36

37 **Abstract**

38 Background: Prebiotic dietary fiber and related metabolites have been suggested to attenuate
39 low-grade systemic and central inflammation through improving gut-brain axis signaling. We
40 here aimed to test whether habitual or short-term high-dose fiber intake is linked to
41 inflammatory markers in blood and to indicators of central hypothalamic inflammation.

42 Methods: In total, 59 adults (19 women, aged 28.3 years \pm 6.6 SD, mean body mass index,
43 BMI, 27.3 \pm 1.5 SD) were included into analyses. Participants completed a food frequency
44 questionnaire, underwent diffusion-weighted magnetic resonance imaging (MRI) at 3 Tesla
45 for provision of mean diffusivity (MD) as a marker of brain tissue inflammation and donated
46 fasting blood. Measurements took place at up to 4 timepoints, i.e. before and after 14 days of
47 supplementary fiber and placebo intake, respectively. High-sensitive C-reactive protein (CRP),
48 tumor-necrosis factor alpha (TNF- α) and interleukin-6 (IL6) were assessed in serum. The study
49 was preregistered at <https://osf.io/uzbav>.

50 Results: Habitual and interventional high-fiber diet was not significantly associated with
51 neither inflammatory markers ($|\beta_{\text{intervention}}| > 0.1$, $p > 0.32$) nor with hypothalamic MD
52 ($|\beta_{\text{intervention}}| = 1.8$, $p = 0.07$) according to linear mixed effects modeling. Male sex and higher
53 body fat mass related to higher CRP. Further, higher BMI was borderline related to lower
54 hypothalamic MD.

55 Conclusions: In this sample of overweight adults, dietary fiber intake was not related to
56 inflammatory blood markers or hypothalamic microstructure. Instead, sex and body
57 composition were of higher importance for prediction of interindividual differences in
58 markers of (neuro)inflammation.

59

60

61 **Significance Statement (max.120 words)**

62 Prebiotic dietary fiber has been discussed to lower systemic and central inflammation. While
63 previous studies investigated the effects of fiber on inflammatory blood markers, the
64 knowledge of the effect of fiber on neuroinflammation is limited. Thus, in this pre-registered
65 randomized controlled trial analysis we examined the relationship between dietary fiber
66 intake and inflammatory markers in blood and hypothalamus. 3T MRI and blood markers were
67 assessed before and after high-fiber intake and placebo in 59 adults. In our overweight study
68 sample of 19-42 years old adults, fiber intake had no significant impact on inflammatory
69 markers. The current null findings can inform future nutrition neuroimaging trials and add to
70 the discussion about how diet may affect brain structure and function.

71

72 Keywords: diffusion weighted imaging, hypothalamus, mean diffusivity, inflammatory
73 markers, brain microstructure, high fiber diet, lifestyle intervention

74 **Introduction**

75 High-fat diet and fat accumulation can trigger low-grade systemic inflammation, leading to
76 maladaptive changes in food intake-related brain areas such as the hypothalamus (Thaler and
77 Schwartz 2010, Sewaybricker et al., 2023). Diets high in saturated fatty acids may activate
78 inflammatory pathways (Rocha et al. 2016) and modulate intestinal microbiota. Thereby, they
79 increase intestinal permeability and induce systemic inflammation (Cani et al. 2008;
80 Deopurkar et al. 2010; Lassenius et al. 2011). Consequently, inflammatory serum factors
81 which cross the blood-brain barrier can provoke dysfunctional changes in brain areas such as
82 the hypothalamus (Van Dyken and Lacoste 2018).

83 In contrast to high-fat diets, high-fiber diets have been discussed to exert anti-inflammatory
84 effects in gut and circulation (Dalile et al. 2019; Medawar et al. 2019). Dietary fibers are
85 converted into short-chain fatty acids (SCFAs) through bacterial fermentation in the colon.
86 SCFAs alleviate inflammatory processes at their production site in the colon and systemically
87 after entering blood circulation (Morrison and Preston 2016).

88 In the gut, SCFA contribute to a decreased permeability of the intestinal membrane by
89 facilitating tight-junction-assembly. Thus, bacteria expressing proinflammatory
90 lipopolysaccharides on their surface are prevented from entering extraintestinal circulation
91 (Luying Peng, Zhong-Rong Li, Robert S. Green, Ian R. Holzman 2009). Hence, extraintestinal
92 inflammation initiated by bacterial components can be contained. Additionally, SCFAs have
93 been suggested to act via the immune pathway influencing systemic and neuroinflammation
94 (Dalile et al. 2019).

95 Moreover, dietary fiber or its derivative SCFAs promote the secretion of gut-derived
96 anorexigenic hormones, such as glucagon-like peptide-1 (GLP-1) and peptide YY (PYY). These
97 hormones induce satiety via the suppression of appetite-stimulating hypothalamic

98 neuropeptide Y (NPY) neurons and the activation of appetite-suppressing pro-
99 opiomelanocortin (POMC) neurons in the hypothalamus (De Silva and Bloom 2012). Thereby,
100 SCFAs may contribute to higher satiety. Higher satiety in turn may lead to less high-fat food
101 consumption (Byrne et al. 2015) resulting in lower inflammatory parameters. An alleviation of
102 inflammatory processes may potentially link to higher functional hypothalamic integrity and
103 therefore a more sensitive regulation of appetite.

104 Human, cross-sectional epidemiological studies report that higher habitual high-fiber diet
105 links to lower levels of peripheral inflammatory markers (Ma et al. 2008; Mazidi et al. 2018;
106 Wannamethee et al. 2009). Interventional studies which examine a potential association
107 between fiber intake and inflammatory processes are however scarce and limited in sample
108 size. One randomized clinical interventional study investigated 35 (18 obese and 17 lean)
109 individuals following either a “Dietary Approaches to Stop Hypertension” diet (DASH, a diet
110 rich in fiber and low in dairy and saturated fat) or a high-fiber supplementation diet (30g/day
111 of psyllium) for 3 weeks respectively in a cross-over design (King et al. 2007). Although both
112 diets reduced C-reactive protein (CRP) levels, the fiber supplement showed slightly stronger
113 effects than the DASH diet. Notably, only lean participants showed an amelioration of
114 inflammatory markers. This clinical interventional study indicates that fiber may causally
115 lower inflammatory markers, especially in lean individuals.

