complexity, we resample the preprocessed R-fMRI data to a 4-mm isotropic resolution. For each individual, a functional connectivity (FC) matrix was first constructed by performing the Pearson correlation analysis between each pair of gray matter nodes (20208 voxels). Then, the FC matrix was further applied to the diffusion map embedding method to calculate the connectome gradient<sup>17, 26</sup>. Specifically, the FC matrix was thresholded to retain the top 10%

143 connections of each node, and the cosine similarity between each pair of nodes was computed. Further, the 144 similarity matrix was scaled into a normalized angle matrix to avoid the negative values<sup>27, 28</sup>. The diffusion map 145 embedding approach was finally applied to identify gradient components that explain most functional connectome 146 variances. Following the previous recommendation, we set the manifold learning parameter  $\alpha = 0.5$  in the diffusion 147 process<sup>29</sup>. Given that the principal gradient to an extreme represents the macroscale axe, we primarily focused on perturbation in the principal gradients of WD<sup>13</sup>. The case-control differences between WD and HCs in the 148 149 connectome gradient were evaluated by a two-sample t-test with age, sex, and education as covariates. The false 150 discovery rate (FDR) was used to achieve multiple comparison corrections at the voxel level. The statistically 151 significant threshold was set to q < 0.05. In addition, the whole-brain voxels were assigned to eight systems 152 according to a cortical atlas with 7 parcels and a Harvard-Oxford probabilistic subcortical atlas. The system-based 153 differences in connectome gradient between WD and HC were further examined using a paired two-sample t-test. 154 The findings were further corrected by multiple comparisons using FDR at 0.05.

#### 155 Association analysis between meta-analytic cognitive terms and gradients changes in WD

The Neuosynth (<u>https://neurosynth.org</u>/)<sup>30</sup> was used to evaluate the relationship between the meta-analytic cognitive terms and functional gradients alternations in WD. The thresholded Z-map derived from the between-group comparisons of the gradient was first divided into WD-positive (WD > HCs) and WD-negative (WD < HCs) maps. The 'decoder' function in Neurosynth was used to identify the spatial correlations between each map and the meta-analytic map of each term in the database<sup>31</sup>. Finally, the top 30 cognitive terms were selected.

#### 162 Correlation analysis between clinical characters and gradients in WD

We examined the relationships between gradients in perturbed regions and clinical characters, such as UWDRS-N, age, ceruloplasmin concentration, and 24-h urinary copper excretion, using partial correlations with age and sex controlled.

#### 166 Association analysis between the GM volume and gradients

To investigate whether structure-function is decoupled in WD, the spatial association between averaged GM volume and averaged functional connectome gradients was estimated using spatial correlation analysis. The spatial correlation analyses were performed based on the whole brain and eight systems. For all spatial correlation analyses, findings were corrected using permutation tests (N = 10,000) at P = 0.05. The results were further corrected for multiple comparisons using FDR at 0.05. The spatial correlation was also calculated at the subject level. Then, the

differences in spatial correlation between WD and HCs across subjects were accessed using a two-sample t-test, and the results were corrected by FDR at 0.05. Finally, using a non-parametric bootstrapping approach (10,000 times), we performed a meditation analysis in which altered gradient was taken as an independent variable, GM volume in altered gradient regions was taken as the mediator, and UWDRS-N was taken as the dependent variable.

#### 176 Association analysis between gene expression and WD's gradients changes

177 The spatial correlations between-group differences of principal gradient and gene expression were respectively 178 examined in cortical and subcortical regions. Given the high dimensionality of AHBA data, we used partial least squares (PLS) regression<sup>32</sup>, a multivariate linear model, to reveal a group of weighted genes (or PLS components) 179 180 that best explained the differences of the gradient. Briefly, we first aligned the gene expression data (10028 genes) and between-group difference Z-map of the principal gradient to a cortical  $atlas^{24}$  and subcortical  $atlas^{25}$ . In PLS 181 182 analysis, the gene expression data was used to identify the linear combinations of genes that best predicted response variables<sup>33</sup> (Z-map between-group difference of the principal gradient). The statistical significance of the first two 183 184 PLS components was tested based on 10,000 permutations of the response variables. A bootstrapping approach was finally used to correct the estimation error of the weight of each gene on each PLS component<sup>33</sup>. 185

#### 186 Enrichment analysis

We first ranked the genes according to their bootstrap weights (absolute value). Then, the top 10 percentile of 10028 genes were applied to a web-based gene set analysis toolkit<sup>34</sup> (<u>https://webgestalt.org</u>) to uncover biological processes enriched in the list of genes. The enrichment ratio is calculated as the number of PLS-derived genes overlapping with each biological process divided by the number of genes expected to overlap by random permutations. Significant enrichment was determined with Bonferroni FDR-corrected q < 0.05.

