## **Abstract:**

**Background:** Coronavirus disease 2019 (COVID-19) in solid organ transplant (SOT) patients is associated with more severe outcomes than non-immunosuppressed hosts. However, exactly which risk factors cause Long COVID in acute COVID cases remains unknown. More importantly, the impact of Long COVID on patient survival remains understudied, especially when examined alongside the effect of SOT.

**Methods:** All patients have been identified with acute COVID in the National COVID Collaborative Cohort registry from July 1, 2020, to June 30, 2022. We compared patient demographics in Long COVID vs. those without Long COVID based on descriptive statistics. Multivariable logistics regressions were used to determine the factors related to the likelihood of developing Long COVID from a case of acute COVID. Multi-variables Cox regression was used to determine the time-to-event outcome of patient survival with Long COVID.

**Results:** This study reviewed data from a cohort of 6,416,500 acute COVID patients. Of that group, 31,744 (0.5%) patients developed Long COVID from ICD diagnosis. The mean (q1, q3) age was 39 (22, 57) years old, and 55% of patients were female. From this cohort, a total of 31,744 (1%) developed Long COVID and 43,565 (1%) had SOT, with a total of 698 SOT patients identified with Long COVID. Mean age of those with Long COVID was 52 (39, 64) years old and 64% of patients were female. Most of the SOT patients were kidney transplant recipients. From the Cox regression analysis of patient survival, there were many significant factors related to patient survival (death), with elderly SOT patients having a much higher hazard ratio of 27.8 (26.3, 29.4).

**Conclusion:** This study has identified the important risk factors that are more likely to cause Long COVID in an acute COVID cohort. We investigated hazard ratios of patient survival based on multivariable Cox models, which found that Long COVID had a more direct impact on survival in elderly patients and those with SOT.

**Keywords:** Acute COVID, Long COVID, Solid Organ Transplantation, Odds Ratio, and Patient Survival.

## Introduction

Long COVID, also known as post-COVID conditions (PCC) or post-acute sequelae of COVID-19 (PASC), is the common term used to describe signs and symptoms that last for longer than four weeks after cases of acute COVID-19. Long COVID is a novel syndrome that is broadly defined by the persistence of physical, psychological, or cognitive symptoms following a probable or confirmed SARS-CoV-2 infection. Available evidence suggests that Long COVID is a substantial public health problem with severe consequences for affected individuals and society at large. Patients commonly report being emotionally affected by health problems related to Long COVID. In the United States, patients have reported mild to severe financial impacts related to COVID-19 in multiple studies<sup>1,2,3</sup>. This concern is underlined by reports that Long COVID patients experience increased disability related to breathlessness and decreased quality of life<sup>4</sup>. Understanding the needs of these patients will allow for the development of healthcare, rehabilitation, and other resources needed to support their recovery<sup>5,6</sup>.

The COVID-19 pandemic's impact on solid organ transplantation (SOT) recipients has been reflective. The SOT patients with COVID-19 appear to be at higher risk of severe outcomes based on their chronically immunosuppressed state and underlying medical comorbidities<sup>7,8,9</sup>. Most SOT patients have one or several associated risk factors for severe COVID-19 or death, such as hypertension, cardiovascular disease, and chronic kidney disease. Hence, some studies reported that SOT patients had a higher COVID-19-related mortality rate than non-transplant patients<sup>3,10,11</sup>. Due to the novelty of COVID-19, there is a lack of data regarding many aspects, including its natural course within immunocompromised hosts, the utility of current treatment regimens employed in non-transplant individuals for SOT patients, and the effect of immunosuppression on the course of the disease<sup>12,13</sup>. Even though comorbidities, such as obesity, have been reported as risk factors for severe disease<sup>14</sup>, an immunocompromised state has not yet been proven to have a worse clinical outcome than SARS-CoV-2 infection. However, SOT patients with Long COVID are particularly unknown due to a high prevalence of underlying chronic kidney disease, diabetes mellitus, hypertension, and calcineurin inhibitor (CNI) use.

