28 Abstract

- 29 Aberrant brain network development represents a putative aetiological component in mental
- 30 disorders, which typically emerge during childhood and adolescence. Previous studies have
- 31 identified resting-state functional connectivity (RSFC) patterns reflecting psychopathology,
- but the generalisability to other samples and politico-cultural contexts has not been
- 33 established.
- 34 We investigated whether a previously identified cross-diagnostic case-control and
- autism spectrum disorder (ASD)-specific pattern of RSFC (discovery sample; aged 5-21 from

36 New York City, USA; n=1666) could be validated in a Norwegian convenience-based youth

- 37 sample (validation sample; aged 9-25 from Oslo, Norway; n=531). As a test of
- generalisability, we investigated if these diagnosis-derived RSFC patterns were sensitive tolevels of symptom burden in both samples, based on an independent measure of symptom
- 40 burden.
- 41 Both the cross-diagnostic and ASD-specific RSFC pattern were validated across
- 42 samples. Connectivity patterns were significantly associated with thematically appropriate
- 43 symptom dimensions in the discovery sample. In the validation sample, the ASD-specific
- 44 RSFC pattern showed a weak, inverse relationship with symptoms of conduct problems,
- 45 hyperactivity, and prosociality, while the cross-diagnostic pattern was not significantly linked46 to symptoms.
- 47 Diagnosis-derived connectivity patterns in a developmental clinical US sample were
 48 validated in a convenience sample of Norwegian youth, however, they were not associated
 49 with mental health symptoms.
- 50

51 1 Introduction

52 Childhood and adolescence constitute periods of life characterised by substantial

53 developmental adaptations. These include rapid physical, hormonal, brain, cognitive, and

- 54 psychological changes, adapted to the increasing complexity of our social environment and
- 55 expectations with age. For example, during this time, the functional networks of the brain
- undergo large-scale reorganisation and maturation (Paus et al., 2008; Power et al., 2010;
- 57 Sydnor et al., 2021). Adolescence is also a period with a marked increase in the incidence of
- 58 psychopathology (Kessler et al., 2007). The co-occurrence of these phenomena has led to the
- 59 hypothesis that increased brain plasticity during this period results in increased susceptibility
- 60 to mental illness (Paus et al., 2008). Several studies have identified plausible links between
- 61 psychopathology in youth and resting-state functional connectivity (RSFC) derived from
- 62 functional magnetic resonance imaging (fMRI). However, the generalisability of such
- network patterns to vulnerability for mental illness in non-clinical samples is currently notwell demonstrated.

In the context of generalisability and vulnerability, a related question is whether 65 RSFC patterns are specific to diagnostic categories of mental disorders or shared across 66 67 disorders. Considerable effort has been made to characterise RSFC patterns associated with 68 both diagnostic syndromes and dimensional symptom scores. Transdiagnostic patterns can be identified by including participants with a range of (comorbid) diagnoses, or by modelling 69 70 dimensional scores of multiple symptom domains. Using these approaches, an increasing number of studies have reported that RSFC patterns relating to psychopathology are 71 transdiagnostic or shared across disorders (Elliott et al., 2018; Karcher et al., 2021; Kebets et 72 al., 2023; Lees et al., 2021; Linke et al., 2021; McTeague et al., 2017; McTeague et al., 2020; 73 74 Sha et al., 2019; Voldsbekk et al., 2023; Xia et al., 2018). For example, in a population-based sample of children (Adolescent Brain Cognitive Development cohort; ABCD), a shared 75 76 psychopathology factor was derived and linked to RSFC using both symptom data (Karcher 77 et al., 2021) and diagnostic data (Lees et al., 2021).