#### 192 Specificity analysis

The specificity analysis was to assess whether known genes (ATP7B) causing WD was enriched in the PLS components. We also performed specificity analysis to uncover the enrichment of other neurological and psychiatric risk genes in the PLS components. The disorder-related risk genes, provided by the AHBA (https://help.brain-map.org/display/humanbrain/Documentation), are listed in **Supplementary Table 1**.

We calculated the enrichment ratio (ER) for each PLS component. The ER is defined as the difference between the mean bootstrap weight of the candidate gene and the mean bootstrap weight of the same number of randomly permuted genes, which was further divided by the standard deviation weight of the permuted genes<sup>35</sup>. Significance was determined by the percentile of the bootstrap weight of the candidate genes relative to the bootstrap weights of

201 randomly selected genes from 10,000 permutations. Positive/negative ER of a given condition indicates that the 202 risk genes are expressed to a higher/lower degree relative to the baseline expression level.

#### 203 Association analysis between structural changes and PLS components

To investigate whether structural changes and disturbances in connectome gradient shared a similar transcriptional specializations, we calculated the spatial correlations between structural changes and each PLS component in WD. Structural changes were defined as the absolute value of between-group difference of the GM volume in high (PLS-score > 0.06) or low (PLS-score < -0.06) gene expression regions. The spatial correlations were corrected for spatial autocorrelations by using a permutation test (N = 10,000).

#### 209 **RESULTS**

#### 210 Perturbation of primary-to-transmodal gradient in WD

211 The principal gradient explained  $12.2 \pm 1.8\%$  of the total variance in the connectome across all individuals (WD: 212  $11.8 \pm 1.7\%$ , HC:  $12.9 \pm 1.8\%$ , Supplementary Fig. 1), which was organized along graded macroscale axe from 213 the primary visual/sensorimotor (VIS/SMN) areas to DMN (Fig. 1a), being consistent with the previous observation of connectome gradients from primary to the transmodal regions in healthy brain<sup>17</sup>. The spatial patterns 214 of principal gradient maps were highly similar between the WD and HCs (Spearman's R = 0.9734, P < 0.0001, 215 216 spatial autocorrelation corrected by permutation tests, Supplementary Fig. 2). The global histogram confirmed that 217 the extreme values were suppressed in WD relative to HCs, while those in the mid-range increased (Fig 1b). For 218 each system, we further computed the gradient score differences between group-averaged maps of WD and HCs by 219 using paired t-test across voxel. The WD had a higher gradient score in VIS, SMN, VAN, FPN, and SUB but lower 220 in LIB and DMN (FDR-corrected q < 0.05, Fig. 1c and Supplementary Table 2). The results of the secondary 221 gradient are provided in Supplementary Figs. 3 and Supplementary Tables 4.

#### 222 Changes in connectome gradient in WD

The WD showed lower gradient scores mostly in the DMN [medial temporal pole (mTP) and medial prefrontal cortex (mPFC), 70.3%] and LIB (19.4%) but higher scores mainly in the VIS [primary visual cortex (V1), 22.8%], SMN[supplementary motor areas (SMA), 19.9%], VAN (insular, 23.3%) and SUB (striatum, thalamus, 20.6%) than the HCs (absolute d = 0.08-0.19, FDR-corrected q < 0.05, Fig. 2a, Supplementary Table 3). For secondary connectome gradients, only one region showed a significantly higher gradient score in WD when compared with

HCs (Supplementary Figs. 4 and Supplementary Tables 5.).

#### 229 Association between gradient changes and cognitive functions in WD

- 230 Higher principal gradient scores in WD were mainly involved in motor-related processes, such as movement, motor
- 231 imagery, and somatosensory (Fig2. B and Supplementary Table 6). Lower principal gradient scores in WD were
- 232 correlated with higher-order cognitive processes, including mental states, mentalizing, theory mind, and social
- 233 (Fig2. B and Supplementary Table 6).

