

36 analysis of predictions. We note that the WCIS is intended specifically for retro-
37 spective forecast evaluation and should not be used as a minimized penalty in a
38 competitive context as it lacks statistical propriety.

40 1 Background

41 1.1 Introduction

42 Given the devastating impact of COVID-19, and in the face of future pandemic
43 threats, it is incumbent upon the epidemic forecasting community to deploy predic-
44 tion tools that provide meaningful and actionable utility to those who need them. An
45 important piece of this effort is candid retrospective evaluation of the utility of fore-
46 casting during the COVID-19 pandemic. In this light, we present a new probabilistic
47 forecast evaluation method, the Weighted Contextual Interval Score (WCIS). It is a
48 relative metric that encodes a simple question. How useful could a forecast have been
49 where and when it was made? Unlike other scores, the WCIS is designed specifically
50 as a retrospective way to judge whether or not forecasting could have been useful.
51 It is not intended for real-time model ranking and ensemble construction. Instead,
52 the WCIS is meant for broader pandemic preparedness efforts, for taking an honest
53 look at how helpful forecasts could have been and thus potentially could be in the
54 future. Despite the high spatial and temporal variability of pandemic scenarios, the
55 WCIS evaluates forecasts in a comparable and communicable way by scoring them as
56 a function of their potential utility.

57 The advent of the COVID-19 pandemic precipitated a massive public health
58 response, including a significant modeling effort [1, 2]. In the United States, this
59 quickly resulted in the formation of the COVID-19 Forecast Hub, a repository for
60 short-term pandemic predictions [3]. Similar to prior collective forecasting efforts
61 focused on seasonal influenza, dengue, and Ebola, the Forecast Hub solicited predic-
62 tions from a large and diverse group of modelers, synthesizing their submissions into
63 ensemble forecasts of COVID-19 cases, deaths, and hospitalizations. These outputs
64 were provided to the United States Centers for Disease Control and Prevention (CDC)
65 for policy making and dissemination to the public [4–9]. In addition to modeling
66 efforts like the Hub at the regional level, COVID prompted a considerable amount of
67 more granular forecasting, such as predictions for individual medical facilities [10, 11].
68 Despite this abundance of pandemic modeling, translating short-term epidemiological
69 forecasts into applicable, actionable, and insightful decision-making remains a signif-
70 icant challenge [7, 12–17]. Understanding whether or not a forecast could have been
71 useful requires understanding the conditions in which the forecast was made. It also
72 requires knowledge about the type of decision the forecast would be used to inform.
73 The WCIS was designed around these two requirements. It uses a utility-based nor-
74 malization scheme to enable intuitive and meaningful comparison of forecast quality
75 despite potentially dissimilar prediction contexts.

76 1.2 Motivation

77 Probabilistic predictions are preferred in many disciplines, including the epidemic
78 forecasting community. Unlike single outcome “point” predictions, probabilistic fore-
79 casts convey the uncertainty of the underlying model. This is particularly important
80 given the difficulty of correctly interpreting a quickly-evolving pandemic [7, 18]. The
81 extant Weighted Interval Score (WIS), an error metric for quantile forecasts that
82 approximates the Continuous Ranked Probability Score, is the primary method used
83 to evaluate Forecast Hub submissions [19, 20]. As summarized by Bracher et al., “the
84 (Weighted Interval) score can be interpreted heuristically as a measure of distance
85 between the predictive distribution and the true observation, where the units are those
86 of the absolute error” [19]. The WIS is an effective metric for real-time prediction
87 scoring, model comparison, and ensemble forecast creation [20]. However, the WIS
88 is limited in its ability to be used for intuitive forecast utility analysis, in particular
89 because the score is scaled on the order of the prediction data [19]. Retrospective pan-
90 demic evaluation involves comparing scenarios of highly different scales. One example
91 of such a comparison would be between regions with large baseline differences in data
92 magnitudes, such as highly vs sparsely populated regions (as in the Forecast Hub).
93 Another situation where scale-related contextualization is essential to consider is the
94 comparison of periods of high vs low epidemic activity (surge vs non-surge). In fact,
95 both of these spatial and temporal scaling challenges are often necessary to consider
96 at the same time (see Additional file 1: Section 1.1 for motivating examples of these
97 issues drawn from state-level pandemic scenarios in the United States).

