Abstract

INTRODUCTION: Growing evidence indicates fine particulate matter (PM_{2.5}) as risk factor for Alzheimer's disease (AD), but the underlying mechanisms have been insufficiently investigated. We hypothesized differential DNA methylation (DNAm) in brain tissue as potential mediator of this association.

METHODS: We assessed genome-wide DNAm (Illumina EPIC BeadChips) in prefrontal cortex tissue and three AD-related neuropathological markers (Braak stage, CERAD, ABC score) for 159 donors, and estimated donors' residential traffic-related PM_{2.5} exposure 1, 3 and 5 years prior to death. We used a combination of the Meet-in-the-Middle approach, high-dimensional mediation analysis, and causal mediation analysis to identify potential mediating CpGs.

RESULTS: PM_{2.5} was significantly associated with differential DNAm at cg25433380 and cg10495669. Twenty-six CpG sites were identified as mediators of the association between PM_{2.5} exposure and neuropathology markers, several located in genes related to neuroinflammation.

DISCUSSION: Our findings suggest differential DNAm related to neuroinflammation mediates the association between traffic-related PM_{2.5} and AD.

150/150 words

1 Background

Exposure to traffic-related air pollution (TRAP) is a significant contributor to public health burden with various detrimental health effects.¹ Fine particulate matter (PM_{2.5}), which has been regulated by the National Ambient Air Quality Standards (NAAQS) as a criteria air pollutant since 1997 in the United States (U.S.),² is an important component of TRAP mainly resulting from tailpipe exhaust, brake wear, tire wear, and resuspended dust.³ PM_{2.5} from traffic emissions has higher toxicity compared to other natural sources in terms of oxidative potential, cell viability, genotoxicity, oxidative stress, and inflammatory response.⁴ The literature to date demonstrates that exposure to PM_{2.5} is associated with a series of neurological disorders, including dementia and Alzheimer's disease (AD).^{5,6}

AD is the most common cause of dementia and its hallmark pathologies include accumulation of beta-amyloid (A β plaques) outside neurons and aggregation of hyperphosphorylated tau protein (neurofibrillary tangle, NFT) inside neurons in the brain.⁷ In the U.S., 9.30 and 75.68 million people are estimated to develop clinical AD or preclinical AD by 2060,⁸ and the total direct medical costs of AD is estimated to reach \$259 billion by 2040.⁹ Due to the growing public concern with these substantial increases in the prevalence of AD, investigations on interventions to prevent progression and onset of AD have targeted the potentially modifiable risk factors of AD, including PM_{2.5}.¹⁰

PM_{2.5} exposure might directly infiltrate the brain¹¹ and accelerate AD pathogenesis and development via neuroinflammation, oxidative stress, and A β accumulation.¹² Increasing evidence from human and animal studies proposes that perturbations in

DNA methylation (DNAm), which regulates the expression of genes, are associated with indicators of AD as well as PM_{2.5} exposure. However, the tissue specificity of DNAm has limited the ability of previous studies to formally investigate mediation. While there is no conclusive evidence of an association between AD and DNAm in blood,¹³ DNAm alterations in a number of genes were observed to be associated with AD pathology and neuroinflammation in brain tissues, such as amyloid precursor protein (*APP*),¹⁴ microtubule-associated protein tau (*MAPT*),¹⁴ apolipoprotein (*APOE*) promoter region,¹⁵ homeobox A3 (*HOXA3*),¹⁶ interleukin-1 beta (*IL-1β*),¹⁷ and interleukin-6 (*IL-6*).¹⁷

The association of PM_{2.5} with DNAm in blood has been extensively studied.¹⁸ DNAm in interleukin-10 (*IL-10*), *IL-6*, tumor necrosis factor (*TNF*), toll like receptor 2 (*TLR2*) genes, which play key roles in neuroinflammation,¹⁹ was reported to be significantly altered in response to short-term exposure to PM_{2.5} and its species.²⁰ However, to the best of our knowledge, no human studies have been published on the association between PM_{2.5} exposure and DNAm in human brain, which is the most relevant tissue when studying AD. The only evidence to date comes from *in-vivo* and *in-vitro* studies. Tachibana et al. demonstrated with a mouse model that prenatal exposure to diesel exhaust altered DNAm in brain tissues collected from 1- and 21-day-old offspring, and the differentially methylated CpG sites were enriched in the gene ontology (GO) terms related to neuronal development.²¹ Wei et al. exposed human neuroblastoma cells to near-road PM_{2.5} and found that DNAm was hypermethylated in the promoter regions of genes encoding synaptic neuronal adhesion molecules that mediate essential signaling at synapse.²²

The mediating role of DNAm for the association between PM_{2.5} and AD pathology has not been well studied, given the limited evidence of an association between PM_{2.5} exposure and DNAm in the brain. The current study investigated the relationship among PM_{2.5}, DNAm and AD neuropathology in the post-mortem human brain among brain donors of the Emory Goizueta AD Research Center (ADRC) brain bank. We recently showed a significant association between traffic-related PM_{2.5} exposure and increased AD neuropathology in this dataset.²³ To elucidate the biological mechanisms for this association, we here investigated whether differential DNAm in the prefrontal cortex tissues mediates the association between long-term exposure to traffic-related PM_{2.5} and the levels of AD-related neuropathological markers. This hypothesis was tested using a combination of the Meet-in-the-Middle (MITM) approach and high-dimensional mediation analysis.