116 In sum, previous studies imply that dietary factors relate to (neuro-)inflammation in distinct
117 ways, and some suggest prebiotic dietary fiber as anti-inflammatory agent. Yet, it remains
118 unclear if a high-fiber diet relates to lower systemic and hypothalamic inflammation in non-
119 lean individuals. Therefore, this randomized controlled study in a homogenous, well-
120 characterized cohort of overweight adults aims to investigate whether dietary fiber exerts
121 beneficial effects on markers of systemic inflammation and hypothalamic microstructure.

122 According to pre-registration (<https://osf.io/uzbav>), we hypothesized that higher habitual
123 dietary fiber intake, measured using self-report of dietary habits over the course of seven
124 days, correlates with (1) lower levels of the inflammatory markers interleukin-6 (IL-6), CRP,
125 and tumor-necrosis factor alpha (TNF- α) in blood, and (2) with lower microstructural
126 coherence in the hypothalamus measured using mean diffusivity (MD) derived from diffusion-
127 weighted magnetic resonance imaging (MRI). In addition, we hypothesized that a two-week
128 prebiotic fiber intervention (30 g inulin/d) would lead to improvements in blood (3) and brain
129 markers (4).

130

131 **Material and Methods**

132 Ethics Approval and Recruitment

133 This study is part of a within-subject cross-over randomized controlled trial (RCT) investigating
134 the effects of a prebiotic intervention on the gut-brain axis (Medawar et al., Gut, in press). The
135 institutional Ethics Board of the Medical Faculty of the University of Leipzig, Germany, raised
136 no concerns regarding the study protocol (228/18-ek) and all participants provided written
137 informed consent. Recruitment took place via the institute's database and advertisements.
138 Remuneration was 9-10€/h and an additional bonus payment of 30€ for completing the study.
139 The RCT was registered at ClinicalTrials.gov (#NCT03829189) and this analysis was pre-
140 registered at <https://osf.io/uzbav>.

141

142 Study Population

143 Out of 106 screened individuals we included a sample of 59 overweight adults (19 females, 40
144 males), aged 19-42 years (28 years \pm 6.2 SD, BMI range 25-30 kg/m², mean 27.3 kg/m² \pm 1.4
145 SD), for a flowchart, see **Extended Figure 1-1**. All participants assigned to either being female

146 or male (alternative options: diverse, preferring not to report). Due to anatomical differences
147 between females and males, we referred to female and male 'sex' considering differences in
148 anthropometrics or brain morphology. Female and male 'gender' was used in all other
149 occasions.

150

151 Inclusion/Exclusion criteria

152 Inclusion criteria for this study were an age range of 18-45 years, a BMI of 25-30 kg/m² upon
153 first baseline assessment, no MRI contraindications, an omnivorous, non-restrictive diet, and
154 no food allergies. Further any type of diet or antibiotic treatment in the last 3 months led to
155 exclusion. Additionally, female participants had to regularly use oral or alternative
156 contraceptives to minimize hormonal variations induced by the menstrual cycle. Pregnant and
157 lactating women were not allowed to take part in the study. Participants were excluded if they
158 suffered from a diagnosed neurological, psychiatric, or metabolic disorder. Diseases of the
159 gastrointestinal tract, cardiovascular system, lung, liver, or kidneys led to exclusion as well as
160 the intake of medication acting on the central nervous system. Daily alcohol intake had to be
161 at a maximum of 50 grams. Limits for cigarette and coffee consumption were set to 10
162 cigarettes and 6 cups of coffee per day. Participants were dropouts when the supplement
163 intake was missed out for more than 48 hours or if more than half of the 26 portions were
164 missed out.

165

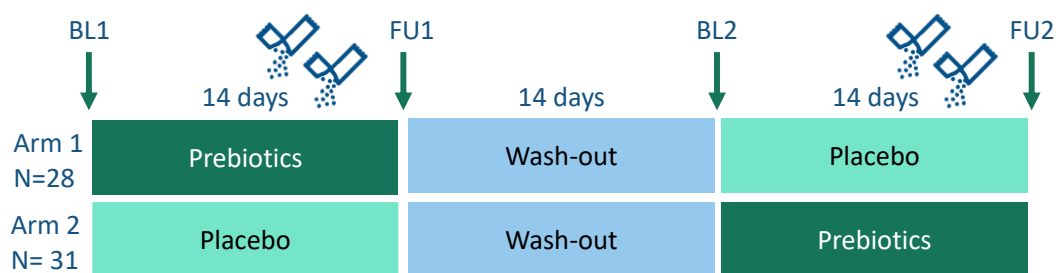

166 Study Design

167 Participants underwent up to four assessments over the course of ~6-10 weeks and in-
168 between two assessments, they supplemented their diet with high-dosed prebiotic fiber (2
169 sachets of 15 g inulin/d), and with placebo (2 sachets isocaloric maltodextrin), respectively for

170 14 days (**Figure 1**). Specifically, daily intake of 30 g inulin contained 63 kcal and 26.7 g fiber
171 (Orafti® Beneo Synergy1, BENE0 GmbH, Mannheim, Germany) and placebo intake consisted
172 of 16 g maltodextrin (63 kcal, 0 g fiber). Randomized allocation to study arm 1 or 2 determined
173 the order of supplement intake. A wash-out period of at least 14 days was set between each
174 of the interventions to avoid carry-over effects from the first intervention on the second.

175

176

177

178 **Figure 1: Study design.** Each participant underwent up to four assessments: Baseline 1 (BL1, before first
179 intervention), Follow-up 1 (FU1, after first intervention), Baseline 2 (before second intervention), Follow-up 2
180 (after second intervention). In-between two assessments participants supplemented their diet either with
181 “prebiotics” (30g of inulin) or “placebo” (isocaloric maltodextrin). Participants were randomly allocated to study
182 arm 1 or 2 which determined the order of supplement intake. A washout period of at least 14 days was set
183 between interventions.