Therefore, this retrospective cohort study was conducted using data available from the National COVID Cohort Collaborative (N3C) program to address these research questions. This study aimed to synthesize existing evidence on the demographics, comorbidities, and SOT aspects of the incidence of Long COVID and patient survival in acute COVID-19 patients, as well as its prevalence. Information from this study could be used to impact transplant patients with long COVID and acute COVID by identifying gaps in demographics and clinical characteristics within the study period. We will identify the impact and potential risk factors for the Long COVID event and SOT effect, and address patient survival in those with Long COVID.

## **Patients and Methods**

### **Data resource**

The N3C Data Enclave is a secure platform through which the clinical data provided by contributing members is stored in a centralized, secure format. The N3C platform is a multi-center, federated research network in the United States that provides real-time access to de-identified healthcare record data of more than 16 million patients from participating healthcare organizations. The data itself can only be accessed through a secure cloud portal hosted by NCATS and cannot be downloaded or removed.

The retrospective cohort study was conducted using data from the N3C platform, as it is a health record repository containing the largest, most representative U.S. cohort of COVID-19 cases and controls to date. In the real-time search, the source data were collected as part of routine healthcare and is historical in nature. The data was extracted and analyzed using Python, SQL, and R in the N3C platform. The study evaluated pre-existing medical conditions, and the research included all patients with acute COVID.

The acute COVID patients were determined *a priori* and included patient demographics, such as age, race, sex, type of organ transplant (multiple transplantations, kidney transplantation, liver transplantation, heart transplantation, lung transplantation, and other/unknown transplantations), and comorbidities (hypertension, diabetes, asthma, malignant cancer, coronary artery disease, congestive heart failure, and peripheral vascular disease).

## **Statistical Analyses**

We used descriptive statistics, such as mean (SD) or median (q1 and q3), as appropriate to report the baseline demographic and clinical characteristics by subgroups, where all patients were stratified by whether they had developed Long COVID or not. Counts and percentages for demographic and clinical characteristics were used in the study population to describe categorical variables. The odds ratio of whether receiving a Long COVID event was determined based on multivariable logistic regressions. Finally, the following co-variables, including age (i.e., < 19, 19–34, 35–49, 50–64, and 65+ years), sex subgroups, and transplant type (multiple, kidney, heart, lung, liver), were used in Cox regression models for patient survival outcome. The results of the Cox regression analyses were displayed using hazard ratios (HRs) and 95% confidence intervals (CIs). P-values lower than 0.05 were considered statistically significant in the statistical models.