#### 234 Correlations between the principal gradients and clinical characters

235 The regions with significantly higher gradient scores in WD were positively correlated with UWDRS-N (R = 0.2575, P = 0.0105) and age (R = 0.4845,  $P = 4.294 \times 10^{-7}$ ). The regions with significantly lower gradient scores in 236 237 WD were negatively correlated with age (R = -0.3462, P = 0.00048). No significant correlations were observed 238 between gradient scores with ceruloplasmin concentration, 24-h urinary copper excretion, and disease duration.

#### 239 Associations between GM volume and primary-to-transmodal gradient

- 240 Evaluating group differences in GM volume between WD and HCs, we found GM volume was significantly 241 reduced in SMN, VIS, DMN, and SUB in WD (Supplementary Fig. 6 and Supplementary Table 7). Conversely,
- 242 significant GM volume was increased in VAN, DAN, LIB, and FPN in WD (Supplementary Fig. 6 and

#### 243 Supplementary Table 7).

244 High spatial correlations between principal gradient and GM volume were observed in VIS, SMN, VAN, SUB, and 245 LIB (Fig. 3b) in both WD and HCs, but not in the other systems and the whole brain (Fig. 3a). In the subject level, 246 the spatial correlation was significantly different in the extentive networks, especially in VIS and SUB (Fig. 3c), 247 indicating function-structure decoupling in these regions. The spatial correlation between the secondary gradient 248 and GM volume is revealed in Supplementary Fig 6.

249 We also found that the GM volume in regions with higher (meditation effect:  $\beta = 0.09, P = 0.0018$ ) and lower 250 (meditation effect:  $\beta = -0.09, P = 0.0428$ ) gradient scores in WD partially mediated the relationship between 251

# gradient and UWDRS-N (Fig. 3d).

#### 252 Associations between gene expression and WD-related gradient changes

253 For cortex, two PLS components explained 23% (PLS-1, P < 0.001) and 21% (PLS-2, P < 0.001) of the covariance 254 between the gradient changes of WD and gene expression (Supplementary Fig. 7). PSL-1 represented a gene 255 expression profile with high expression mainly in SMN and VIS but low expression in LIB and DMN (Fig. 4a). 256 PLS-2 characterized by high expression in VAN but low expression in FPN (Fig. 4a). The gene enrichment

257 analysis shown that PLS-1 involved in regulation at metal ion transport, ion transmembrane transport, and 258 transporter activity (FDR < 0.05, Fig. 4b), determining the metal ion homeostasis. By contrast, PLS-2 mainly 259 reflected the muscle system process, circulatory system process, and neuron projection development, as well as 260 regulation at metal ion transport and ion transmembrane transport (FDR < 0.05, Fig. 4b). Specificity analysis 261 revealed that PLS-1 and PLS-2 were enriched for the risk genes (Fig. 4c), such as Schizophrenia (PLS-1: FDR = 262 0.0095, ER = -3.05; PLS-2: FDR = 0.0023; ER = -3.37), Depression (PLS-1: FDR = 0.0206, ER = -2.46; PLS-2: 263 FDR = 0.044, ER = 1.90), and Parkinson's disease (PLS-2: FDR = 0.044, ER = 1.94). The GM volume changes had 264 a significant positive correlation with PLS-1 scores higher than 0.06, indicating that structural impairments and 265 gradient perturbation in cortical regions may be mediated by the similar transcriptional specializations (Fig. 4d).

266 For subcortical regions, two PLS components explained 28% (PLS-1, P = 0.0264) and 22% (PLS-2, P = 0.0437) of 267 the covariance between the gradient changes of WD and gene expression (Supplementary Fig. 7). PSL-1 268 represented a gene expression profile with high expression mainly in the pallidum and thalamus but low expression 269 in hippocampus and striatum (Fig. 5a). PSL-2 revealed a high gene expression in the pallidum, striatum, and 270 amygdala but low expression mainly in the thalamus (Fig. 5a). Specificity analysis showed that PLS-1 (Fig. 271 **5b**)was enriched for the risk gene of WD (PLS-1: P = 0.022, ER = -1.946), with PLS-1 and PLS-2 additionally 272 enriched for the gene causing Schizophrenia (PLS-1: FDR = 0.0155, ER = -2.73) and Alzheimer's disease (PLS-2: 273 FDR = 0.0425, ER = -2.16). The GM volume changes had a significant negative correlation with PLS-1 scores 274 higher than 0.06, indicating that structural impairments and gradient perturbation in subcortical regions also be 275 mediated by the similar transcriptional specializations (Fig. 5c).