184

185 During the first three days of the intervention period the participants were asked to take one
186 portion (15 g) of the supplement daily. Starting on day 4 and continuing through day 14, the
187 amount of intake consisted of two portions daily (30 g). On day 15 (day of measurement) one
188 sachet was added to a standardized breakfast shake after overnight fast and blood draw, so
189 that one intervention period included 26 portions. We recommended to take the supplement
190 before 5 p.m. to achieve a proper digestion before sleep. Fasting blood samples,
191 anthropometrics, dietary habits and MRI were acquired on all four assessment days.

192

193

194

195 Inflammatory markers

196 Participants were asked to fast from the evening prior to the blood drawing (mean 12.5 h ±
197 2.2 SD). The fasting blood samples were collected by trained staff at the same time point for
198 each of the four measurements (using safety-multifly needles (21G, 200mm)). Blood samples
199 were centrifuged at 3,500 revolutions per minute at 7°C for 6 minutes and the serum was
200 aliquoted within one hour of obtainment. Processed aliquots were stored in a -80°C freezer
201 within one hour of collection until the study was completed to analyze all samples in one
202 batch. Analysis was conducted by Synevo Studien Service Labor GmbH c/o IMD Institut für
203 Medizinische Diagnostik Berlin-Potsdam GbR, Berlin, Germany. We measured IL-6, CRP, and
204 TNF- α .

205

206 Anthropometric data

207 Body mass index (BMI) was measured as body weight (kg) divided by squared body height
208 (m^2). Participants were weighed in light clothes and without shoes in a fasted state on the
209 same weight scale (100 g resolution, Seca GmbH, Germany) and their height was measured
210 while standing against the wall with a fixed measuring scale (0.5 cm resolution, Seca GmbH,
211 Germany). Percent body fat mass was measured using bioimpedance analysis with
212 BIACORPUS RX 4004M (Medi Cal Healthcare GmbH, Karlsruhe, Germany) and two electrodes
213 each at both hands and feet. Body fat mass was sex-standardized using z-transformation
214 before analysis.

215

216 Habitual dietary fiber intake

217 For estimation of the amount of habitual dietary fiber intake, participants were asked to
218 complete the validated German food frequency questionnaire (DEGS1 FFQ) (Haftenberger et

219 al. 2010) at each assessment. An in-house scoring tool was used to estimate the consumption
220 of single food items and resulting daily nutrient intake based on self-report of frequency and
221 quantity within seven days (Thieleking et al. 2023). We measured the amount of fiber intake
222 using two different units: fiber in grams per day (absolute intake) and fiber per 1000kcal per
223 day (relative intake) to adjust for overall caloric intake.

224

225 MRI acquisition

226 MRI was performed on a 3T Siemens Prismafit scanner with a 32-channel head coil. MRI was
227 acquired using a T1-weighted MPRAGE sequence using the ADNI protocol with the following
228 parameters: TR = 2300ms; TE = 2.98ms; flip angle = 9°; FOV: (256 mm)²; voxel size: (1.0mm)³;
229 176 slices. Diffusion-weighted MRI (dwMRI) was acquired using the following parameters: TR
230 = 5200ms; TE = 75ms; flip angle = 90°; FOV: (220 mm)²; voxel size: (1.7mm)³; 88 slices; max.
231 b=1000 s/mm² in 60 diffusion directions; partial Fourier=7/8; GRAPPA-factor = 2; interpolation
232 = OFF. Ap/pa-encoded b0-images were acquired for distortion correction.

233

234 MRI data preprocessing

235 Anatomical images were automatically processed with the FreeSurfer v6.0.0p1 longitudinal
236 stream, total intracranial volume per person and per time point was extracted based on the
237 unbiased within-subject template space and image (Reuter et al. 2012). Several processing
238 steps, such as skull stripping, Talairach transforms, atlas registration as well as spherical
239 surface maps and parcellations were then initialized with common information from the
240 within-subject template, to increase reliability and statistical power.

241 DwMRI preprocessing was performed with standard pipelines, including denoising (MRtrix
242 v3.0; (Veraart, Fieremans, and Novikov 2016) of the raw data, removal of Gibbs-ringing artifact

243 from all b0-images using the local subvoxel-shift method (Kellner et al. 2016) and outlier
244 replacement using the EDDY tool (Andersson et al. 2016; Andersson and Sotiropoulos 2016)
245 in FSL 6.0.1. (Smith et al. 2004). Subsequently, data was corrected for susceptibility distortions
246 using topup (FSL) (Andersson, Skare, and Ashburner 2003). Brain masks of the unwarped b0-
247 images were created using BET (Smith 2002) from FSL to correct for head motion and eddy
248 currents using the EDDY tool (FSL; Bastiani et al. 2019). We applied tensor model fitting using
249 DTIFit (FSL) to generate mean diffusivity (MD).

250

251 Quality control of preprocessed DWI data.

252 Using EDDY QC tools (FSL 6.0.1), quality control on person-wise and group-wise level have
253 been performed with EDDY QUAD and EDDY SQUAD v1.0.2, respectively (Bastiani et al. 2019).
254 The group-wise QC metrics (motion parameters, eddy currents, signal-to-noise ratio (SNR) and
255 contrast-to-noise ratio (CNR)) have been compared to standard values (see **Table 1, Extended**
256 **Fig. 2-1, 2-2**). Based on this assessment, we did not exclude any participants from analysis.

257 **Table 1: Diffusion-weighted imaging (DWI) Quality Control.** Group-wise quality metrics
258 provided by eddy squad for DWI data.

	Signal-to-noise ratio (SNR)	Contrast-to-noise ratio (CNR)	avg. absolute motion [mm]	avg. relative motion [mm]
Mean	40.93	4.13	0.27	0.12
SD	7.15	0.73	0.19	0.06
Mean +/- 1 SD	33.78	3.40	0.46	0.17
Mean +/- 2 SD	26.64	2.67	0.65	0.23

259 Overall, data quality of DWI data was judged as very good without extreme values according to quality
260 metrics provided by eddy squad.

