Abstract

Measurable residual disease (MRD) in adults with acute myeloid leukemia (AML) in complete remission is an important prognostic marker, but detection methodology requires optimization. The persistence of mutated NPM1 or FLT3-ITD in the blood of adult patients with AML in first complete remission (CR1) prior to allogeneic hematopoetic cell transplant (alloHCT) has been established as associated with increased relapse and death after transplant. The prognostic implications of persistence of other common AML-associated mutations, such as IDH1, at this treatment landmark however remains incompletely defined. We performed testing for residual IDH1 variants (IDH1m) in pre-transplant CR1 blood of 148 adult patients undergoing alloHCT for IDH1-mutated AML at a CIBMTR site between 2013-2019. No posttransplant differences were observed between those testing IDH1m positive (n=53, 36%) and negative pre-transplant (overall survival: p = 0.4; relapse: p = 0.5). For patients with IDH1 mutated AML co-mutated with NPM1 and/or FLT3-ITD, only detection of persistent mutated NPM1 and/or FLT3-ITD was associated with significantly higher rates of relapse (p = 0.01). These data, from the largest study to date, do not support the detection of IDH1 mutation in CR1 blood prior to alloHCT as evidence of AML MRD or increased post-transplant relapse risk.

Introduction

Detection of measurable residual disease (MRD) prior to allogeneic hematopoetic cell transplant (alloHCT) in patients with acute myeloid leukemia (AML) in remission is associated with increased relapse and and worse survival after transplant¹⁻³. It has been recently reported that detection by ultra-sensitive next generation sequencing (NGS) of mutated *NPM1* or *FLT3*

internal tandem duplication (*FLT3*-ITD) persistence in first complete remission (CR1) blood is strongly associated with increased relapse and death compared to testing negative⁴. The genomic etiology of AML is heterogenous and well-described⁵ but the prognostic implication of detecting persistence of all common AML-associated mutations in cytomorphological complete remission remains incompletely defined. Variants in isocitrate dehydrogenase (*IDH*) genes are observed in around 20% of patients diagnosed with AML (7% for *IDH1*), with clinical outcomes reported to differ due to co-occurance of other mutations, *IDH* subtypes, treatment strategies, and patient factors⁶⁻¹⁰. Targeted therapy for *IDH1*-mutated AML is available, and an association between residual *IDH1* mutations and post-transplant clinical outcomes may help provide evidence regarding post-alloHCT maintenance approaches¹¹⁻¹⁴. Studies have examined the relationship between residual *IDH1* in CR and subsequent clinical outcomes^{15,16}, but definitive nation-level standardized evidence to inform decision making for the clinical utility of *IDH1* as a target for AML MRD testing was not previously available.

Methods

Adult patients (18 years or older) undergoing first alloHCT for *IDH1* mutated AML in CR1 at a Center for International Blood and Marrow Transplant Research (CIBMTR) site in the United States between 2013-2019 who participated in the CIBMTR data database (NCT01166009) or repository (NCT04920474) protocols, had an available remission blood samples collected within 100 days before alloHCT, and follow-up clinical data including relapse and survival were included in this study. Genomic DNA was extracted from remission blood and sequenced as described previously⁴. The day of transplant was considered as day 0. Median follow-up time

was calculated for censored patients. Overall survival (OS) was estimated by Kaplan-Meier (log rank tests) and Cox proportional hazards models (forward selection); cumulative incidence of relapse was examined by Fine-Gray regression models with non-relapse mortality as a competing risk. Additional details are provided in the supplement.

Results and Discussion

148 patients with *IDH1* mutated AML and undergoing alloHCT in CR1 at a CIBMTR reporting site between 2013 and 2019 were included in the study, with a median follow-up time of 24 months. Relapses were reported in 37 patients (25%), the majority occurring within 1 year after alloHCT (n = 28, 76%; supplemental Figure 1). Pre-transplant remission flow cytometry results were reported to the CIBMTR by the transplant centers for 97% of the patients (n = 144) with a positivity rate of 8% (n = 11). Although there were no statistically significant differences in clinical outcomes when comparing the positive and negative groups (OS: p = 0.3; relapse: p = 0.07; Figure 1A, supplemental Figure 2), patients testing positive by flow cytometry pre-transplant had a trend of higher cumulative incidence of relapse 6 months after alloHCT.

NGS MRD analysis identified residual *IDH1* mutations in the pretransplant remission blood of 53 (36%) patients at a median variant allele fraction (VAF) of 1.5% (range 0.09-48.5%), with a 100% validation rate by digital droplet PCR for the variants with an orthogonal assay available (supplemental Table 2, supplemental Figure 3). Logistic regression indicated that *IDH1* NGS-MRD positivity was more likely in patients older than 40yrs (OR: 1.02 with every 1-year increase after 40, p = 0.04). No statistically significant difference between the NGS-MRD *IDH1*

positive and negative groups in clinical outcomes was detected (Figure 1B, supplemental Figure 4A), which remained true after further subgroup analyses by age (supplemental Figure 4B) or when stratifying by high ($\geq 2.5\%$) or low VAF groups (<2.5%, supplemental Figure 4C).

Patients with *IDH1* mutated AML also often have mutations in *NPM1* and/or *FLT3*-ITD⁵. Our previous study focusing on patients with *NPM1* and/or *FLT3*-ITD mutated AML showed that patients with either of these mutations detected in CR1 prior to alloHCT had increased relapse and lower OS⁴. Within this cohort of *IDH1* mutated patients, we had information on the baseline mutational status of *NPM1* and *FLT3*-ITD, allowing for investigation into the impact of these co-mutations. A subset of 69 patients (47%) were co-mutated for *NPM1* and/or *FLT3*-ITD at baseline, and those with residual *NPM1* and/or *FLT3*-ITD mutations had higher rates of relapse rate compared to those with *IDH1* only or NGS-MRD negative groups (p = 0.01, 43% vs 11% or 15% at 2yr, Figure 2A, supplemental Figure 5A). The cohort excluding patients with baseline mutations *NPM1* and/or *FLT3*-ITD (n = 79, 53%) did not show any significant clinical outcome differences based on *IDH1* persistence (Figure 2B, supplemental Figure 5B).

We also examined the impact of the conditioning intensity regimens used for alloHCT in these patients and residual *IDH1* variants and saw no association with clinical outcomes (supplemental Figure 6). However, since assignment to conditioning regimen was not randomly assigned, there were more older patients (age > 60yrs) receiving reduced intensity (RIC)/non-myeloablative conditioning (NMA) compared with younger patients (71% vs. 21%; chi-square test: p < 0.001). Additionally, due to small sample size of the subgroups, there were insufficient number of patients to properly examine the interaction between age, conditioning intensity and residual *IDH1* mutations.

The goal of this study was to determine for AML patients the association between prealloHCT persistent *IDH1* mutations and post-transplant clinical outcomes. We show that the detection of persistent *IDH1* mutations in the blood of adult patients with AML in CR1 prior to first alloHCT is common and not associated with increased relapse or death after transplant compared to those testing negative. For patients with *IDH1* mutated AML co-mutated with *NPM1* and/or *FLT3*-ITD, detection of persistent *NPM1* and/or *FLT3*-ITD was associated with higher rates of relapse. These data, from the largest study to date, do not support the detection of isolated *IDH1* mutation in CR1 blood prior to alloHCT as evidence of AML MRD or increased post-transplant risk.