98 The WCIS is an adaptation of the WIS that is framed around the two following
99 ideas. First, any meaningful measurement of forecast quality must arise from the con-
100 text into which predictions are disseminated. In other words, a useful forecast improves
101 real-time knowledge and/or decision-making capabilities. The reverse also holds: a
102 forecast is not useful if it is incapable of (or if it provides information detrimental to)
103 gaining real-time information or improving decision-making. Second, for the purposes
104 of enabling the comparison of forecast performances in disparate scenarios without
105 post-processing, a helpful score should be a relative metric. Taken together, these two
106 concepts informed the central idea of the WCIS: that a consistently meaningful score
107 must have endogenous contextualization. In essence, the WCIS normalizes forecast
108 performance as a function of the ability of the forecast to be used in the specific envi-
109 ronment in which it was made. This way, despite potentially occurring in radically
110 different spatial and temporal scenarios, individual evaluations can be meaningfully
111 compared to others.

112 Before moving to its technical basis and formulation in the next sections, it is
113 necessary to address the intended purpose of the WCIS, and similarly, tasks for which
114 it should not be used. The WCIS is not a statistically proper score (see Additional
115 file 1: Section 1.3), which means it should not be used in competitive forecasting
116 contexts. In these situations, such as real-time evaluation of COVID-19 Forecast Hub
117 submissions, scores that are not statistically proper have the potential to be gamed
118 [21]. Again, the WCIS is not designed for and should not be used for such purposes.
119 It was not created to replace the WIS, which functions well for real-time forecast
120 scoring and ensemble generation. Instead, the WCIS is designed to reflect relative

121 forecast quality using a flexible and contextually specific parameterization of utility.
122 As is demonstrated in the test cases below, this results in a score that is not just
123 intuitively interpreted, but is easy to compare and convey visually. We believe that
124 these attributes are highly important in the context of pandemic preparedness efforts,
125 given the need to more strongly connect the modeling and policy-making spheres of
126 the public health community. Decision-makers need to be able to assess whether or
127 not forecasting has the capacity to positively contribute to pandemic response. We
128 believe that the WCIS enables an intuitive and flexible exploration of this question.

129 1.3 Review of the Weighted Interval Score

130 The Weighted Contextual Interval Score (WCIS) builds directly from the Weighted
131 Interval Score (WIS). Bracher et al. [19] provide an excellent explanation of the
132 mechanics of the score and its applications in epidemiology, and we endeavor to use
133 the same symbology whenever possible. For brevity, the entire WIS formulation is not
134 reviewed here, but the key elements (that are also important pieces the WCIS) are
135 necessarily summarized:

$$IS_{\alpha}(F, y) = (u - l) + \frac{2}{\alpha} (l - y) \mathbb{1}\{y < l\} + \frac{2}{\alpha} (y - u) \mathbb{1}\{y > u\} \quad (1)$$

$$WIS_{\alpha\{0:K\}}(F, y) = \frac{1}{K + \frac{1}{2}} \left(w_0 \cdot |y - m| + \sum_{k=1}^K \{w_k \cdot IS_{\alpha_k}(F, y)\} \right) \quad (2)$$

- 136 • We assume a submission of K interval forecasts drawn from a predicted distribution
137 F , a probabilistic representation of the target variable. Each of the K forecasts
138 represents a $(1 - \alpha_k)$ prediction interval (PI). These intervals are delineated by
139 their lower and upper bounds l and u , the $\frac{\alpha}{2}$ and $1 - \frac{\alpha}{2}$ quantiles of the predicted
140 distribution, respectively. For example, a 95% interval would be represented by an
141 α_k of 0.05, its lower and upper bounds defined by the 0.025 and 0.975 quantiles of
142 F .
- 143 • A predictive median m (point prediction) is submitted, and the true target value y
144 is known.
- 145 • For each interval $k \in \{1, 2, \dots, K\}$, an individual Interval Score (IS) is calcu-
146 lated, penalizing both the width/sharpness of the interval: $u - l$, and (if necessary)
147 the amount by which the interval missed the true value: $\frac{2}{\alpha} (l - y) \mathbb{1}\{y < l\} +$
148 $\frac{2}{\alpha} (y - u) \mathbb{1}\{y > u\}$ [21]. Note that the “miss” component is scaled by the inverse of
149 α , thus narrower prediction intervals are penalized less for missing than are higher
150 confidence submissions.
- 151 • The WIS is a weighted average of each of the K Interval Scores and the abso-
152 lute error of the predictive median, with the weights w_k used for the average
153 corresponding to $\frac{\alpha}{2}$ for each interval.