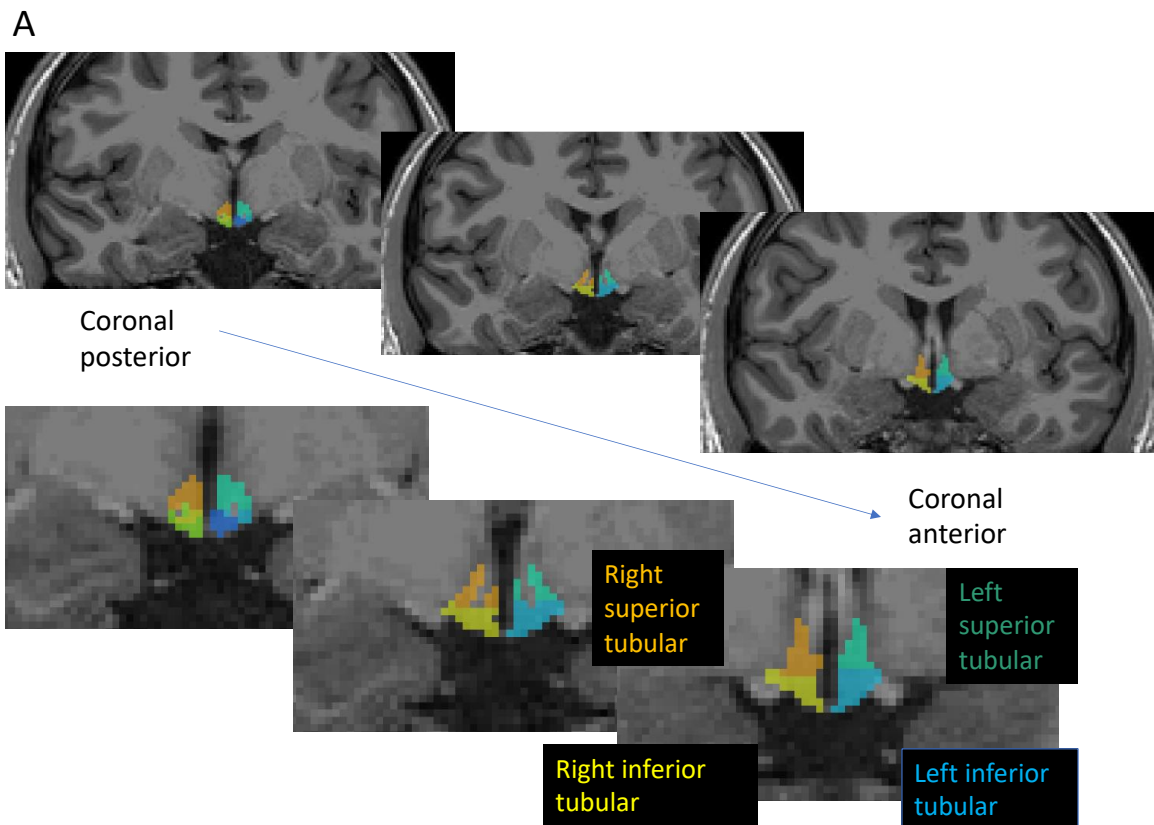

261

262

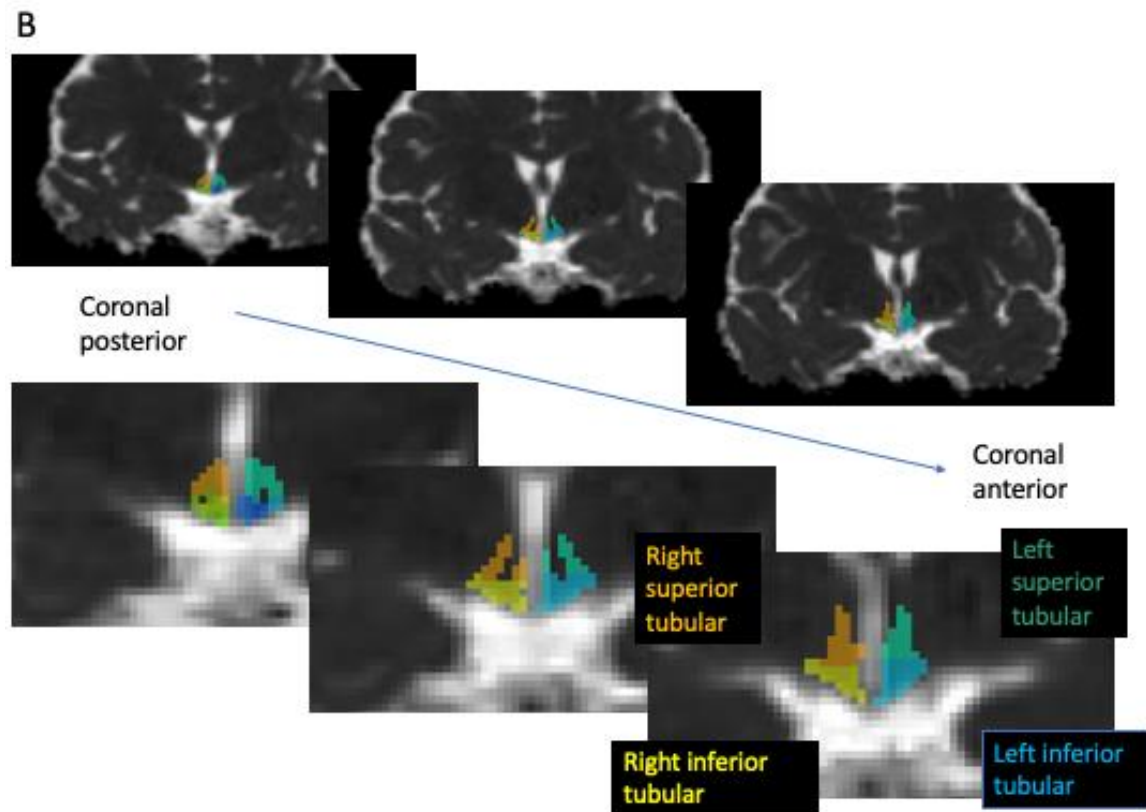

263

264 Hypothalamus segmentation.

265 Deviant to the pre-registration, we used automated segmentation of the bilateral
266 hypothalamus using a deep learning algorithm (Billot et al. 2020) implemented in python
267 scripts (v3.6) due to faster and more reliable results. Briefly, four hypothalamic regions were
268 segmented at each hemisphere (**Figure 2**). Visual checks for correct segmentation on the
269 structural image were done for all subjects. Volumes for total bilateral hypothalamus were
270 extracted for each individual and for each of the up to four datapoints. Subnuclei were
271 disregarded for statistical inference analysis to reduce Type II errors.