2 Methods

2.1 Study design

The current cross-sectional analysis included study participants recruited by the Emory Goizueta ADRC. The ADRC was founded in 2005 and has maintained a brain bank to facilitate AD research. The study participants were research participants evaluated annually, and others were patients treated by Emory Department of Neurology physicians and diagnosed clinically with AD (biomarker defined) or probable AD. The prefrontal cortex tissues were obtained from the participants who had consented to donate biospecimens to the ADRC brain bank. There were 1011 donors enrolled by the third quarter of 2020. After applying the following inclusion criteria, 264 donors remained eligible for the current study: 1) the availability of residential addresses within Georgia (GA) state; 2) age at death equal to or over 55 years (death earlier than 55 possibly due to competing risks); 3) deceased after 1999 (due to the availability of air quality data); 4) no missing values in neuropathology outcomes and key covariates including age at death, race, sex, educational attainment, and APOE genotype. Among these donors, genome-wide DNAm was measured in 161 available samples from the donors deceased after 2007, and after quality control, 159 were included in the current analysis. Written informed consent was provided for all donors, and samples were obtained following research protocols approved by the Emory University Institutional Review Board.

2.2 Neuropathology assessment

The ADRC performed thorough neuropathologic evaluations on the brains of all donors using established comprehensive research evaluations and diagnostic criteria.²⁴ These neuropathological assessments include a variety of stains and immunohistochemical preparations, as well as semi-quantitative scoring of multiple neuropathologic changes by experienced neuropathologists using published criteria.²⁵ In this project, AD-related neuropathological changes were evaluated using Braak stage, Consortium to Establish a Registry for AD (CERAD) score, and a combination of Amyloid, Braak stage, and CERAD (ABC) score which were developed based on the A β plaques and NFTs.²⁶ Braak stage is a staging scheme describing NFTs with six stages (Stage I-VI) with a higher stage indicating a wider distribution of NFTs in brain. CERAD score describes the prevalence of A β plaques with four levels from no neuritic plaques to frequent. ABC score combines the former two (along with the Thal score for A β plaque distribution across various brain regions)²⁷ and is transformed into one of four levels: not, low, intermediate, or high level of AD neuropathologic changes.

2.3 Air pollution assessment

Annual concentrations of traffic-related PM_{2.5} were estimated for the 20-county area of Metropolitan Atlanta, GA for 2002-2019. The spatial resolution of the PM_{2.5} data were 250×250m (for 2002-2011) and 200×200m (for 2012-2019). The grid cells of the corresponding side length were evenly distributed throughout the study area. The process for estimating 2002-2011 PM_{2.5} concentrations was previously published.^{28,29} Briefly, a calibrated Research LINE-source dispersion (R-LINE) model for near surface releases was applied for calculating annual averages of traffic-related PM_{2.5}. The model

yielded a normalized root mean square error of 24% and a normalized mean bias of 0.3% by comparing with the estimates of the receptor-based source apportionment Chemical Mass Balance Method with Gas Constraints.²⁸ For estimating 2012 to 2019 PM_{2.5} concentrations, we trained a land-use random forest model based on the 2015 annual concentrations of traffic-related PM_{2.5} obtained from Atlanta Regional Commission,³⁰ road inventory and traffic monitoring data shared by the Georgia Department of Transportation, land cover data accessed via the National Land Cover Database, and ambient PM_{2.5} data obtained from Atmospheric Composition Analysis.³¹ The random forest model was trained with the R package *randomForest*³², and two user-defined parameters (i.e., the number of trees and the number of variables randomly tried at each split) were determined by a balance of the efficiency and the out-of-bag R² value. The final model reached an out-of-bag R² of 0.8 and a root-mean-square deviation of 0.2 µg/m³. This model was used to predict annual traffic-related PM_{2.5} for 2012-2019 with a spatial resolution of 200m. More details can be found elsewhere.²³ Finally, we spatially matched geocoded residential addresses to the centroid of closest grids and calculated the individual long-term exposures as the average of specific exposure windows (1 year, 3 years, and 5 years prior to death).

2.4 Genome-wide DNA methylation

DNA was isolated from fresh frozen prefrontal cortex in 161 samples using the QIAGEN GenePure kit. DNAm was assessed with the Illumina Infinium MethylationEPIC BeadChips in batches of 167 prefrontal cortex samples including 6 replicates. The raw intensity files were transformed into a dataset that included beta values for each the

CpG sites, and these beta values were computed as the ratio of the methylated signal to the sum of the methylated and unmethylated signals, which ranged from 0 to 1 on a continuous scale. Pre-processing and statistics were done using R (v4.2.0). We followed a validated quality control and normalization pipeline as previously published.³³ The detailed data processing and sample quality control can be found in the Supplementary Methods. One hundred and fifty-nine samples passed the quality check, and after excluding SNP probes, XY probes and other low-quality probes, 789,286 CpG sites remained. The final DNAm beta values were further normalized to reduce the probe type differences and corrected by *ComBat* to remove the batch effect before the downstream analysis.³⁴ We estimated the cell-type proportions (neuronal vs. non-neuronal cells) for each sample using the most recent prefrontal cortex database and the R package *minfi*.^{35,36}

2.5 Covariate assessment

The confounding structure was determined according to literature review and our previous studies, which was illustrated by directed acyclic graphs (DAGs) in the Supplement (Figure S1). Individual-level demographic characteristics [sex, race (Black vs. White), educational attainment (high school or less, college degree, and graduate degree), age at death, APOE ϵ 4 genotype] were obtained from the medical records. APOE ϵ 4 genotype was continuous with a 3-point scale (0 = no ϵ allele, 1 = one ϵ 4 allele, and 2 = two ϵ 4 alleles). Area Deprivation Index (ADI) for each donor was estimated at the residential address as a proxy for neighborhood socioeconomic status, based on a publicly available database at the level of the Census Block Group for

2015.³⁷ Post-mortem interval (hours) of sample collection was provided by our lab collaborators.