154 2 Methods

155 2.1 Contextualizing Point Forecasts

156 Although the WCIS (like the WIS) is an interval score, it is framed around a point
157 score that we call the Contextual Relative Error (CRE). The CRE maps the absolute
158 error of a point forecast x to its contextual utility. This is achieved by specifying
159 δ , the utility threshold parameter. (Note that δ is the only parameter in the WCIS
160 formulation that does not already appear in the WIS score).

$$CRE(x, y, \delta) = \min \left\{ \frac{|x - y|}{\delta}, 1 \right\} \quad (3)$$

161 δ is the magnitude of the absolute error above which a forecast loses its utility.
162 The CRE is so named because instead of mapping to the distance between a predicted
163 value and its target like absolute error, it maps to an interval from 0 to 1. A score of 0
164 indicates a forecast with maximum possible utility (with an absolute error of 0), and a
165 score of 1 indicates a useless forecast (with an absolute error of δ or more). See panel
166 (a) of Additional file 1: Fig. S1 for a graphical representation of the CRE. An impor-
167 tant feature to note is the “plateau” of the metric when the absolute error exceeds δ .
168 This might seem problematic, given that beyond the δ threshold the absolute error
169 is capable of increasing without any commensurate increase in the CRE. This is, in
170 fact, the desired behavior of the CRE and warrants a slight re-framing of perspective.
171 Selecting δ requires, when applying the CRE (and the WCIS, as it is a generalization
172 of the CRE from point to interval scores), identification of a practical limit for how
173 a forecast is used or interpreted in a particular context or for a particular purpose.
174 For example, in many scenarios we have a finite capacity to respond to an expected
175 outcome. If the “demand” imparted by an incorrect forecast exceeds that capacity,
176 we are unable to alter our response despite an apparent increase in need. Therefore,
177 an incorrect forecast with an absolute error of 2δ wastes exactly as many resources
178 as a incorrect forecast of magnitude δ , where δ precipitates the maximum allocation
179 in response to the forecast. A different way to interpret δ is as an “absorbable error
180 magnitude.” The test cases later in the paper frame δ this way, wherea decision maker
181 has limited capacity to recover from plans made according to forecasted outcomes. If
182 the forecast is wrong enough that it precipitates an action that cannot be recovered
183 from, such a forecast has met or exceeded the δ threshold.

184 Note that δ is both a normalizer and a limit. Thus a forecast with an absolute
185 error greater than δ is not at all useful, and a forecast with an absolute error less
186 than δ is evaluated as a ratio of δ . This gives the CRE (and the WCIS) the ability
187 to provide information about both forecast quality and how frequently forecasts are
188 useful, which, as demonstrated later, is helpful for intuitive analysis and performance
189 visualization.

190 2.2 Contextualizing Interval-Form Forecasts

191 We begin by introducing the Contextual Interval Score (CIS). The CIS is both a
192 probabilistic extension of the Contextual Relative Error, and a contextualized version

193 of the Interval Score. Like the CRE, it maps a forecast’s error to the δ -parameterized
194 utility space, and like the IS, it generates a score for a single interval forecast. (In fact,
195 the CIS can be equivalently formulated in two different ways, based on either the IS or
196 the CRE. For brevity, we use the IS-based formulation here but, particularly if more
197 intuition about the score is desired, we suggest referencing Section 1.2 in Additional
198 file 1 for the explanation of the CRE-based formulation.)

$$CIS_{\alpha}(F, y, \delta) = \min \left\{ \frac{\alpha}{2\delta} IS_{\alpha}(F, y), 1 \right\} \quad (4)$$

199 The WCIS is the simple average of the CIS across all α -intervals and the CRE of
200 the predictive median m :

$$WCIS_{\alpha\{0:K\}}(F, y, \delta) = \frac{1}{K+1} \left(CRE(m, y, \delta) + \sum_{k=1}^K CIS_{\alpha_k}(F, y, \delta) \right) \quad (5)$$

201 Note that we still retain the descriptor “Weighted” in the WCIS title even though
202 there are no weights directly included in its formulation, whereas each component
203 of the WIS is multiplied by $\frac{\alpha}{2}$. However, in our formulation, the same weights are
204 effectively applied directly to the individual constituent CIS scores. Instead of the
205 “miss” components of the score being multiplied by $\frac{2}{\alpha}$, the “width” term is scaled
206 by $\frac{\alpha}{2}$. Thus when the average is taken to create the WCIS the scaling effect is the
207 same as the WIS, but the weights are applied in this way because it preserves the
208 interpretability of the individual single-interval CIS components as described above.
209 Another notable difference is the WCIS uses $K+1$ for the denominator of the average
210 (unlike $K+\frac{1}{2}$ in the WIS) because like the single-interval components, the predictive
211 median component of the score has a maximum penalty of 1. This, and the bound on
212 each CIS term, means the WCIS also takes values only on the interval from 0 to 1.
213 Note the natural equivalence between the WCIS for interval forecasts and the CRE for
214 point forecasts, which mirrors that between the WIS and the absolute error. In both
215 cases, the interval scoring method preserves the behavior and intuitive interpretation
216 of the corresponding point forecast technique.