# 276 **DISCUSSION**

Macroscale hierarchy has been widely regarded as a key principle of brain organization<sup>13</sup>. It has been involved in 277 multiple systems that span from primary to transmodal networks<sup>17</sup>. Hierarchical representations account for the 278 279 spatial arrangement of local processing streams throughout the cerebral cortex, ensuring sensory signals progressively to integrating as abstract representations<sup>17</sup>. Since WD has been clinically characterized as a disorder 280 with multiple neurological and psychiatric phenotypes<sup>36</sup>, it may result in errors in information flow from 281 sensorimotor to cognitive processing. Accordingly, here we assessed the pattern of functional hierarchy in larger 282 283 samples of WD and HCs, based on an advanced connectome gradient approach. Both WD and HCs groups revealed 284 that principal functional gradient mapping captured the macroscale axis of connectivity variations with primary network and transmodal DMN anchored at two opposite ends and the remaining networks emerging in-between<sup>17</sup>. 285 286 Naturally, this gradient of WD was globally suppressed at both ends compared to HCs. Consistent with these

results, VBM analysis also illustrated that in WD, GM volume significantly decreased in multiple systems, including SMN, VIS, and transmodal areas. Further spatial correlations between gradient and GM volume revealed function-structure decoupled in VIS, VAN, and SUB, suggesting hierarchical imbalances related to structural alterations. In sum, our multimodal analysis provides converging evidence for that structural vulnerability might shape the aberrant connectome hierarchy.

292 At the regional level, patients with WD exhibited an extended principal gradient, showing an increase in gradient 293 score in primary systems such as the SMA and V1, and a decrease in transmodal regions including the mTP and 294 mPFC. Generally, an important role of SMA and V1 in motor control and visual processing has been identified in the motor and visual system, particularly for postural stabilization of the body and spatial pattern recognition<sup>37-40</sup>. 295 296 Consistent with the clinical impairment in these regions, WD-related abnormalities of intrinsic brain activity in the SMN and VN have been highlighted in RS-fMRI<sup>8</sup> and tomography-electrophysiology studies<sup>41</sup>. Likewise, cortical 297 298 thickness damage in these regions was also reported to be correlated with the neurological symptoms in  $WD^{42}$ . 299 DMN areas, such as mPFC and mTP, are thought to be involved in several different functions, such as 300 self-referential, introspective cognition as well as mentalizing<sup>43, 44</sup>. Of note, patients with WD have neuropsychological and attention network deficits<sup>9, 45</sup>. Moreover, containing these and other nodes in DMN, 301 302 multiple previous RS-fMRI studies have already reported a series of results indicative of functional connectivity alterations in WD<sup>7</sup>. These results were also confirmed by our meta-analysis, revealing WD-related increased 303 304 gradient scores in the areas involving low-level sensory and motor-related processes but brain regions with 305 decreased gradient scores mainly involving higher-order cognitive function. Interestingly, we also observed an 306 increased gradient score in unimodal areas, such as the insular, which is located between the primary systems and 307  $DMN^{17}$ . Collectively, these findings suggest that the imbalance in the functional hierarchy might arise from the 308 disorder of local processing streams transformed system-by-system in WD cerebral cortex. More notably, our 309 results also showed increasing gradient scores in SUB, such as the putamen and thalamus. The SUB is the most damaged brain structure in WD. Due to the impaired regions leading to disrupted networks<sup>16</sup>, the interaction among 310 311 SUB and between subcortio-cortical networks could impact the topology of the subcortical macroscale connectome 312 in WD. Again, recent studies have reported that connectivity among SUB was highly associated with deficits in 313 neurological symptoms<sup>46</sup> while subcortico-cortex was related to neuropsychological disorder in WD<sup>9</sup>. In this 314 context, the relationship between gradient and UWDRS-N was mediated by GM volume alteration, furtherly 315 attesting that structural vulnerability impacts macroscale hierarchy and ultimately leads to deficits in WD 316 phenotype. Taking all the above into consideration, our findings indicate that complex clinical symptoms of WD

might arise from perturbation in functional hierarchy across individuals that is not merely due to aberrant spatial
 patterns, but rather linked to system-level deficits.