2.6 Statistical analysis

Previously, we found higher residential PM_{2.5} exposure was associated with increased AD neuropathology in the Emory Goizueta ADRC brain bank.²³ To identify DNAm patterns in brain tissue that potentially mediate the association between PM_{2.5} exposure and increased neuropathology markers, we 1) conducted an epigenome-wide association study (EWAS) for the long-term PM_{2.5} exposures 1 year, 3 years, and 5 years prior to death and then investigated whether any differentially methylated CpG sites that were significantly associated with PM_{2.5} exposure in the EWAS were also associated with increased neuropathology markers; and 2) conducted a combination of Meet-in-the-Middle (MITM) approach and high-dimensional mediation analysis (HDMA) to identify any mediating CpGs that did not reach genome-wide significance in the EWAS of PM_{2.5}. The MITM approach and HDMA work complementarily to maximize the detection of potential mediators.

Firstly, we conducted an EWAS to assess associations of long-term PM_{2.5} exposures 1 year, 3 years, and 5 years prior to death and methylation levels of CpG sites. Specifically, we used robust multiple linear regression models as implemented in the R package *MASS* to identify differentially CpG sites associated with PM_{2.5} exposures.³⁸ To account for measured confounding factors, we included sex, race, educational attainment, age at death, PMI, ADI, and proportion of neuronal cells in the model. Potential batch effect and other unwanted variation were further corrected using the R

packages *sva*³⁹ (estimating surrogate variables included in the EWAS model as covariates) and *Bacon*.⁴⁰ The *sva* was used to obtain surrogate variables to be included in the models. To account for multiple testing, the *Bonferroni* threshold was used for statistical significance ($0.05 / 789,286 = 6.33 \times 10^{-8}$), while no cut-off was applied on the magnitude of DNA methylation difference.⁴¹

Any CpG sites that were significantly associated with PM_{2.5} exposure were then investigated for their associations with neuropathology markers. These associations were extracted from an EWAS of each neuropathology marker (CERAD, Braak stage, ABC score) with methylation levels of all CpG sites, using robust multiple linear regression models with the neuropathology markers converted to continuous outcomes and DNAm beta values of CpG sites as exposures, adjusting for sex, race, educational attainment, age at death, PMI, APOE genotype, and proportion of neuronal cells. We used *Bacon*⁴⁰ to control for unmeasured confounding and bias due to the minor inflation/deflation indicated by raw *p*-values.

For the MITM, we compared the 1,000 most significant CpGs from the two sets of EWAS on all CpG sites for PM_{2.5} exposures and neuropathology markers to identify the differentially methylated CpG sites that were associated with both exposures and outcomes. In other words, the raw *p*-values of all 789,286 CpG sites were sorted increasingly, which were derived from the two set of EWAS models conducted on PM_{2.5} exposure and neuropathology markers, respectively. We selected the CpG sites among the lowest 1000 for both PM_{2.5} exposure and neuropathology markers. The MITM approach is widely used in high-dimensional setting to identify intermediate biomarkers.⁴²

Then, we conducted a HDMA using the R packages *HIMA* and *DACT* to identify any potential mediating CpG sites between PM_{2.5} exposure and neuropathology from all 789,286 CpG sites. *HIMA* is an R package for estimating and testing high-dimensional mediation effects for omics data, which adopts the multiple mediator model's framework with reducing the dimensionality of omics data via sure independence screening and minimax concave penalty.⁴³ The divide-aggregate composite null test (*DACT*) is a more recent method for HDMA, which utilizes the Efron empirical null framework to calculate a weighted sum of *p*-values obtained from exposure-mediator (EWAS of PM_{2.5} exposure as described above) and mediator-outcome (EWAS of neuropathology markers as described above) models for testing the significance of all mediators⁴⁴. We corrected for multiple testing in *HIMA* and *DACT* using the *Bonferroni* method. Lastly, for the mediating CpG sites identified by either *HIMA* or *DACT*, we used the R package *mediation* to conduct a causal mediation analysis obtain their indirect effects.⁴⁵⁻⁴⁷ The *mediation* is a frequently used tool which implements the mediation methods and suggestions proposed by Imai et al.^{48,49} The average causal mediation effect (i.e., indirect effect) and total effect estimated by *mediation* were summarized for the CpG sites with positive indirect effects that were in line with the hypothesized adverse effect of traffic-related PM_{2.5} on neuropathology markers. In contrast to the MITM approach described earlier, HDMA examine multiple mediators together in a framework of mediation analysis, which allowed us to ascertain the extent to which the particular indirect effects were associated with the mediators.

To aid the interpretation of model results, we conducted a gene ontology analysis using the R package *missMethyl* based on the top 1000 CpG sites with lowest raw *p*-

values⁵⁰. The gene ontology analysis was conducted for the EWAS results of PM_{2.5} exposure as well as for the EWAS results of the three neuropathology markers. All CpG sites were annotated using an online annotation data for the 'IlluminaHumanMethylationEPIC'.⁵¹ Additional functional insight on single CpG sites was obtained by searching the corresponding CpG site in publicly available databases, including EWAS catalog⁵².

All analyses were completed in R (v4.2.0).