272

273
274 **Fig. 2: Examples of automatically segmented hypothalamus subnuclei on a participant's T1-weighted image**
275 **(A) and respective mean diffusivity (MD) maps (B) in coronal slices.** Colors give hypothalamic subnuclei (light
276 blue = left inferior tubular, yellow= right inferior tubular, orange = right superior tubular, turquoise= left superior
277 tubular).
278

279 Hypothalamic MD. To avoid partial volume effects at the border to the adjacent ventricle, we
280 first extracted MD values of the third ventricle based on FS LONG template and the ventricle
281 region according to the Deskian/Killiany atlas (labels 14) (Thomas et al. 2019). Next, we
282 extracted bilateral hippocampus as a control region of non-interest (based on FS LONG
283 automatic segmentation (aseg.mgz) and Deskian/Killiany atlas labels 17 + 53). MD images
284 were coregistered to the respective subject- and time point-specific FS LONG with FSL's FLIRT
285 using 6 degrees of freedom. Then, the registration matrix was used to coregister the MD
286 images to the anatomical space. Using fsstats (FSL), the mean MD of the third ventricle has
287 been used as an upper threshold for calculating the mean MD of the hypothalamus and the
288 hippocampus, respectively. Analysis code is openly available at
289 <https://gitlab.gwdg.de/omega-lab/hypothalamus-segmentation-and-md-extraction>.

290

291 Statistical analyses

292 R version 4.2.2 was used to perform statistical analysis with linear mixed effects models. We
293 controlled for possible confounding effects of body fat mass and BMI since visceral adipose
294 tissue has previously shown to increase proinflammatory cytokines such as TNF- α
295 (Hotamisligil, Shargill, and Spiegelman 1993) and a higher BMI has been linked to increased
296 hypothalamic MD (Thomas et al. 2019). Deviant to the pre-registration, we decided to use
297 lmer function (instead of lm function) in hypotheses 1) and 2) from the R-package lme4 to
298 account for subject as a random factor in order to use all timepoints (up to four per individual)
299 as repeated measures. This required to additionally control for intervention condition and
300 timepoint. Hypotheses 1-4 were tested with the following models:

301 H1) Null model: `lmer(inflammatory_markers~age+sex+`
302 `body_fat_mass+intervention_condition+timepoint+ (1|subj)),`
303 R1: `lmer(inflammatory_markers~fiber_intake+age+sex+ body_fat_mass`
304 `+intervention_condition+timepoint+ (1|subj))`

305

306 H2) Null model: `lmer(hypothalamic_MD~ age+ sex+BMI+intervention_condition+timepoint+`
307 `(1|subj))`

308 R1: `lmer(hypothalamic_MD~ fiber_intake+age+ sex+BMI+`
309 `intervention_condition+timepoint+ (1|subj))`

310

311 H3) Null model: `lmer(inflammatory_markers~ intervention_condition+timepoint+ (1|subj))`

312 R1: `lmer(inflammatory_markers~ timepoint*intervention_condition +`
313 `intervention_condition + timepoint + (1|subj))`

314

315 H4) Null model: $\text{Imer}(\text{hypothalamic_MD} \sim \text{intervention_condition} + \text{timepoint} + (1 | \text{subj}))$

316 R1: $\text{Imer}(\text{hypothalamic_MD}_i \sim \text{time point} * \text{intervention_condition} + \text{intervention_condition} +$

317 $\text{timepoint} + (1 | \text{subj}))$

318

319 **Results**

320 Descriptives

321 Main analysis included 59 participants with complete baseline assessments (19 women, 40

322 men) and up to 3 additional assessments adding to maximal 205 observations per outcome

323 (flowchart detailing missing values in **Extended Fig. 1-1**). Participants were 19 to 45 years old

324 (28.3 years \pm 6.57 SD), their body fat mass ranged from 7.6% to 39.8% (mean 27.1 % \pm 6.6 SD)

325 and self-reported daily habitual fiber intake was diverse and moderate (mean 16.3 g/d \pm 6.3

326 SD, range 1.5 to 30.5) (**Table 2**). Hypothalamic volume and MD values ranged from 707 to

327 1050 mm³ and 0.87*10⁻³ to 1.1*10⁻³ mm²/s, respectively. We observed sex differences in

328 hypothalamic volume size, with higher volumes in males compared to females independent

329 of head size differences. Data across all time points are given in **Extended Fig. 3-1, Extended**

330 **Table 3-1.**

331 As 86% of IL-6 measures laid under the lower limit of quantification we decided to omit IL-6

332 from statistical analyses (see below for a qualitative evaluation of intervention effects). CRP

333 was used on a log-scale due to skewed distribution (skewness 0.09 for log-transformed data

334 as opposed to 8.18, if not log-transformed).

335 **Table 2: Characteristics of study participants at first assessment (baseline, BL, 1).**

	BL1 (n = 59)
Sex	
F	19 (32.2%)

339 **Habitual fiber intake, inflammatory markers, and hypothalamic microstructure**

340 As preregistered, we assessed whether habitual dietary fiber intake linked to inflammatory
341 markers and hypothalamic MD. Against our hypotheses, we could not observe significant
342 associations between absolute or relative habitual fiber intake and TNF- α or CRP (model
343 comparisons, all $p > 0.37$, **Extended Table 3-2 and 3-3**). Neither did we detect significant
344 associations between fiber intake and hypothalamic MD, or hippocampal MD as control region
345 (model comparison, all $p > 0.27$; **Extended Tables 3-4 and 3-5**).