217 **3 Results**

218 The WCIS is expressly intended to be a flexible scoring method and as such there
219 are many possible and highly variable ways to apply it. We use this Results section
220 to present two demonstrative use cases. Both scenarios evaluate COVID-19 hospital-
221 ization forecasts, but each works at a different scale and uses a necessarily different δ
222 formulation. The first scenario applies the WCIS to results from a multi-facility-level
223 forecasting model. We use this first application primarily to develop the intuition for
224 the δ selection process. We show via a direct demonstration how δ can be chosen to
225 represent contextually specific utility as a function of time-varying data, and explore
226 how the choices made during this parameterization map onto the output of the WCIS.

227 Since this section focuses more on the WCIS formulation and less on interpreting the
228 real-world applicability of the predictions, we use forecasts from a model developed
229 in-house. Conversely, the second test case evaluates four weeks ahead predictions from
230 the COVID-19 Forecast Hub’s ensemble model, examining hospitalization forecasts
231 from May 2021 to May 2022 [3]. This period includes both the Delta and Omicron
232 variant waves and allows for a larger exploration of the utility and communicability of
233 the WCIS. Data for these analyses are sourced from the COVID-19 Reported Patient
234 Impact and Hospital Capacity by Facility dataset for the first section and from the
235 Forecast Hub’s repository for the second [22, 23].

236 **3.1 Facility-level Analysis (First Test Case)**

237 As introduced above, our first test case evaluates a facility-level hospitalization model.
238 More specifically, the model forecasts daily COVID-19 bed occupancy, for each indi-
239 vidual hospital in Maryland, from one to twenty-one days out, from July 2021 to July
240 2022. Because our δ selection reflects capacity management within the three-week
241 forecast window, we only use hospitals listed as “short-term” type (this excludes long-
242 term and pediatric facilities) and for relevance only include facilities that had at least
243 ten COVID-19 patients at some point during the time range specified. The partic-
244 ular time range used was chosen because contextualization is vital when comparing
245 and contrasting scenarios with highly different levels of pandemic activity, and July
246 2021 to July 2022 includes the Omicron wave in Maryland. This scenario and facility
247 selection yields 42 hospitals with an overall capacity range of 30 beds at the smallest
248 facility to 919 beds at the largest facility.

249 The model used is a Time Series Dense Encoder, using the prior ninety days for
250 each hospital at each time point to predict the following twenty-one days [24]. For a
251 complete model formulation see Additional file 1: Section 2.1 but in brief, this model
252 type was selected because it is a state-of-the-art general-purpose time series forecaster
253 that is efficient to train and flexible across different covariates, prediction horizons,
254 output types, and loss functions. We note that the purpose of this test case is to
255 explore and explain the formulation and application of the WCIS. Thus, we developed
256 this relatively basic model in order to apply the WCIS to a facility-level scenario, not
257 to refine a specific method for forecasting hospitalizations. The predictions from this
258 section are not necessarily indicative of those performed in real time. Because the data
259 used for training and scoring this model may contain retrospective corrections of errors
260 that were present in the real time data, it has the potential for higher performance
261 when compared to an equivalent in-situ forecaster.

262 The δ -parameterization used for this analysis is intended to characterize the capac-
263 ity of each facility to absorb an incorrect allocation of COVID-19 bed space based on a
264 flawed forecast. We assume that capacity allocations are made at forecast time, under
265 the in-situ assumption that forecasts perfectly reflect future outcomes. Thus, the δ
266 value represents an achievable capacity correction during the time interval separating
267 the making of the forecast and the realization of its true target value. For example,
268 the δ value for a seven-day-ahead forecast for each facility is the amount of COVID-
269 19 beds that each individual hospital can add or take away over a week. Specifically,

270 this δ is determined as follows. The daily capacity change for each hospital is calcu-
271 lated as the mean of all single day, non-zero capacity changes over the entire available
272 time series for each facility. δ for a particular forecast is then set as the product of
273 the forecast horizon and the facility-specific daily change capacity. This means that
274 the further out a forecast is, the larger (and thus more forgiving) the delta value is,
275 based on the idea that the more time a facility has to respond to a poor allocation of
276 resources, the greater the magnitude of the response can be. Please note that the partic-
277 ular formulation chosen here is not intended to provide an assessment of forecast
278 quality outside the utility scenario posited by the assumptions given above. How-
279 ever, it demonstrates an important capability of utility threshold selection: δ can be a
280 defined as a dynamic function of data that can change in time and space. Since con-
281 textually meaningful forecast utility varies significantly over these same dimensions,
282 a broadly applicable and interpretable score must be similarly adaptable.