3 Results

3.1 Study population characteristics

A total of 159 donors were included in the current analysis, and their demographic characteristics and neuropathologic markers are described in Table 1. The average age of death was 76.6 years (SD=9.98) and 56% of the study population were male. The study population was predominantly white (89.3%) and well-educated with 123 (78.7%) completing college or more and living in less deprived neighborhoods (ADI: mean = 36.3, SD = 24.2). The majority of study sample (95.6%) were diagnosed with AD or other forms of dementia, and the prevalence of the APOE ϵ 4 allele (56% with at least one APOE ϵ 4 allele) in this population was much higher than that in the general population in the U.S.⁵³

As illustrated by the 1-year traffic-related PM_{2.5} exposure (Figure 1A), donors living in urban areas had a higher level of PM_{2.5} exposure compared to those living in suburban areas. The median of 1-year exposure was 1.21 $\mu\text{g}/\text{m}^3$ [interquartile range (IQR)=0.78]. As PM_{2.5} concentrations have decreased over the last decades, 3-year and 5-year exposures were slightly higher (3-year exposure: median=1.32 $\mu\text{g}/\text{m}^3$ [IQR=0.74], 5-year exposure: median=1.39 $\mu\text{g}/\text{m}^3$ [IQR: 0.81]) (Figure 1B).

3.2 Association between PM_{2.5} exposure and DNAm in the brain

After correcting for multiple tests and adjusting for bias and measured and unmeasured confounding, two CpG sites (cg25433380 and cg10495669) were consistently associated with PM_{2.5} across different exposure windows (Figure 2, Table 2; summary statistics for all 789,286 CpG sites are provided as Tables S4-6 in spreadsheets). For

example, a 1 $\mu\text{g}/\text{m}^3$ increase in 1-year $\text{PM}_{2.5}$ exposure was associated with 0.0065 increase in the DNAm beta value of cg25433380 ($p = 1.58 \times 10^{-8}$). cg25433380 and cg10495669 are on chromosome 9 and 20, respectively, and cg10495669 is assigned to the gene encoding RanBP-type and C3HC4-type zinc finger-containing protein 1 (*RBCK1*). The two CpG sites were not significantly associated with any neuropathology markers (Table 2).

3.3 Meet-in-the-Middle approach and high-dimensional mediation analysis

For the MITM approach, we explored the overlapping CpG sites among the top 1000 CpG sites for the EWAS of $\text{PM}_{2.5}$ and the EWAS of neuropathology markers (results presented in Tables S7-S9 in spreadsheets) and identified four overlapping CpG sites (Table S1). Specifically, DNAm in cg01835635 (apolipoprotein A4 gene, *APOA4*) was associated with CERAD score as well as $\text{PM}_{2.5}$ exposure for the 1-year and 3-year exposure windows. DNAm in cg09830308 (mixed lineage kinase domain like pseudokinase gene, *MLKL*) was associated with Braak stage as well as $\text{PM}_{2.5}$ exposures for the 1-year, 3-year, and 5-year windows; cg16342341 (sorbin and SH3 domain-containing protein 2 gene, *SORBS2*) was associated with CERAD score as well as 1-year $\text{PM}_{2.5}$ exposure; and cg27459981 (*MLKL* gene) was associated with Braak stage and ABC score as well as $\text{PM}_{2.5}$ exposures for the 3-year and 5-year windows.

The HDMA via *HIMA* did not identify any CpG sites as significant mediators. In the HDMA using a combination of *DACT* and causal mediation analysis, we identified twenty-two CpG sites to mediate the positive association between $\text{PM}_{2.5}$ exposure and ABC score (Table 3), while none were observed for Braak stage and CERAD score.

One CpG site (cg16342341, *SORBS2* gene) was associated with all three exposure windows (1, 3 and 5-years prior to death), and eight with two exposure windows. Of note, cg16342341 (*SORBS2*) was also identified in the MITM approach described above. The total effect estimated for all mediation analyses was positive but insignificant in this subsample of the cohort (see Christensen et al. 2023 for the significant total effect in the full cohort).²³ The summary statistics for all CpG sites detected by *DACT* are summarized in the Supplement (Table S2).

3.4 Secondary analyses

A gene ontology analysis was conducted for the top 1000 CpG sites associated $PM_{2.5}$ and for the top 1000 CpG sites associated with the neuropathology markers. None of the KEGG pathways reached significance after correcting for multiple tests. Therefore, we summarized the top 10 KEGG pathways for each of the $PM_{2.5}$ exposures or neuropathology markers in the Supplement (Table S3). One pathway, which is the longevity regulating pathway, was associated with both 3-year exposure to $PM_{2.5}$ and CERAD score. Eight genes (*HSPA1A*, *HSPA1L*, *IRS1*, *KRAS*, *NRAS*, *RPTOR*, *IRS2*, *ATG5*) in this pathway were enriched by differentially methylated CpG sites that were associated with 3-year $PM_{2.5}$ exposure, and ten genes (*ADCY3*, *ADCY5*, *NFKB1*, *PRKAG2*, *RPTOR*, *TSC2*, *EHMT1*, *ULK1*, *AKT1S1*, *ATG5*) with CERAD score. Of note, *AKT1S1* was also among the genes that were identified in the HDMA (*DACT* and causal mediation analysis).