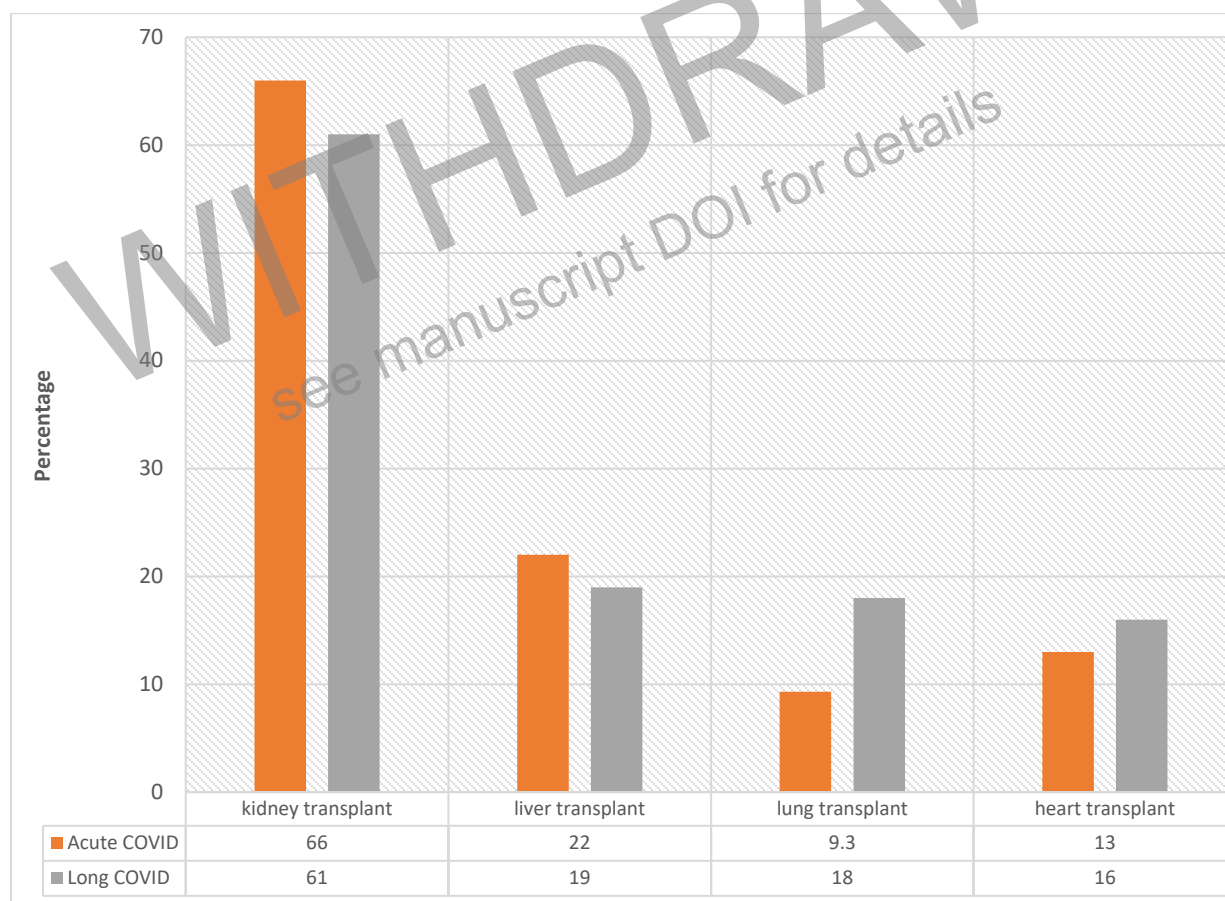

## **Results**

### **Patient Demographic**

The time period in this study was chosen from July 1<sup>st</sup>, 2020, to June 30<sup>th</sup>, 2022. A total of 6,416,500 patients were found to have acute COVID, with a subset of 31,744 (0.5%) of those patients developing Long COVID (from ICD diagnosis) and 43,565 (1%) having had a SOT. The mean (q1, q3) age was 39 (22, 57) years old, and 55% of patients were female. A total of 698 individuals were identified to be transplant patients with Long COVID. The demographic comparison of these patients is shown in Table 1. Hypertension before COVID indicators, diabetes before COVID indicators, congestive heart failure before and post COVID indicators, coronary artery disease before and post COVID indicators, and peripheral vascular disease before and post COVID indicators were all common comorbidities; however, these were significantly more common in those who developed Long COVID.

Those who had acute COVID were significantly more likely to be kidney transplant recipients relative to other organ transplant types (58% of acute COVID versus 51% of Long COVID SOT patients

had a kidney transplant, P value < 0.001) because most SOT patients are kidney transplant recipients. It is interesting to find that liver transplant recipients had 15% of acute COVID versus 9.8% of Long COVID (P value < 0.001). Conversely, lung (7.0% vs. 13.0%, P value < 0.001) and heart (10% vs. 13.0%) transplant recipients made up a smaller proportion of those patients with acute COVID than those with Long COVID. The categorical transplant variables include kidney transplant (61%) as the highest of the transplants, followed by liver transplant (19%), lung transplant (18%), and heart transplant (16%), as shown in Figure 1.

**Figure 1:** Among SOT transplants with acute COVID and long COVID, most patients are kidney transplant recipients. But the number of lung transplant patients with Long COVID was double the number of lung transplant patients with acute COVID.