283 Using Figures 1 and 2, we are able to interpret some important aspects of how
284 this selection of δ maps onto the scoring of our facility-level model. First, consider
285 the relationship between the breadth of the confidence intervals and the δ region in
286 Figure 1, which visualizes a single facility. The larger prediction intervals for the four-
287 teen day-ahead forecasts indicate less model certainty than those of the two day-ahead
288 predictions and, all else equal, would yield a worse score. However, δ is significantly
289 higher for the fourteen day-ahead scenario, given the assumption that facilities have
290 more time to adapt to inaccurate forecasts over longer horizons. This results in gen-
291 erally better performance for the fourteen-day model. However, there remain in the
292 fourteen-day scenario several forecasts that still receive a high penalty despite the
293 more forgiving δ parameterization. Note that these instances tend to occur when the
294 forecast median approaches or exceeds the utility threshold. Moving to Figure 2, we
295 can see that these trends are also visible in the aggregate performance across all 42
296 facilities. Comparing the WIS to the WCIS over these instances reveals a relatively
297 linear relationship in the more forgiving scenarios, i.e. non-wave with a larger delta.
298 During the wave, when absolute performance was broadly worse (as evidenced by the
299 WIS values), the δ -limit was reached significantly more often. We also draw attention
300 to the differences in marginal distributions that are visible in the scatter plot column
301 of Figure 2. The scaling and limiting action of the WCIS distributes performances sig-
302 nificantly more evenly than the WIS (see Additional file 1: Section 2.2 for plots with
303 these marginal distributions included).

304 In general, we are able to observe that given a contextually relevant δ choice, the
305 score is able to simultaneously convey an intuitive sense of both relative quality and
306 the overall frequency of useful forecasts, as shown in the histograms of Figure 2.

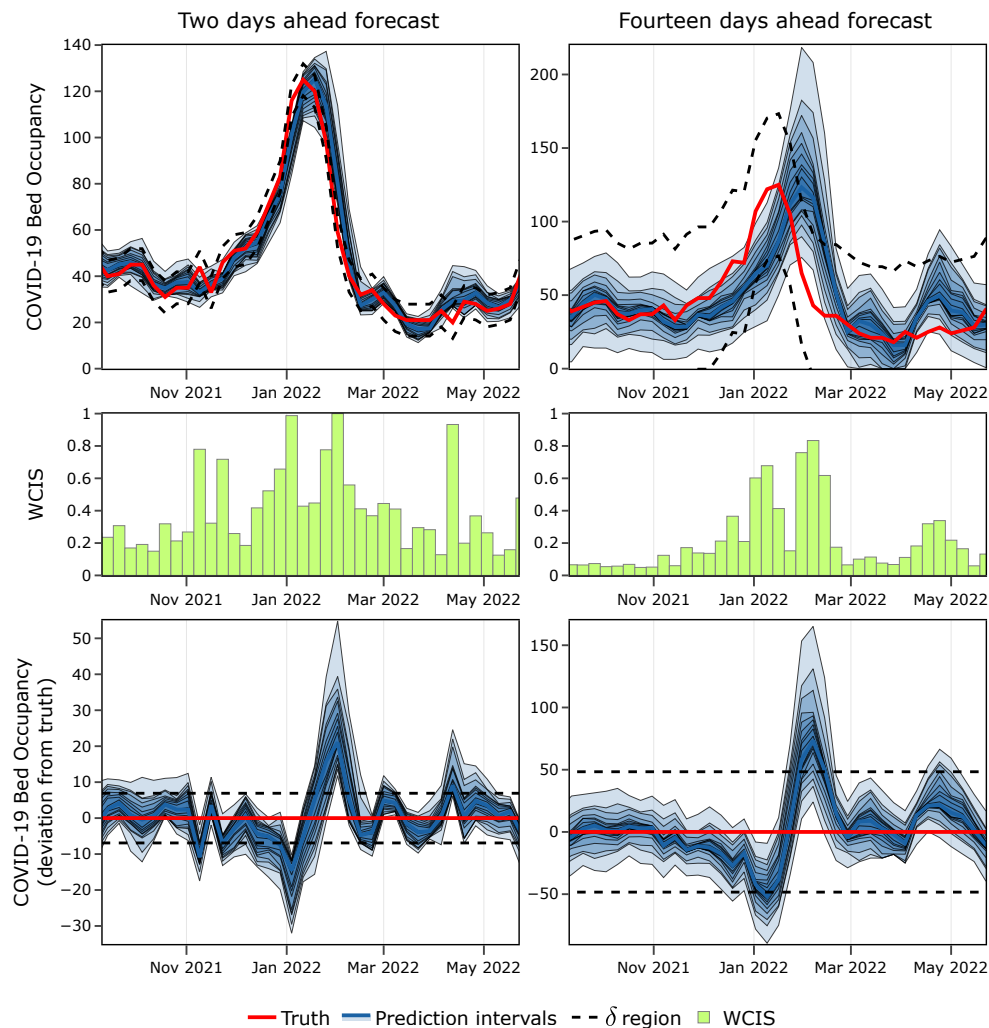

Fig. 1 Illustrated here are facility-level forecasts over two prediction horizons for one hospital: the University of Maryland Medical Center. The top and bottom rows both show the same forecasts, truth data, and δ (utility threshold) region. The top row displays these values normally, whereas the bottom row shows how far each value deviates from the truth. The middle row displays the WCIS, aligned with the data in the other rows. (Note that the facility-level analysis includes more prediction intervals and more dates than are shown in this figure, the extent of both displayed here are reduced for clarity.)