4 Discussion

In the current study of 159 donors from the Emory Goizueta ADRC brain bank, we identified differential DNAm in prefrontal cortex tissues at two CpG sites to be significantly associated with long-term PM_{2.5} exposure. The two CpG sites (cg25433380 and cg10495669) that were associated with PM_{2.5} exposure were consistently associated with long-term exposures to traffic-related PM_{2.5} 1 year, 3 years, and 5 years prior to death, after controlling for measured and unmeasured confounding. While cg25433380 and cg10495669 were not associated with increases in neuropathology markers, we identified 4 CpG sites that overlapped between the top 1000 CpG sites associated with PM_{2.5} and neuropathology markers (MITM approach) and 22 CpG sites that mediated the adverse effect of PM_{2.5} exposures on AD-related neuropathology markers using HDMA. The longevity regulating pathway was enriched by differentially methylated CpG sites associated with PM_{2.5} (3-year exposure window) and CERAD score.

This is the first study showing an association between PM_{2.5} exposure and differential DNAm in the brain (cg25433380 and cg10495669). Scarce evidence related to air pollution has been reported on cg25433380. Higher DNA methylation levels of cg10495669 in nasal cells have been associated with 1-year ambient PM_{2.5} exposure among 503 children in Massachusetts.⁵⁴ *RBCK1*, the gene which cg10495669 is assigned to, is involved in carcinogenesis and inflammation pathways. Yu et al. suggested that *RBCK1* promoted the ubiquitination and degradation of p53.⁵⁵ The impairment of p53 expression and activity might participate in neurodegeneration, as p53 can bind to genes that regulate expression of synaptic proteins, neurite outgrowth, and axonal regeneration, which indicated a neuroprotective role against AD

development.⁵⁶ In addition, *RBCK1* can regulate the proinflammatory-cytokines-induced nuclear factor kappa B (NF- κ B) activation which serves as a pivotal mediator of inflammatory responses.⁵⁷ NF- κ B activation is a common feature of many neurodegenerative diseases,⁵⁸ and the increased expression and/or activation of NF- κ B has been largely observed in post-mortem studies of AD patients.⁵⁹ However, the two CpG sites were not found to be associated with any neuropathology markers in the current analysis. More research is warranted on these CpG sites to investigate their potential role in AD development with a larger sample size and participants of more diverse disease stages from preclinical to severe dementia.

We identified four CpG sites (cg01835635, cg09830308, cg16342341, and cg27459981) that overlapped between the top 1000 CpG sites associated with both PM_{2.5} and neuropathology markers via MITM approach. Three of them (cg16342341, cg09830308 and cg27459981) or their related genes have been previously associated with AD or PM_{2.5} exposure. Cg09830308 and cg27459981, assigned to *MLKL*, were both associated with Braak stage and PM_{2.5} exposure 3 and 5 years prior to death. *MLKL* plays a critical role in TNF-induced cell death (i.e., necroptosis). Caccamo et al. found that necroptosis was activated in postmortem brains of AD patients and positively correlated with Braak stage, and *MLKL* expression was significantly higher compared to control cases' brain tissues.⁶⁰ Similarly, Jayaraman et al. reported that necroptosis signaling was highly activated in the hippocampus of AD patients, as illustrated by the increased mRNA expression of genes, including *MLKL*.⁶¹ Furthermore, Wang et al. demonstrated that the knockdown of *MLKL* significantly increased the ratio of A β 42 to A β 40, a potential diagnostic marker of AD, in an AD model HEK293 cell line.⁶²

Collectively, PM_{2.5} exposure might induce the TNF-mediated neuroinflammation, resulting in necroptosis, and thus contribute to AD pathogenesis.

Cg16342341, assigned to *SORBS2*, was also identified as a potential mediator in the HDMA, where it mediated the association of all PM_{2.5} exposure windows with ABC score. As *SORBS2* is well known for its role in AD and neuroinflammation^{63,64} and was associated with PM_{2.5} exposure in rats⁶⁵, our findings contribute to the evidence of *SORBS2* playing a role in PM_{2.5}-induced neuropathologic changes of AD. *SORBS2* represses IL-6 and TNF- α expression in the mouse embryonic fibroblasts,⁶⁶ and Chen et al. demonstrated that its level was lower in the brains of AD model mice compared to wild type mice,⁶³ implying a role of *SORBS2* in regulating neuroinflammation. In a human study, genetic variation in *SORBS2* was associated with age at onset of AD.⁶⁴ While evidence on the association between PM_{2.5} exposure and *SORBS2* is more scarce, Chao et al. reported that prenatal exposure to PM_{2.5} induced upregulation of microRNAs targeting *SORBS2* gene in fetal rat cortex tissues.⁶⁵

We also identified 21 other CpGs as potential mediators of the association between long-term exposure to traffic-related PM_{2.5} and ABC score using HDMA, and two of these CpGs (cg07963191 and cg27297993) have been previously reported in association with AD. Cg07963191 was assigned to the dual 3',5'-cyclic-AMP and -GMP phosphodiesterase 11A gene (*PDE11A*) that participates in neuroplasticity and neuroprotection.⁶⁷ Cg27297993 was assigned to the gamma-aminobutyric acid B receptor 1 gene (*GABBR1*). *GABBR1* is the main inhibitory neurotransmitter, which was reported to be downregulated in the brains of AD patients.⁶⁸ Iwakiri et al. observed a negative correlation between *GABBR1* and NFT formation in the hippocampus of

seniors, suggesting an increased or stable expression of *GABBR1* may contribute to neuronal resistance to AD development.⁶⁹