78 The convergence of studies on a shared factor across disorders from studies using 79 both symptom scores as well as binary diagnosis information supports the notion of a latent vulnerability factor on which the diagnostic categories represent extremes (Sprooten et al., 80 81 2022). The above-mentioned findings linking a shared latent mental illness factor to brain 82 measures are promising with regard to detecting neural signatures of psychopathology risk in the youth brain. However, an important question is whether these clinical RSFC patterns are 83 sensitive to symptom burden and by extension putative risk in youth samples that are not 84 enriched with mental disorder diagnoses. 85

Recently, we estimated both diagnosis-specific and cross-diagnostic RSFC patterns in 86 87 a clinical developmental sample. Investigating shared associations across RSFC data and diagnostic information, we identified a pattern specific to a diagnosis of autism spectrum 88 89 disorder (ASD). The other diagnosis categories did not exhibit a significant specific RSFC 90 pattern, instead they exhibited a shared patterns across attention-deficit hyperactivity disorder (ADHD), ASD, other neurodevelopmental disorders, anxiety, mood-disorders, and other 91 diagnoses versus no diagnosis (Voldsbekk et al., 2023). A possible interpretation of this 92 finding is that cross-diagnostic and ASD-specific patterns represent the two most reliable 93 94 RSFC markers of psychopathology. For any such patterns to be clinically relevant, they

- 95 would need to show generalisability to vulnerability for mental illness, expressed as elevated
- clinical symptom scores, in non-clinical samples. Thus, in the current study we aimed to 96
- 97 investigate whether the two identified diagnosis-derived RSFC patterns are sensitive to
- mental health symptoms in a Norwegian convenience-based sample of youth. To do this, we 98
- 99 investigated whether a) the cross-diagnostic and ASD-specific RSFC patterns previously
- identified could be validated in the validation sample, and b) if these RSFC patterns associate 100
- with levels of symptom burden in the validation sample. As a further test of external validity, 101
- 102 we also tested whether c) the RSFC patterns previously identified associate with levels of
- 103 symptom burden in the discovery sample.
- 104

105 2 Material and Methods

106 2.1 Samples

2.1.1 Discovery sample - HBN 107

Children and adolescents from New York City, USA were recruited to be part of the HBN 108 cohort (Alexander et al., 2017). The majority have a least one diagnosed mental disorder. In

- 109 the previous study (Voldsbekk et al., 2023), 1880 participants in HBN took part. 1689 of
- 110
- these were in the discovery sample. Of these, 1666 had available symptom score data used 111
- 112 for the current investigation. Missing values in the symptom data were imputed with
- knnimpute in MATLAB (MathWorks, 2020). To check that imputation did not influence the 113
- results, we reran the analysis in the 1610 participants without missing data and no imputation. 114
- This analysis revealed similar associations between RSFC and symptom level as the original 115 analysis (correlations were r=.99 between imputed and non-imputed result for both the cross-116
- diagnostic and ASD patterns). For more details regarding MRI data cleaning and quality 117
- assurance steps, see Voldsbekk et al. (2023). The final sample consisted of 1666 participants 118
- (641 females, mean \pm sd age: 10.91 \pm 3.14, range: 5-21). See Figure 1 and table S1 for 119
- distributions of sample characteristics. 120
- 121

122 2.1.2 Validation sample – Brainmint

- Children and adolescents in the Oslo region were recruited to participate in the Brains and 123
- minds in transition (Brainmint) study. Participants were recruited through convenience 124
- 125 sampling by advertising in social media, aiming to recruit young people from the general
- population interested in contributing to a study investigating brain development and mental 126
- health. All participants provided written informed consent prior to their participation in the 127
- study. For participants under the age of 16, both parents/legal guardians provided written 128
- informed consent on their behalf. Per May 4th 2023, 759 participants had undergone magnetic 129
- resonance imaging (MRI) and 697 had responded to questionnaires. Of these, 531 had 130
- available both fMRI and symptom score data. No participants had missing data and so all 131
- were included in the sample used for the current analysis (390 females, mean \pm sd age: 17.69 132
- 133 \pm 2.83, range: 9-25). See Figure 1 and table S1 for distributions of sample characteristics.
- 134
- 2.2 Mental health measures 135
- In the previous study (Voldsbekk et al., 2023), we investigated diagnosis-derived patterns of 136
- RSFC in HBN (discovery sample). Diagnostic information was collected using a 137
- 138 computerised version of the Schedule for Affective Disorders and Schizophrenia - Children's