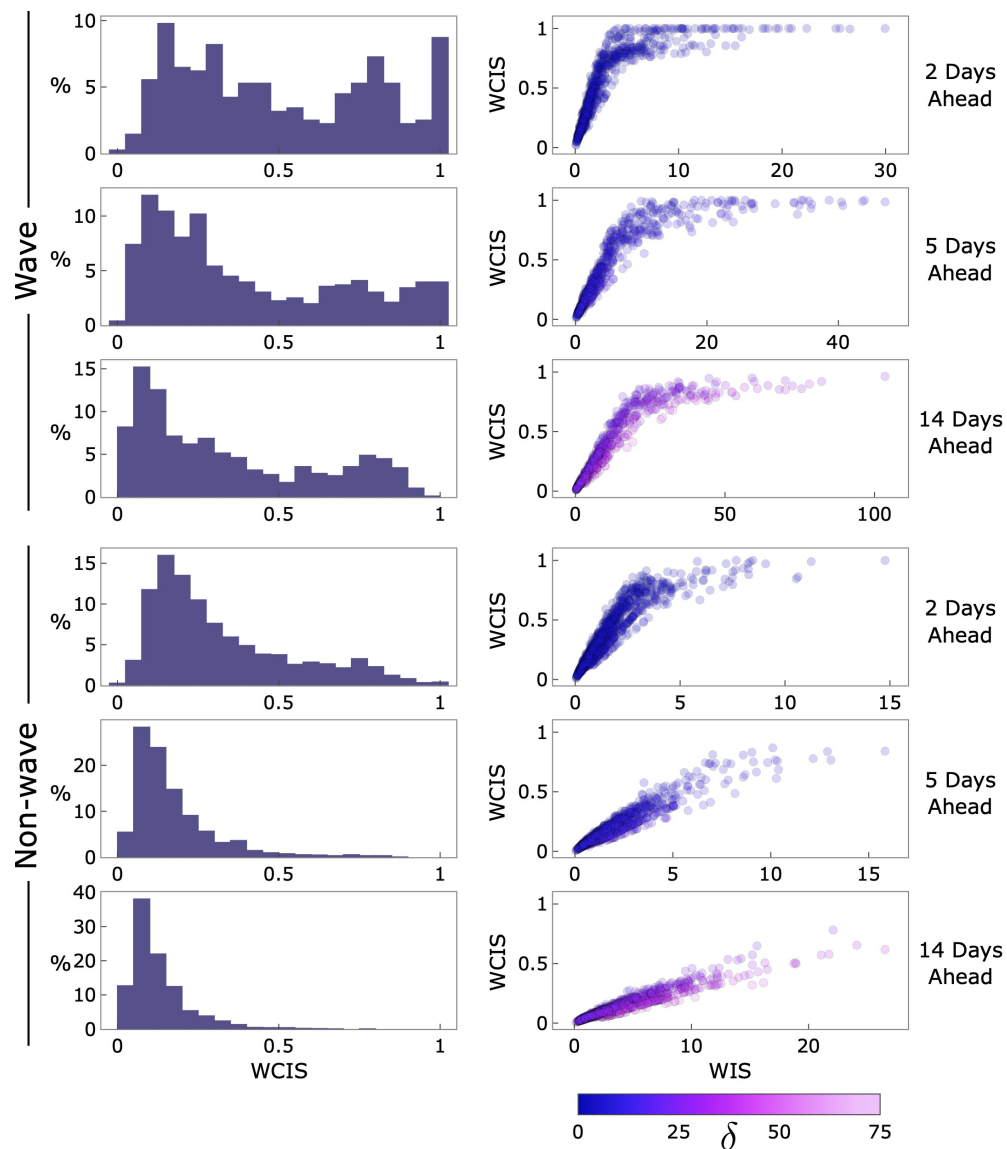

Fig. 2 Results in this figure are generated from all 42 hospitals, for all prediction dates in the facility-level model. The top three rows are from forecasts during the Omicron wave, and the bottom three from before and after the wave. We define the wave as lasting from November 14 2021 through May 15 2022, as illustrated in Additional file 1: Fig. S4.