To derive more functional insights, we conducted gene ontology analysis based on KEGG pathway database for the top 1000 CpGs associated with PM_{2.5} exposure or neuropathology markers.⁵⁰ Proline-rich AKT1 substrate 1 (*AKT1S1*) was one of the genes enriched in the longevity regulating pathway, an overlapping pathway between PM_{2.5} exposure and CERAD score. Of note, differential DNA methylation in cg00633834, which is assigned to *AKT1S1*, was also identified in HDMA. *AKT1S1* can activate mammalian target of rapamycin (mTOR)–mediated signaling pathways when phosphorylated,⁷⁰ and mTOR signaling was observed to have higher activity in AD brains, suggesting a role of *AKT1S1* in the accumulation of A β and tau proteins.⁷¹

The current analysis employed the MITM approach and HDMA simultaneously to maximize the potential of identifying the differentially methylated CpG sites lying on a pathway from PM_{2.5} to AD-related neuropathology. The application of the MITM approach was based on the investigation of epigenomics vs. PM_{2.5} exposures and AD-related neuropathology vs. epigenomics, which lent credibility to the association between PM_{2.5} exposure and AD-related neuropathology by breaking it down and linking it up with DNAm.⁷² Furthermore, while conventional methods of multiple testing correction (e.g., Bonferroni method) may overlook potential relevant CpG sites, especially given a small sample size, the MITM approach serves as a supplement by taking into account the biological relevance regardless of their statistical significance.⁷² However, the MITM approach assumes that all intermediate variables are independent, which is not always the case in real-world scenarios. The HDMA focuses more on

quantifying the indirect effect of the mediator and considers the potential correlation among mediators.⁴³ Admittedly, we did not observe many consistencies, except for cg16342341 (*SORBS2*), between the two approaches.

Our study has several strengths. We established for the first time a potential mediation effect of DNAm for the association between PM_{2.5} and neuropathological changes of AD. The neuropathological changes of AD were quantified via multiple markers, including Braak stage, CERAD score, and ABC score, which covers the essential components (i.e., NFTs and A β plaques) for the neuropathological diagnosis of AD. Further, the neuropathology markers were assessed by experienced neuropathologists at Emory Goizueta ADRC following a standardized protocol, which minimized the misclassification bias of outcomes. Finally, the high-resolution PM_{2.5} exposure assessment model enabled the characterization of spatial variation in individual exposure and reduced the potential measurement error.⁷³

Our study has several limitations. First, the temporal sequence between DNAm changes and AD neuropathology could not be clearly defined because both were assessed post-mortem. Second, traffic-related PM_{2.5} exposure was estimated based on the residential address of donors at death. Moving shortly prior to death could have introduced measurement errors in exposure assessment. The selection of exposure windows was arbitrary, as the disease process of AD may start many years before death and vary by patients. Third, the results were from a single brain bank and participants with a high APOE ϵ 4 carrier rate, so the generalizability should be tested in other brain banks or autopsy cohorts. Fourth, even though most of the study population was White, and we controlled for race, the ancestry effect on DNA methylation might

persist as residual confounding. Fifth, the current analysis only focused on the effects of PM_{2.5}, while other air pollutants such as nitrogen oxides or ozone might also play a role for AD.^{74,75} Finally, while the sample size of 159 brain samples was relatively large considering the challenges in collecting such samples, the high dimensionality of the genome-wide DNAm data raises concerns about the reliability of our findings.

Our findings provide important information on the biological mechanisms underlying the PM_{2.5} toxicity on AD pathogenesis. Future studies evaluating the mediating role of DNAm on AD-related outcomes should consider: 1) performing the analysis among early-stage AD patients or patients with mild cognition impairment to further illustrate the role of PM_{2.5} in AD etiology; 2) performing genome-wide DNAm together with transcriptomics, proteomics, and/or metabolomics to capture a holistic picture of the underlying mechanism.

Consent Statement

Written informed consent was provided for all subjects, and samples were obtained following research protocols approved by the Emory University Institutional Review Board.

Acknowledgements

We want to thank Dr. Jeremy A. Sarnat (Emory), Dr. Armistead Russell (Georgia Tech), Ms. Kyung-Hwa Kim and Ms. Abby Marinelli from the Atlanta Regional Commission for providing data and guidance towards the air pollution exposure assessment.

Conflicts

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Funding Sources

This work was supported by the HERCULES Pilot Project via NIEHS P30ES019776 (Huels), the Goizueta Alzheimer's Disease Research Center: Pilot Grant via NIA P50AG025688 (Huels/Liang), the Rollins School of Public Health Dean's Pilot and Innovation Grant (Huels), NIA R01AG079170 (Huels/Wingo). The air pollution exposure assessment was supported by the NIH grant R21ES032117 (Liang).

Key Words

Traffic-related fine particulate matter, Alzheimer's disease, neuropathology, DNA methylation.

Tables

Table 1. Selected population characteristics among the donors included in the current analysis.