319 In addition to offering a novel perspective on the structural underpinning of perturbation in the functional hierarchy, 320 we incorporated a PLS regression to establish a link between WD-related gradient changes and gene expression. 321 Within the cortex, PLS-1 reflected regulation of gene expression at ion transmembrane transport, metal ion 322 transport, and transporter activity. PLS-2 also mediated the regulation of ion transmembrane transport, but more 323 reflected regulation of neuron projection development and axon development, as well as a muscle system process. 324 In biology, the transporter is a transmembrane protein that moves ions across biological membranes to accomplish different biological functions, such as cellular communication and maintaining homeostasis<sup>47</sup>. Ion transport is a 325 biological process that transports ions against the concentration gradient-from high concentration to low 326 327 concentration<sup>48</sup>. Neuron projection is any process extending from a neural cell, such as axons and dendrites, its development is the progression from neural formation to the mature structure<sup>49</sup> and also promotes neuron 328 differentiation<sup>50</sup>. The muscle system, in vertebrates, is controlled through the nervous system, and its impaired 329 330 leads to different movement disorders<sup>51</sup>. Indeed, WD is a disorder of copper transport within the cell resulting in copper accumulation in the brain<sup>52</sup>, which further triggers neuron degeneration. Therefore, PLS-1 likely represents 331 332 biological mechanisms underlying ion homeostasis inside and outside nerve cells. On the other hand, PLS-2 was 333 more associated with neural organization and cell growth as well as controlling muscle signaling. The specificity 334 analysis exhibited that PLS-1 and PLS-2 were both associated with risk genes for schizophrenia and depression and 335 that PLS-2 was additionally associated with genes causing Parkinson's disease. Although no association between 336 WD pathogenic gene (ATP7B) and PLS components was observed within the cortex, our results explained why 337 WD patients present multiple complex neurological and psychiatric symptoms at the biological level.

More importantly, within subcortical regions, we demonstrated that PLS-1 was associated with WD pathogenic 338 339 gene, which indicates that the ATP7B gene has lower expression in subcortical regions. The present work is the 340 first to provide evidence for the role of the WD pathogenic gene impacting subcortical function, which is also 341 attested by an animal model study, revealing that dysfunctional ATP7B protein is related to the local copper 342 accumulation of SUB and the manifestations in WD<sup>4</sup>. The relevance of these PLS components with other risk genes 343 was also calculated by specificity analysis, showing that PLS-1 was associated with risk genes of schizophrenia 344 while PLS-2 was related to genes causing Alzheimer's disease. Consistent with our results, recent studies have reported that the risk genes of schizophrenia<sup>53</sup> and Alzheimer's disease<sup>54</sup> are significantly associated with 345 346 subcortical dysfunction. Interestingly, we found that the spatial pattern of GM volume alteration is similar to that of 347 PLS-1 with higher expression in subcortical regions, and this association was also exhibited in the cerebral cortex.

These findings indicate that the GM volume impairments and gradient perturbation are mediated by similar transcriptional specializations.

Findings have to be interpreted in the context of potential limitations. Gene set from AHBA were sampled from donors without a diagnosis of WD. Moreover, the associations between connectome gradient and gene expression were susceptible to intersubject variability. Likewise, the group-averaged gradient was associated with gene expression data, which could not provide a powerful genetic biomarker for individual prediction. In the future, a larger sample of whole-brain gene expression data from WD patients is required to further represent and validate the relationship between connectome gradient and transcriptome. Future studies should also add within-subject design to perform individual-level prediction for WD.

357 This study revealed the gradient perturbations related to cognitive terms and clinical phenotypes in WD. Then, we 358 mapped associations of these gradient differences with specific GM volume alterations and transcriptional 359 expressions. Further, we uncovered the biological underpinnings of these gradient-derived gene sets by enrichment 360 analysis. The biological underpinnings was determined by underlying factors including 1) function-structure 361 decoupled characterized by spatial correlation alterations in WD; 2) high associations between gene expression and 362 gradient-differences and identified biological process within the cerebral cortex; 3) implications in psychiatric and 363 neurological diseases and for the first time characterizing the role of ATP7B impacting subcortical function; 4) GM 364 volume impairments and perturbation of connectome gradients are mediated by the similar transcriptional 365 specializations. In sum, these findings mapping the structural and transcriptomic underpinnings of gradient 366 perturbation in WD provide a deep insight into WD neurobiological underpinnings underlying the emergence of 367 complex neurological and psychiatric phenotypes.