- 139 version (KSADS) (Kaufman et al., 1997), which is a clinician-administered semi-structured psychiatric interview based on DSM-5. We then labelled diagnoses as belonging to either of 140
- these categories: "ADHD", "ASD", "anxiety disorders", "mood disorders", "other 141
- neurodevelopmental disorders", "other disorders" or "no diagnosis". 142
- 143 For testing the external validity and generalisability of diagnosis-derived RSFC patterns, the current study obtained HBN symptom scores from the Strength and Difficulties 144
- Questionnaire (Goodman, 1997), which is a 25-item questionnaire measuring emotional and 145
- behavioural problems. The SDQ has five syndrome measures: emotional symptoms, conduct 146
- problems, hyperactivity/inattention, peer relationship problems, and prosocial behaviour. For 147
- this analysis, we used only the summary syndrome measures. In HBN, the SDQ items were 148
- parent-reported. See Figure S1 for symptom load distributions on SDQ summary measures 149
- across diagnostic categories in HBN. 150
- Symptom scores in Brainmint were investigated using the same approach as in HBN, 151 only in this sample the SDQ responses were self-reported. 152
- 153

Figure 1. Sample distributions. A. Age. B. Sex. C. SDQ summary syndrome scores. HBN; Healthy 155 brain network sample. Brainmint; Brains and minds in transition sample. SDQ; Strengths and 156

- 157 difficulties questionnaire.
- 158
- 159 2.3 MRI acquisition
- 160 HBN MRI data were acquired at four different sites: a mobile scanner at Staten Island (SI),
- Rutgers University Brain Imaging Centre, Citigroup Biomedical Imaging Centre (CBIC) and 161

Harlem CUNY Advanced Science Research Centre. A detailed overview of the MRI protocolis available elsewhere

(http://fcon_1000.projects.nitrc.org/indi/cmi_healthy_brain_network/MRI%20Protocol.html).
Brainmint MRI data were acquired at Oslo University Hospital Ullevål, using a 3.0 T
GE SIGNA Premier scanner using a 48-channel head coil. Structural MRI data was acquired
using an T₁-weighted MPRAGE sequence (repetition time (TR): 2.526 s, echo time (TE):
2.836 ms, flip angle (FA): 8°, field of view (FOV): 256 mm), slice thickness: 1 mm, locations

- 169 per slab: 196 (no overlaps). Resting-state functional MRI (rs-fMRI) data was acquired using
- a T2*-weighted blood-oxygen-level-dependent echo-planar imaging (EPI) sequence with a
- 171 TR of 800 ms, TE of 30 ms, multiband acceleration factor = 6, number of slices: 60, 750
- 172 repetitions and voxel size = $2.4 \times 2.4 \times 2.4$ mm.
- 173
- 174 2.4 MRI pre-processing

175 Rs-fMRI images in HBN were processed with the following pipeline. First, FSL MCFLIRT

- 176 (Jenkinson et al., 2002) was applied for motion correction, as well as high-pass temporal
- 177 filtering (cut-off: 100s), spatial smoothing (FWHM: 6mm) and distortion correction as part of
- 178 FEAT (Woolrich et al., 2001). The rs-fMRI images were registered to a T1-weighted
- 179 structural image using FLIRT (Jenkinson et al., 2002) and boundary-based registration
- 180 (Greve & Fischl, 2009). Next, for additional removal of artefacts and noise, we performed
- 181 non-aggressive ICA-AROMA (Pruim, Mennes, Buitelaar, et al., 2015; Pruim, Mennes, van
- 182 Rooij, et al., 2015) and FIX (Griffanti et al., 2014; Salimi-Khorshidi et al., 2014). Estimations
- 183 of temporal signal-to-noise ratio (tSNR) and mean framewise displacement (FD) were
- 184 calculated by MRIQC (Esteban et al., 2017) and used as covariates in subsequent analyses.