	N=159
Age at death, mean (SD)	76.6 (9.98)
Sex, No. (%)	
Female	70 (44.0)
Male	89 (56.0)
Race, No. (%)	
Black	17 (10.7)
White	142 (89.3)
Educational attainment, No. (%)	
High school or less	36 (22.6)
College degree	76 (47.8)
Graduate degree or more	47 (29.6)
Area Deprivation Index, mean (SD)	36.3 (24.2)
Diagnosis of dementia	
AD	86 (54.1)
Other dementia	66 (41.5)
No dementia	7 (4.4)
APOE genotype	
No ϵ 4 allele	70 (44.0)
Single ϵ 4 allele	68 (42.8)
Two ϵ 4 allele	21 (13.2)
Postmortem interval (hours), mean (SD)	11.7 (9.68)
Proportion of neuronal cells (%), mean (SD)	31.9 (8.21)
Braak stage, No. (%)	
Stage 1	16 (10.1)
Stage 2	11 (6.9)
Stage 3	20 (12.6)
Stage 4	17 (10.7)

	N=159
Stage 5	22 (13.8)
Stage 6	73 (45.9)
CERAD score	
No	35 (22.0)
Sparse	4 (2.5)
Moderate	10 (6.3)
Frequent	110 (69.2)
ABC score	
Not	15 (9.4)
Low	29 (18.2)
Intermediate	22 (13.8)
High	93 (58.5)

Abbreviations: SD, standard deviation; AD, Alzheimer's disease; APOE, apolipoprotein E; CERAD, Consortium to Establish a Registry for AD; ABC, a combination of Amyloid, Braak stage, and CERAD (ABC) score.

Table 2. CpGs associated with traffic-related PM_{2.5} exposure prior to death and their association with neuropathology markers.

CpG	chr	Position	Gene		Coefficients ^a	p-values ^b
A. CpGs with PM_{2.5} exposures						
cg25433380	9	388,531	Intergenic	1-year exposure	0.0065	1.58×10 ⁻⁸
				3-year exposure	0.0066	5.82×10 ⁻⁹
				5-year exposure	0.0063	1.12×10 ⁻⁹
cg10495669	20	137,531,767	<i>RBCK1</i>	1-year exposure	0.0127	1.69×10 ⁻⁸
				3-year exposure	0.0128	1.78×10 ⁻⁸
				5-year exposure	0.0114	5.96×10 ⁻⁸
B. CpGs with neuropathology markers						
cg25433380	9	388,531	Intergenic	Braak stage	0.08	0.729
				CERAD	0.05	0.629
				ABC	0.04	0.825
cg10495669	20	137,531,767	<i>RBCK1</i>	Braak stage	0.02	0.929
				CERAD	0.12	0.397
				ABC	0.09	0.593

Abbreviations: PM_{2.5}, fine particulate matter; chr, chromosome; *RBCK1*, RanBP-type and C3HC4-type zinc finger-containing protein 1.

^a The coefficients for PM_{2.5} exposures represent the change in the beta values of CpG sites associated with one-unit increase in the exposures; the coefficients for neuropathology markers represent the change in the neuropathology markers associated with one-interquartile-range increase in the beta values of CpG sites.

^b The Bonferroni threshold: $0.05/789,286 \approx 6.33 \times 10^{-8}$.

Table 3. Indirect effect estimated by causal mediation analysis via the R package *mediation* of CpG sites selected by high-dimensional mediation analysis for the associations between PM_{2.5} exposure and ABC score ^a.

Abbreviations: PM_{2.5}, fine particulate matter; chr, chromosome; ACME, average causal mediated effect (i.e., indirect effect).

^a All CpG sites that were selected by *DACT* and had a positive ACME were associated with ABC score. No positive associations were found for Braak stage and CERAD score.

^b Only the exposure windows were shown for which significant indirect effects were found.

^c The *p*-values of mediation effect testing conducted by *DACT*.

^d The ACME was associated with one-interquartile-range increase in beta values of CpG sites.

^e Effect estimates, associated with 1-unit increase, of PM_{2.5} exposures on neuropathology markers.

Figures

(A) Map of Metropolitan Atlanta

1-year $PM_{2.5}$ exposure:

United States Highways:

Cities over 50,000 residents:

(B) Statistics of individual averaged annual $PM_{2.5}$ exposures

	$PM_{2.5}$ ($\mu\text{g}/\text{m}^3$)		
	1-year	3-year	5-year
Min	0.18	0.34	0.33
Median	1.21	1.32	1.39
Max	3.27	3.44	3.55
IQR	0.78	0.74	0.81