307 **3.2 State-level Analysis (Second Test Case)**

308 For this test case, we apply the WCIS to real-world predictions drawn from the Fore-
309 cast Hub, asking how much contextual utility hospitalization forecasts provided at
310 the state level from May 2021 to May 2022 [3]. (Note that Forecast Hub hospitaliza-
311 tion predictions were performed at daily resolution, but for the sake of visualizing a
312 longer-term analysis we aggregate to and evaluate at weekly totals.)

313 The WCIS always requires a specific interpretation of the use-case for forecasts
314 in the selection of the utility threshold δ . Similar to Section 3.1, we choose to assess
315 hospitalization predictions as a function of potential capacity changes. However, we
316 assume a different decision-making scenario for hospital capacity at the state level
317 than for its facility level counterpart. Due to the disaggregate decision-making appa-
318 ratus across statewide hospitals and the inherent institutional inertia that must be
319 overcome for larger scale change, we take a more conservative approach to estimating
320 the absorbable error magnitude. Specifically, δ is the 0.9 quantile of the prior devia-
321 tions in each state's hospital bed capacity over the prediction horizon of the forecast.
322 We assume prior bed capacity deviations are indicative of a state's capacity to make
323 changes, and that it is more difficult to make changes over a shorter timeline. Thus, any
324 deviation over a shorter-term horizon can also occur for longer term horizons, but not
325 the reverse. For example, when examining one week ahead predictions, only historical
326 capacity changes over the course of a single week are considered. For four weeks ahead
327 predictions, capacity changes for one, two, three, and four weeks ahead are considered.
328 Finally, the 0.9 quantile is selected as the threshold under the assumption that states
329 are not necessarily able to repeat their largest historical deviations, but can approach
330 them. To be clear, this choice of δ is a heuristic for the amount of resource alloca-
331 tion, staffing changes, and other matters that hospitals might practically accomplish
332 in response to an assumed change in pandemic dynamics. It is intended to demon-
333 strate the WCIS given a reasonable, data-driven parameterization of forecast utility.
334 Namely, a response predicated on a forecast outside the δ -range as defined here would
335 require corrective action of a magnitude that could not be reasonably expected over
336 such a forecast's prediction horizon.

Fig. 3 Heatmap of the WCIS for 4 week ahead hospitalization forecasts, performed by the Forecast Hub’s ensemble model. The central and largest grid shows the most granular results: region- and time-specific performance. On the right and lower sides of the grid are average performances over time and space, respectively. The shaded line plot at the bottom of the figure is the target hospitalization variable aggregated across all regions. Note that its domain is aligned exactly with those of the time-dependent heatmaps above, to provide insight into the trends of the overall pandemic alongside the more granular information in the heatmaps. (See Additional file 1: Section 3 for heatmaps over differing prediction horizons).

337 WCIS performance results for four weeks ahead state-level hospitalization predic-
338 tions are demonstrated in Figure 3. Since the WCIS was designed primarily as a way
339 to meaningfully evaluate and compare forecasts in disparate contexts, we can easily
340 use it to observe several important aspects of hospitalization forecasting performance.
341 For example, during surges and declines, forecast utility decreases substantially. We
342 can intuit that this is a consistent trend across different locations both by directly
343 observing the large central grid and by examining the lower, spatially averaged array
344 of the figure. In contrast, if we examine the right-side, temporally averaged array, we
345 observe that there is less variability in space than there is in time. Thus, by mak-
346 ing an up-front determination about what constitutes a useful prediction (performing
347 the δ -parameterization), we are capable of making, displaying, and intuitively evalu-
348 ating forecasts. This allows, given a well-informed choice of δ , for meaningful overall
349 analysis without needing to repeatedly delve into the specific circumstances during
350 which each forecast was made. Without contextual normalization, conveying informa-
351 tive and comparable performance would be much more challenging. This capability,
352 demonstrated by the ease of interpreting Figure 3, is the overall aim for our creation
353 of the WCIS. It permits substantive and easily interpretable performance evaluation.

354 4 Discussion

355 The WCIS is framed around our belief that a useful forecast contributes meaningful
356 and/or actionable information given uncertain future outcomes. Determining whether
357 or not forecasts accomplish this necessitates an explicit definition of utility. This brings
358 up an important philosophical difference between the WCIS and other techniques.
359 The WCIS formulation, centered around a user-defined utility threshold δ , arises from
360 our assertion that there will never be a one-size-fits-all solution for assessing and com-
361 paring short-term forecast quality. One must always consider prediction context and
362 purpose lest standard metrics tell a misleading story. Additionally, different forecast
363 use-cases yield different judgments of predictions. The helpfulness of a model that pre-
364 dictes rainfall, for example, will be judged very differently by a user deciding whether
365 or not to bring an umbrella on a walk as compared to a user deciding whether or not
366 to issue regional flood warnings. An incorrect forecast of light rain with a realization
367 of heavy rain is good enough for the first user but may be catastrophic for the second.
368 Again, forecast purpose is essential to consider. The WCIS ensures this by building a
369 definition of forecast utility directly into the formulation of the score.