In Brainmint, preprocessing of rs-fMRI images were run using fMRIPrep v22.0.1
(Esteban et al., 2019), an automated pipeline consisting of head motion correction, high-pass
temporal filtering, spatial smoothing and distortion correction using MCFLIRT, slice-timing
correction using 3dTshift from AFNI, registration to structural reference image using FLIRT
and boundary-based registration, and, finally, non-aggressive ICA-AROMA. Same as for
HBN, estimations of tSNR and FD were calculated by MRIQC (Esteban et al., 2017).

- 191
- 192 *2.5 Network analysis*

193 RSFC in HBN were derived using the Schaefer parcellation with 100 parcels and 7 networks

194 (Schaefer et al., 2018). These networks include visual A, visual B, visual C, auditory,

- 195 somatomotor A, somatomotor B, language, salience A, salience B, control A, control B,
- 196 control C, default A, default B, default C, dorsal attention A and dorsal attention B. The
- 197 connectivity matrix was then estimated as the L2-norm ridge regression partial correlation
- 198 between parcel timeseries using FSLNets (<u>https://fsl.fmrib.ox.ac.uk/fsl/fslwiki/FSLNets</u>), as
- implemented in MATLAB (MathWorks, 2020). This resulted in 4950 unique partialcorrelations (i.e., edges).
- 201 RSFC in Brainmint were derived using the same approach as in HBN, making the202 edges comparable.
- 203
- 204 2.6 Out-of-sample validation

- In the previous work (Voldsbekk et al., 2023), we investigated diagnosis-specific RSFC 205
- patterns by running non-rotated behavioural partial least squares (PLS) in PLS Application 206
- (Krishnan et al., 2011). Non-rotated behavioural PLS yields maximal covariance across two 207
- 208 matrices without rotating the behavioural matrix – in this case, maximal RSFC covariance
- 209 across each diagnosis (a behavioural matrix containing either 1 or 0 for each participant for
- each diagnosis category). This test was run for each diagnosis category separately, while 210
- controlling for all other diagnosis categories using contrasts. This analysis revealed an ASD-211
- 212 specific pattern, as well as a cross diagnostic case-control pattern. The other diagnosis
- 213 categories did not exhibit a diagnosis-specific RSFC pattern.
- 214
- 2.6.1 Out-of-sample validation 215
- See Figure 2 for an overview of the out-of-sample validation pipeline. First, we decomposed 216
- the Brainmint RSFC data by multiplying them with the brain weights estimated in the HBN 217
- PLS analysis. These Brainmint brain weights were then correlated with the original 218
- Brainmint RSFC data to get Brainmint connectivity loadings. Then, to assess the validation 219
- of the brain pattern across the two samples, we correlated the Brainmint connectivity 220
- loadings with HBN connectivity loadings for each latent variable (LV) using Pearson's 221
- 222 correlation. Their significance was tested using permutations (n=1000), randomly
- shuffling the rows (participants) of the Brainmint RSFC data. We calculated *p*-values by 223
- dividing the count of permuted maximum R values (including the observed non-224
- permuted value) \geq the non-permuted R values by the number of permutations. Prior to 225
- 226 analysis, Brainmint RSFC data was adjusted for age, sex, tSNR and FD, same as HBN RSFC
- data prior to running PLS. This was done by using FSLNets' "nets unconfound" in 227
- MATLAB (MathWorks, 2020). As a proxy for significance, connectivity loadings were 228
- thresholded at Z-scores<|3| in visualisations, akin to the procedure in our previous work using 229 230 PLS.