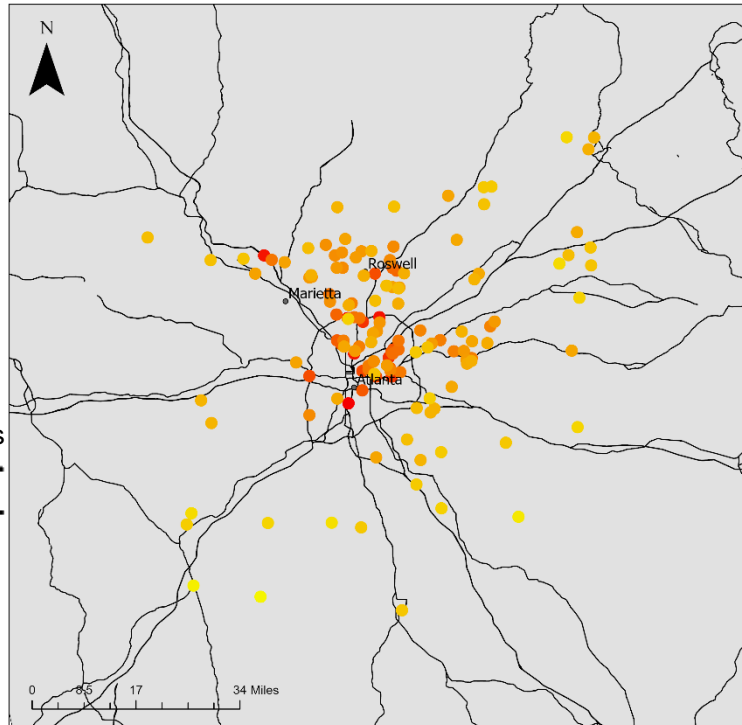

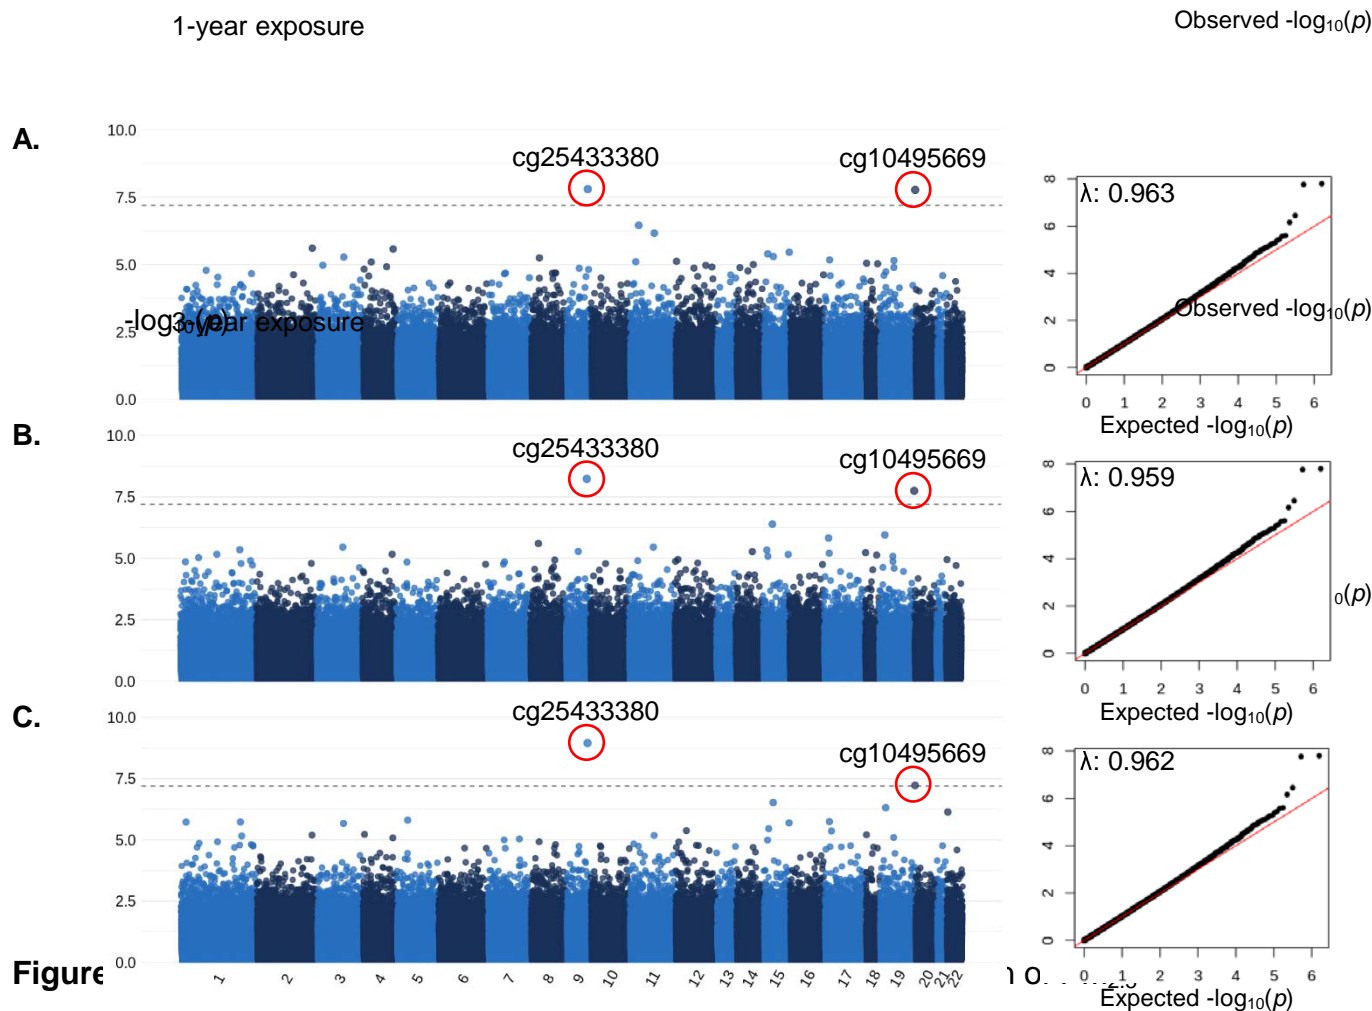

Figure 1. Statistics and distribution of $PM_{2.5}$ exposures in Metropolitan Atlanta (study area), Georgia, United States. (A) Map of Metropolitan Atlanta with individual 1-year averaged annual $PM_{2.5}$ exposure. The dots denote the donors' residential address and are colored according to their $PM_{2.5}$ exposures as showed in the legend. Red means a higher exposure level. (B) Statistics of individual averaged annual $PM_{2.5}$ exposures for 1 year, 3 years, and 5 years.

exposures (A. 1-year / B. 3-year / C. 5-year average exposure prior to death) and DNA methylation in postmortem frontal cortex tissue. λ denotes the inflation factor. Adjusted for covariates: age at death, sex, race, educational attainment, post-mortem interval, area deprivation index, and cell type composition. Unmeasured confounding and bias were adjusted with surrogate variable analysis and R package *Bacon*. Bonferroni threshold: $0.05/789,286$.