346 Notably, male sex predicted lower levels of CRP ($\beta = -0.6$, $p < 0.001$, **Fig. 3A**). Additionally,
347 higher body fat (sex-standardized, $\beta = 0.16$, $p = 0.002$) related to higher CRP levels,
348 independent of the amount of fiber intake (**Fig. 3A**). This link was not observed for TNF- α
349 (male sex, $p = 0.17$, body fat, $p = 0.22$). Moreover, lower hypothalamic MD was borderline
350 associated with higher BMI (**Fig. 3B**, all $p < 0.052$, **Extended Table 3-4**).

351

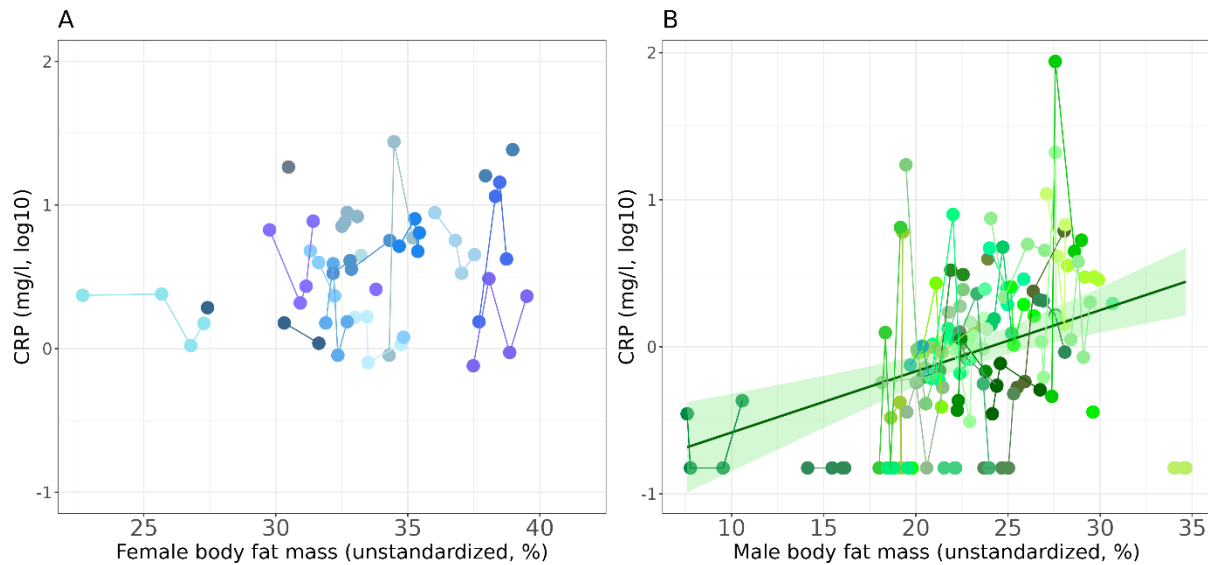

352

353 **Fig. 3: Visualization of unstandardized regression coefficients of baseline models for log-transformed CRP (A)**
354 **and hypothalamic mean diffusivity (MD) (B), including habitual fiber intake as predictor of interest in**
355 **comparison to null models (not depicted). Bars depict 95% CI.**
356

357 Additionally, we explored potential correlations between inflammatory markers and body fat
358 mass in percent stratified by sex due to the observed prediction of lower CRP levels by male
359 sex. Higher body fat somewhat correlated with higher CRP in both females and males, yet the

360 association was not significant in females (**Fig. 4**; female: $r = 0.03$, $p = 0.74$, $n = 18$; male: $\beta =$
361 0.18 , $t = 2.8$, $p = 0.01$, $n = 40$). We did not observe significant associations with TNF- α and body
362 fat (all $p > 0.35$).

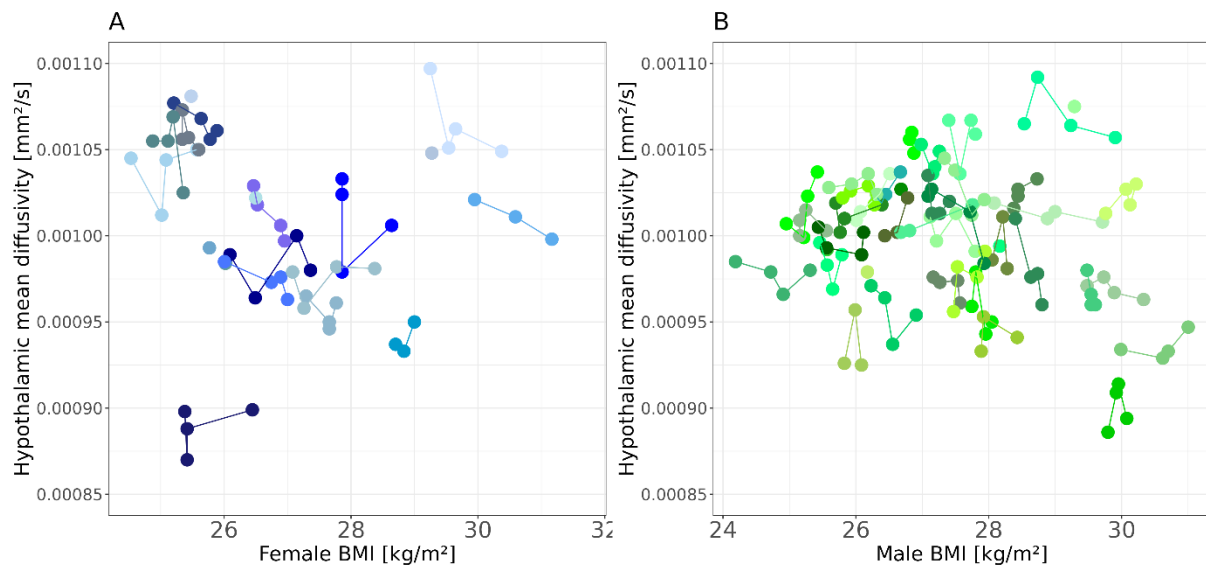

364 **Fig. 4:** Correlations of body fat mass (FM) in % and log-transformed CRP in females (A) and males (B). Colors code
365 for participant (shading, up to four records) and sex (blue female, green male). Lines indicates regression fit with
366 the lightgreen ribbons represent pointwise 95% CI of the means.
367

368

369

370 When exploring the borderline association between higher BMI and lower hypothalamic MD
371 stratified for sex, the effect was not evident (**Fig. 5**; model comparisons, females: $p = 0.35$,
372 males: $p = 0.12$).