- Figure 2. An overview of the out-of-sample validation pipeline. RSFC; resting-state functional 233
- connectivity. HBN; Healthy brain network sample. Brainmint; Brains and minds in transition sample. 234

235

2.6.2 Testing the association of the brain pattern with symptom scores 236

237 To assess whether the brain pattern was associated with symptom scores, we correlated the derived Brainmint RSFC pattern with Brainmint symptom data. Specifically, we investigated 238 the Spearman's rank correlation between diagnosis-derived brain weights and symptom 239 240 dimensions from SDQ. To assess the reliability of the associations between brain weights and symptom dimensions, we ran 1000 bootstraps using resampling with replacement. Reliability 241 242 was defined as whether bootstrapped (with replacement) 95% confidence interval overlapped with zero (i.e., not overlapping with zero being considered reliable). Finally, as a test of 243 244 external validity, we also ran these correlations between the HBN RSFC pattern and SDQ

- symptom dimensions in HBN. 245
- 246

247 **3 Results**

248 The correlation between Brainmint and HBN connectivity loadings was significant for both

- the cross-diagnostic pattern (r=.39, permuted p < .001; see Figure 3A) and ASD (r=.49, 249
- permuted p < .001; see Figure 4A), indicating that both brain patterns were validated across 250
- 251 samples. As shown in Figure 3B, the cross-diagnostic RSFC pattern implicated weaker
- 252 connectivity within the control network, in addition to weaker between-network connectivity
- between the salience network and control network, as well as between the default mode 253
- 254 network (DMN) and limbic network. In terms of symptom dimensions, this connectivity
- 255 pattern exhibited significant positive associations with anxiety, conduct problems,
- hyperactivity, and peer problems in HBN, as well as a negative association with prosocial 256
- 257 behaviour (see Figure 3C). In Brainmint, there were no significant associations between the cross-diagnostic connectivity pattern and symptom dimensions (see Figure 3D). 258
- As shown in Figure 4B, the RSFC pattern for ASD implicated weaker within-network 259 connectivity in the somatomotor network, dorsal attention (DA) network, salience network 260 261 and DMN. In terms of symptom dimensions, this RSFC pattern was significantly associated with more symptoms of peer problems and hyperactivity in HBN, as well as lower degree of 262 conduct problems and prosociality (see Figure 4C). In Brainmint, the ASD-specific RSFC 263 pattern was associated with higher levels of prosocial behaviour and fewer symptoms of 264
- 265 hyperactivity and conduct problems (see Figure 4D).
- 266

292

293 **4** Discussion

The current study aimed to investigate whether psychopathology-related RSFC patterns are 294 295 informative of vulnerability for mental illness in undiagnosed individuals by validating

connectivity patterns derived in a developmental clinical sample from the US in a Norwegian 296

convenience-based sample of youth. However, the RSFC pattern was only sensitive to 297 symptom burden in the discovery sample. Specifically, we found that the RSFC patterns were

298 299 associated with symptom dimensions thematically overlapping with core symptom

- characteristics in the discovery sample, while in the validation sample we found a weak, 300
- inverse relationship for ASD. This latter association was small at the group-level, with great 301
- variation at the individual level. Taken together, these results show that although diagnosis-302

derived RSFC patterns replicate across samples, their utility is greatly limited due to theirlack of sensitivity to symptom burden.

Replicability and generalisability of neuroimaging findings remain a challenge in the 305 field (Botvinik-Nezer & Wager, 2022). Historically, small sample sizes and lack of 306 methodological rigour have resulted in poor replication rates, possibly reflecting that many 307 published findings are potential false positives (Ioannidis, 2005). To overcome such 308 challenges, increasing effort has been put into developing procedures for reproducible 309 310 science (Niso et al., 2022). With the advent of multivariate machine learning approaches in neuroscience, issues related to statistical power and extensive univariate testing in small 311 samples have been improved (Botvinik-Nezer & Wager, 2022). However, these multivariate 312 approaches come with new challenges, such as data leakage, overfitting and the need for 313 sufficiently large data sets to ensure robustness (Botvinik-Nezer & Wager, 2022; Davatzikos, 314 2019; Poldrack et al., 2020; Varoquaux, 2018). Although the current study aimed to 315 316 overcome some of these challenges, we still did not obtain generalisable results.