370 The core of the WCIS is the combined normalization and thresholding imposed
371 by the δ parameterization, which incorporates a vital aspect of real-world forecast
372 utility. Namely, past a certain point, changes in a prediction's absolute error do not
373 equate to changes in outcomes predicated on that forecast. Even when one forecast is
374 more accurate than another, if both are beyond the utility horizon then the "better"
375 one is not actually more useful, just arbitrarily closer to the truth. This idea is the
376 basis for the plateaued CRE point scoring function, which in turn is the basis for the
377 WCIS. While a metric that does not always increase the penalty as forecast accuracy
378 diminishes may seem counterintuitive, we believe that for characterizing contextual

379 utility, a score with a limited scope of relevance is actually more intuitive than a score
380 that gets arbitrarily worse (or better) no matter how far away it is from being helpful.

381 The WCIS builds on the Weighted Interval Score, adding the δ -parameterization
382 to impel users to directly characterize contextual utility. Judging predictions in this
383 way allows for a powerful and effective normalization of the error, making the WCIS
384 easy to interpret and compare across heterogeneous forecasting scenarios. Importantly,
385 this robust efficacy exists *only for each individual definition of utility*. We belabor this
386 point because it is inherent to our overall assertion about forecast interpretability: that
387 a specific use case is necessary to meaningfully evaluate prediction quality. Without an
388 explicit link to how forecasts are used, there is no way to consistently and meaningfully
389 evaluate them over variable spatial and temporal conditions. Other evaluation metrics
390 are in essence arbitrary until they are contextualized, whereas the WCIS builds this
391 contextualization directly into the formulation of the score.

392 5 Conclusions

393 Determining the future role of pandemic forecasting, as well as identifying areas of
394 forecasting that need improvement, must at some point include the translation of
395 modeling results to policy and decision makers. The WCIS is expressly intended to
396 function well in this process, allowing for intuitive characterization of forecast utility
397 that can be easily communicated to an audience with less technical expertise. Figure
398 3 demonstrates this directly. Without effective contextual normalization, generating
399 such a display would be challenging given large differences in error magnitude, likely
400 requiring a transformation (such as log-scaling) that limits interpretability. Instead,
401 the WCIS allows for a direct, clearly defined interpretation of forecast utility to be
402 displayed and compared in a technically meaningful and intuitively understandable
403 way.

404 We created the WCIS to enable and encourage honest and contextually specific
405 discourse about the utility of short-term epidemic predictions. It incorporates predic-
406 tion uncertainty, keeps the technical definition of utility as simple as possible, and
407 generates an intuitively interpretable and comparable numerical output. Our intent is
408 to allow for people without specific technical experience to be able to interact with and
409 evaluate probabilistic forecasting in a meaningful way. As the public health commu-
410 nity learns from COVID-19 and prepares for future challenges, explicit analysis of the
411 utility of historical predictions is essential. We hope the WCIS will help with effective
412 and meaningful communication between modelers and practitioners in this effort.

413 Declarations

- 414 • **Ethics approval and consent to participate:** Not applicable. Ethics approval
415 was not sought or required for this study. All human health data used are
416 population-level COVID-19 outcomes sourced from publicly available online repos-
417 itories.
- 418 • **Consent for publication:** Not applicable.
- 419 • **Availability of data and materials:** Code and processed data for both the
420 facility- and state-level analyses are accessible from a publicly available GitHub

- 421 repository [<https://github.com/cpt-diabetes/wcis>]. Forecast and ground truth data
422 used for our state-level analysis are available from the COVID-19 Forecast
423 Hub repository [<https://doi.org/10.5281/zenodo.6301718>]. The original source for
424 ground truth hospitalization data is the COVID-19 Reported Patient Impact and
425 Hospital Capacity by Facility repository [<https://healthdata.gov/d/j4ip-wfsv>].
426 • **Competing interests:** The authors declare that they have no competing interests
427 • **Funding:** This study was supported by the United States National Science
428 Foundation (NSF) under grant no. 2108526.
429 • **Authors' contributions:** MM conceived of the study, performed the analysis, and
430 wrote the manuscript. MM and FP developed the methodology. LMG supervised the
431 project and provided essential methodological guidance. All authors read, edited,
432 and approved the final manuscript.
433 • **Acknowledgements:** Not applicable.