All patients for comorbidities reported whether there was a statistical difference based on P-values. Hypertension, diabetes, coronary artery disease, peripheral vascular disease, and congestive heart failure

were common comorbidities in the SOT cohort, but were significantly more common in those who had Long COVID and acute COVID.

Further analysis in more recent cohorts can be done through some sensitivity analysis by the inclusion of acute COVID without Long COVID individuals matched by age, sex, and race.

### **Results from Statistical Models**

In the acute COVID cohort, results of the logistics regression analysis of long-term COVID is shown in Table 2, with a higher odds ratio (OR) of Long COVID present amongst patients older than 65 years (OR:1.73, 95% CI: 1.66–1.81), with hypertension (OR: 1.36, 95% CI: 1.32–1.40), with diabetes (OR: 1.09, 95% CI: 1.05–1.14), with asthma (OR:1.85, 95% CI: 1.79–1.91), with malignant cancer (OR: 1.12, 95% CI: 1.07–1.16), with congestive heart failure (OR: 1.27, 95% CI: 1.22–1.32), with peripheral vascular disease (OR: 1.02, 95% CI: 0.96–1.07), and with dementia (OR: 1.18, 95% CI: 1.08–1.29). The results of patient survival from the Cox regression models are shown in Table 3. Females were less likely to die, as seen by the hazard ratio (HR = 0.69; 95% CI: 0.68–0.70) while adjusting for Male patients. The HR of age categories ranged from 2.74 in patients aged < 19 years (95% CI: 2.57–2.92) to 27.8 in elderly patients over 65 years old (95% CI: 26.3–29.4). The detrimental effect of Long COVID in elderly SOT patients can be observed as the hazard ratio was so high at 27.8 (26.3, 29.4).

### **Conclusion and Discussion**

This study utilizes the largest, most representative U.S. cohort of COVID-19 cases and controls to date, evaluating the risk of Long COVID and patient outcomes from patients with acute COVID. In this cohort of patients followed over a two-year period, 1% developed Long COVID and 2% had SOT. The long COVID is a big concern for all individuals who have been infected with acute COVID. The risk factors for developing Long COVID, are not yet fully understand, several kay factors that may increase the risk of developing Long COVID in individuals who have had acute COVID, such as age and comorbidity. For individuals who have undergone organ transplantation, the risk of developing long COVID may be higher due to their immunosuppressed state. One potential concern is the impact of long COVID on the

transplanted organ. The long COVID is affecting the function of transplanted organs, particularly the lungs and the kidneys. Advanced age and having had a transplant were associated with an increased impact on patient survival.

This study identified risk factors for developing Long COVID from an acute COVID. We also investigated hazard ratios of patient survival based on multivariable Cox models. From this, we find that elderly SOT patients were much more likely to die from Long COVID. For individuals who have undergone organ transplantation, the risk of patient survival is much higher may be due to their immunosuppressed state. Immunosuppressive medications are used to prevent rejection of the transplanted organ, but they can also weaken the immune system, making it more difficult to fight off infections. Furthermore, individuals who have undergone organ transplantation may have pre-existing conditions that put them at higher risk for long COVID infection, such as diabetes, hypertension, and Peripheral vascular disease. Therefore, it is important for individuals who have undergone organ transplantation to take all necessary precautions to prevent COVID infection.

Finally, there may be environmental, lifestyle factors, and a genetic component that contribute to the risk of developing long COVID. Therefore, the risk factors for long-term COVID-19 are still being studied. More research is needed to fully understand the risk factors and to develop effective treatments for those who develop Long COVID in the future.

Table 1: Patient demographics and clinical characteristics among Long COVID patients versus acute COVID patients without Long COVID

Characteristic variables	Overall	Acute COVID without Long COVID	Long COVID	P value
Gender				<0.001
Male	2872550 (45%)	2861210 (45%)	11340 (36%)