Generalisation of RSFC patterns related to psychopathology has been hampered by 317 challenges related to the stability and reliability of RSFC results, as well as variations in 318 319 mental health profiles across cohorts (Uddin et al., 2017). Data driven approaches to symptom clustering have to some degree yielded reproducible clusters or hierarchies of 320 symptom structure across samples (Caspi et al., 2014). Recently, we derived brain-based 321 latent dimensions of psychopathology using symptom covariance with functional brain 322 networks in HBN (Voldsbekk et al., 2023). Similar brain-based dimensions of 323 psychopathology were identified in ABCD, combining measures of both brain structure and 324 RSFC (Kebets et al., 2023). By decomposing the HBN data using feature weights estimated 325 in ABCD from Kebets et al., we found that the symptom dimensions replicated, however the 326 RSFC patterns did not (Voldsbekk et al., 2023). Previous attempts at replication of brain-327 symptom mapping in independent samples have shown similar findings of replicating latent 328 329 clinical dimensions, but weak or non-replicable RSFC patterns (Linke et al., 2021). In light of 330 this, it is surprising that the current study could validate diagnosis-based case-control and ASD-specific RSFC patterns from HBN to Brainmint. Of course, the validated RSFC pattern 331 was not fully overlapping across the two cohorts. For example, notable differences can be 332 333 observed in the higher connectivity profile associated with the cross-diagnostic pattern, in which HBN is exhibiting a greater number of networks involved compared to Brainmint. In 334 addition, the clinical associations of this pattern in the discovery sample were not reproduced 335 336 in the validation sample.

The current validation effort is conducted across two widely different samples, both in 337 terms of age, sex distribution, and other demographical variables, and in their mental health 338 339 profile. While the HBN sample consists of mainly children with diagnosed neurodevelopmental disorders, the Brainmint sample consists of adolescents recruited from 340 341 the community. Some of these adolescents have elevated symptom burden and may meet the diagnostic criteria of a mental disorder, but this sample is not enriched with diagnoses as is 342 the case with HBN. The symptom distribution is also different, with higher prevalence of 343 anxiety symptoms in Brainmint, as compared to conduct problems and peer problems in 344 HBN. In line with this, there is also a marked difference in the sex distribution across the two 345 346 samples, with higher prevalence of males in HBN and the majority being female in

Brainmint. Given these differences, it is all the more striking that the RSFC patterns were
validated. Concomitantly, this may also explain the difference in clinical associations. One
possible explanation could be that the RSFC patterns do reflect some vulnerability to
psychopathology, only it is not sensitive enough to be associated with mental health

351 symptoms in a widely different sample.

352 Prior work seem to converge on the finding that RSFC patterns relating to psychopathology are transdiagnostic or shared across disorders (Elliott et al., 2018; Karcher 353 et al., 2021; Kebets et al., 2023; Lees et al., 2021; Linke et al., 2021; McTeague et al., 2017; 354 McTeague et al., 2020; Sha et al., 2019; Voldsbekk et al., 2023; Xia et al., 2018). This would 355 suggest that if anything, RSFC patterns represent possible general markers of 356 psychopathology rather than disorder-specific markers. This has implications for their utility 357 as biomarkers, meaning RSFC patterns may be used to detect general vulnerability, but not 358 vulnerability specific to specific disorders. In line with this, a recent systematic review based 359 360 on studies only of the general population conclude that general psychopathology is related to various RSFC patterns across studies (Hoy et al., 2023). With regards to specific 361 psychopathology, there was only one finding reported across more than one study, namely an 362 363 association between a neurodevelopmental symptom dimension and lower connectivity within the DMN (Karcher et al., 2021; Modabbernia et al., 2022). These findings are 364 strikingly consistent with our previous work in HBN – a developmental clinical sample 365 (Voldsbekk et al., 2023). This suggests that RSFC-psychopathology associations should 366 extend from clinical samples to population samples, consistent with the understanding of 367 psychopathology as a dimensional structure. Of note, this highlights the relevance of 368 investigating the overlap and reproducibility of RSFC-psychopathology associations from 369 clinical to population-based samples. The current study represents one attempt at this. 370