#### **Figure legends** 496

498 Fig. 1 Connectome gradient mapping in WD patients and HCs. (a) The principal gradient was organized along 499

a gradual axis from the primary visual/sensorimotor networks to the default mode network. (b) Global histogram of 500 the gradient. the extreme gradient values were suppressed in the WD patients relative to those of HCs. (c) 501 System-based histogram of the gradient. Arrows indicate the direction of the significant differences between the 502 WD patients and HCs. VIS, visual network; SMN, sensorimotor network; DAN, dorsal attention network; VAN, 503 ventral attention network; SUB, subcortical regions; LIB, limbic network; FPN, frontoparietal network; DMN, 504 default mode network.

505

507 Fig. 2 Gradient differences and their associations with cognitive function. (a) Voxel-wise statistical 508 comparisons between the WD patients and HCs and distribution of the regional case-control difference in different 509 systems. Higher/lower values in WD are presented as warm/cold colors. The statistical significance level was set as 510 FDR voxel level-corrected q < 0.05. (b) Word clouds of cognitive functions associated with brain regions that 511 exhibited higher (red) or lower (blue) gradient scores in WD. The font size of a given cognitive term corresponds to 512 the correlation coefficient of the between-group Z-map of the principal gradient with the meta-analytic map of that 513 term generated by Neurosynth. (c) Association between regional gradient score and individual UWDRS-N score 514 and age. VIS, visual network; SMN, sensorimotor network; DAN, dorsal attention network; VAN, ventral attention 515 network; SUB, subcortical regions; LIB, limbic network; FPN, frontoparietal network; DMN, default mode 516 network. 517

519 Fig. 3 Spatial associations between connectome gradient and GM volume in WD and HC. (a) Global 520 association between gradient and GM volume in WD patients and HCs. (b) System-based associations between 521 gradient and GM volume in WD patients and HCs. The P values were corrected by FDR. (c) Global and 522 system-based associations between gradient and GM volume at the individual level and their group differences 523 were measured by a two-sample t-test and corrected by FDR. (d) GM volume significantly mediated associations of 524 regional gradients with UWDRS-N score. \*, P < 0.05; \*\*, P < 0.01; \*\*\*, P < 0.001; GV, GM volume; VIS, visual 525 network; SMN, sensorimotor network; DAN, dorsal attention network; VAN, ventral attention network; SUB, 526 subcortical regions; LIB, limbic network; FPN, frontoparietal network; DMN, default mode network. 527

529 Fig. 4 Association between WD-related gradient alterations and gene expression within the cortex. (a) Maps 530 of gene expression within the cortex. The color scale indicates the score for PLS-1 and PLS-2, namely the weighted 531 average expression level of 10028. (b) Gene enrichment analysis. Genes associated with PLS-1 were enriched for 532 ion transport, ion transmembrane transport, and transporter activity, determining the metal ion homeostasis, and 533 PLS-2 for muscle system process and neuron projection development, as well as ion transport and ion 534 transmembrane transport. In the volcano plots, the x-axis indicates log2 of enrichment ratio and the y-axis indicates 535 -log10 of FDR. Color codes indicate the number of genes related to the biological processes that overlap with the 536 input list of top 10 percentile genes; the dotted line indicates FDR = 0.05. (c) Specificity analysis. Concerning risk 537 genes, PLS-1 (red) and PLS-2 (blue) were enriched for genes associated with Schizophrenia, and depression, while 538 PLS-2 was additionally enriched for those associated with Parkinson's disease. The dotted line indicates FDR = 539 0.05. (d) Associations between GM volume changes and scores higher than 0.06 and lower than -0.06 in both 540 PLS-1 and PLS-2. The PLS-1 scores higher than 0.06 was significantly correlated with GM volume changes. GV, 541 GM volume. 542

544 Fig. 5 Association between WD-related gradient alterations and gene expression within the subcortical 545 regions. (a) Maps of gene expression within the subcortical regions. The color scale indicates the score for PLS-1 546 and PLS-2, namely the weighted average expression level of 10028. (b) Specificity analysis. PLS-1 was 547 significantly enriched for WD pathogenic genes (ATP7B); the histogram shows bootstrap weights of 10000 548 permutations; the dotted line indicates the bootstrap weight of the candidate genes. Concerning risk genes, PLS-1 549 (red) was enriched for genes associated with Schizophrenia, while PLS-2 (blue) was enriched for those associated 550 with Alzheimer's disease. The dotted line indicates FDR = 0.05. GV, GM volume. (c) Associations between GM 551 volume changes and scores higher than 0.06 and lower than -0.06 in both PLS-1 and PLS-2. The PLS-1 scores 552 higher than 0.06 was significantly correlated with GM volume changes. 553