373

374 **Fig.5: Hypothalamic mean diffusivity (MD) in relation to body mass index (BMI) in females (A) and males (B).**
375 Colors code for participant (shading, up to four records) and sex (blue female, green male). Lines connect
376 individuals.

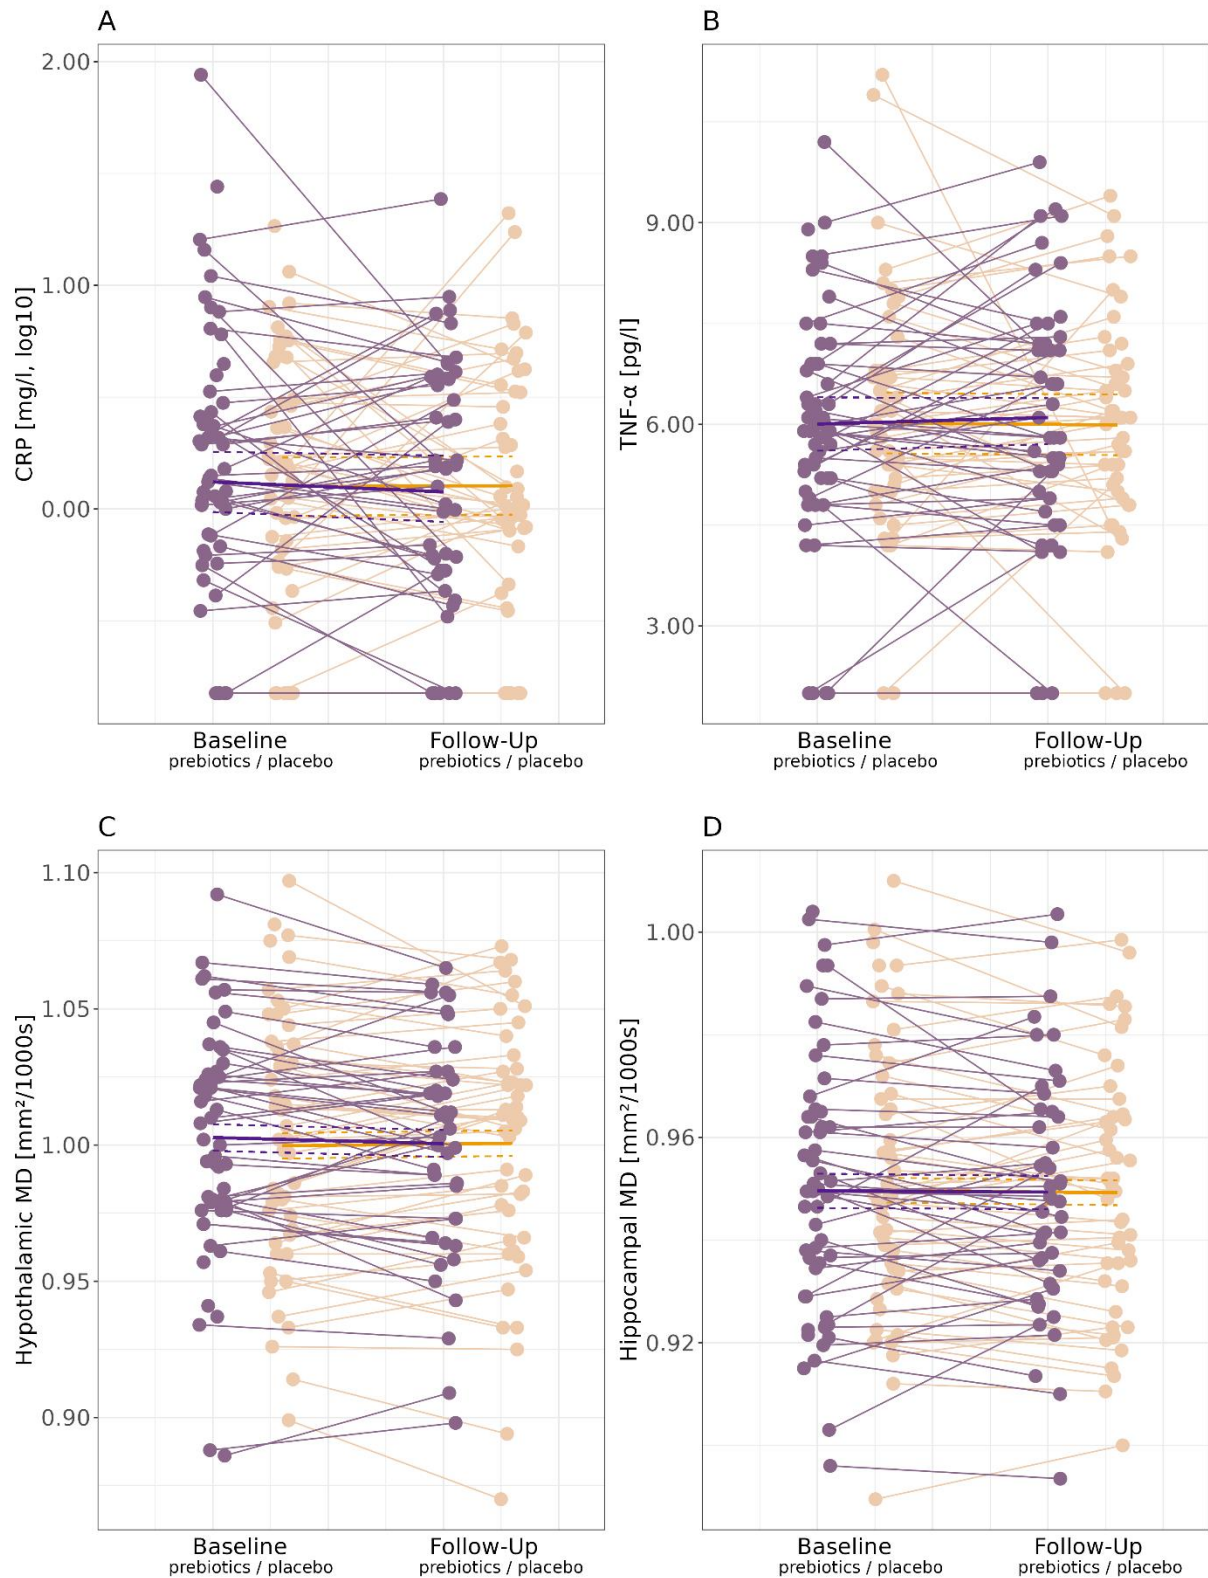

377

378

379

380 **Effects of 14 days of high-dosed prebiotic fiber intake on inflammatory markers and** 381 **hypothalamic microstructure**

382 The two-week high-fiber intervention, compared to placebo, did not have significant effects
383 neither on inflammatory markers (Fig. 6A-B, Extended Table 6-1 and 6-2, model comparison
384 $p = 0.59$ for $\text{TNF-}\alpha$, model comparison $p = 0.29$ for CRP) nor on brain microstructure, i.e.,
385 neither hypothalamic MD (Fig. 6C, Extended Table 6-3, model comparison $p = 0.08$) nor the
386 MD of the control region, the hippocampus, were altered by the high-dosed fiber intake (Fig.
387 6D, Extended Table 6-4, model comparison $p = 0.87$).

388

389

390

391

392

393

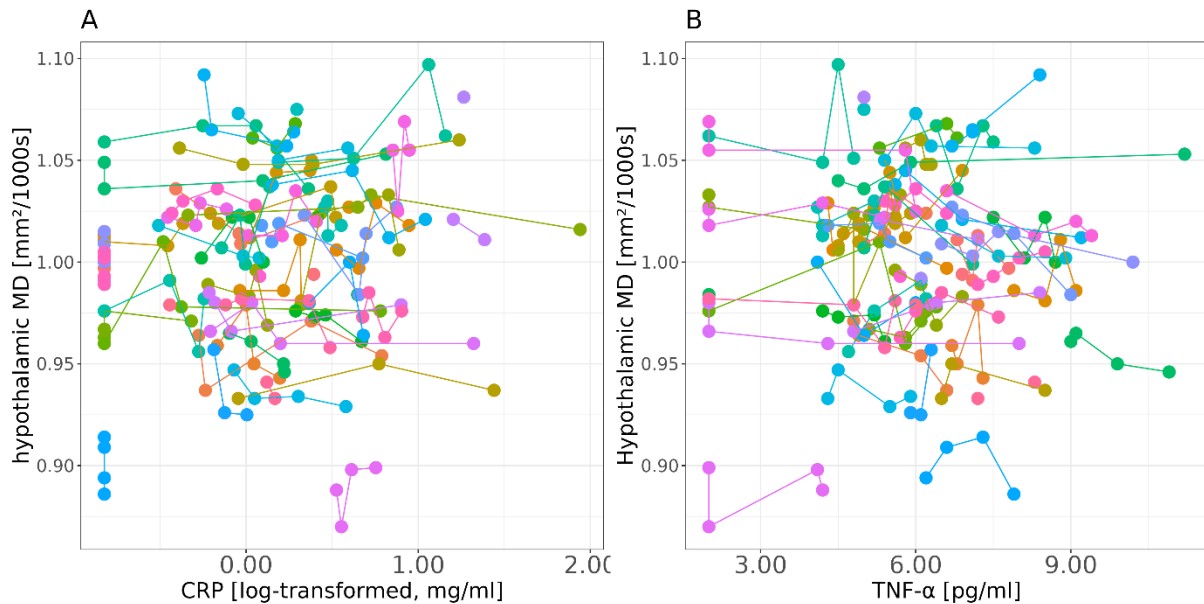

394

Fig.6: Changes in log-transformed CRP (CRP_log10, A), TNF-α (B), hypothalamic MD (C), and hippocampal MD (D) from baseline (BL) to follow-up (FU) measurements before and after 14 days of prebiotic fiber intake (violet) and placebo (light orange), respectively. Lines give individual's change, bold lines give mean change per condition, dashed lines 95% confidence interval of the mean.

395 When looking qualitatively at IL-6, when assigning 0 to values with below detection threshold
396 and focusing on participants with two or more measurements, IL-6 measures changed in 8