Consistent with the symptom load distribution in HBN across diagnostic categories, 371 372 the RSFC pattern in HBN picked up associations with peer problems, hyperactivity, and 373 prosocial behaviour for the ASD-specific pattern and all symptom dimensions for the crossdiagnostic pattern. This represents a sanity check that the diagnosis-derived RSFC pattern in 374 HBN picks up similar associations with symptom load as the diagnosis groups they are 375 modelled to represent. Reliability of mental health measures has remained a challenge in the 376 377 field (Nikolaidis et al., 2022). Here we show that RSFC patterns derived from diagnostic information exhibit associations with an independent measurement of symptom load that are 378 overlapping with symptom load associations observed for each diagnostic category. This 379 supports that these RSFC patterns reflect something that overlaps with their corresponding 380 diagnostic categories. However, this sensitivity of the RSFC pattern was not generalisable to 381 Brainmint. The RSFC pattern in Brainmint picked up an inverse relationship with prosocial 382 383 behaviour, hyperactivity, and conduct problems for the ASD-specific pattern, indicating that higher prosociality and lower conduct problems and hyperactivity was associated with a more 384 "ASD-like" brain pattern. This finding is paradoxical and the opposite of what one would 385 expect. While it is too early to conclude based on one preliminary association only, it is 386 worth noting that the strength of this association was low. Similarly, there was no significant 387 associations with the cross-diagnostic pattern in Brainmint. Given these weak group-level 388 associations, with great variation at the individual level, adding too much emphasis to this 389

preliminary finding is unwarranted. Instead, this result adheres to the previous literaturefinding generalisation of RSFC results a challenge (Uddin et al., 2017).

392 Some further limitations should be noted. First, RSFC results are influenced by methodological choices (Sala-Llonch et al., 2019; Shirer et al., 2015). To increase 393 reproducibility of RSFC networks, we utilised an established parcellation scheme (Schaefer 394 395 et al., 2018). Second, the two samples underwent slightly differing fMRI preprocessing pipelines. This difference should diminish, rather than inflate, any ability to reproduce 396 findings, meaning that the current study represents a conservative approach to reproducibility 397 with higher chance of false negatives than false positives. Third, the symptom dimensions 398 from SDQ were measured by parent-report in HBN and by self-report in Brainmint. This 399 difference may have induced systematic variations in the data across the two samples, as it is 400 known that parent-report and self-report have small-to-moderate correlations (Gaete et al., 401 2018). This limitation represents a possible explanation for why we did not find overlapping 402 403 associations between RSFC patterns and symptom level across the two cohorts. In addition, 404 this may explain why the community-based sample seemed to exhibit a higher symptom burden than the clinical sample. This limitation represents an important reminder that low 405 406 reliability in mental health measures impedes scientific discovery (Nikolaidis et al., 2022) 407 and underscores that the current results must be interpreted with caution. Fourth, the age, sex, and clinical distributions across the two samples differed, meaning we cannot rule out 408 409 whether the lack of generalisability across samples reflect these differences in distributions 410 rather than a lack of reproducibility of RSFC-symptom patterns per se. 411

412 **5** Conclusions

This work demonstrates that diagnosis-derived RSFC patterns in a US developmental clinical 413 sample can be extended to a Norwegian convenience-based sample of youth. Both the cross-414 diagnostic and the ASD-specific RSFC patterns were validated across samples. However, 415 416 although both connectivity patterns exhibited significant associations with thematically appropriate symptom dimensions in both the discovery sample (HBN), they were not found 417 to be sensitive to overlapping dimensions of symptom burden in the validation sample 418 (Brainmint). Implications of this work is that generalisation of RSFC results remains a 419 420 challenge. For any psychopathology-related RSFC patterns to be generalisable and clinically 421 relevant, their sensitivity to symptom burden across samples represents a prerequisite. 422 423