397 participants after fiber (5 decreases, 3 increases) and in 11 participants after placebo (7
398 decreases, 4 increases), while the majority did not change.

399

400 In exploratory analysis, we investigated a potential association between peripheral (CRP, TNF-
401 α) and central (hypothalamic MD) inflammatory markers across all four time points. We used
402 linear mixed regression to model the effect of serum inflammatory markers on MD corrected
403 for sex, age, BL/FU visit and intervention as covariates and subject as random factor. Chi-
404 squared tests were used to compare models including the marker against models containing
405 only variables we corrected for. Neither the comparison of log-transformed CRP ($p = 0.93$) nor
406 TNF- α ($p = 0.06$) showed a significant effect (**Fig. 7, Extended Tables 7-1 and 7-2**).

407

408 **Figure 7: Peripheral compared to central markers of inflammation.** (A) log-transformed CRP, (B) TNF- α . Colors
409 code for participants, (up to four records per subject), lines connect participants.

410

411 Exploratory analysis of habitual and intervention effects of dietary fiber on hypothalamic
412 volume (corrected for total intracranial volume) did not reveal significant changes (time by
413 group interaction: $|\beta| = 5.12$, $p = 0.21$, **Extended Tables 7-3 and 7-4**).

414

415 **Discussion**

416 In this well-characterized sample of 59 overweight young to middle aged adults, systemic and
417 (neuro-)inflammatory processes measured in blood and hypothalamus were not significantly
418 related to prebiotic fiber intake, i.e. neither to self-reported, habitual intake nor to short-term
419 high-dosed interventional intake for 14 days. Exploratory analyses indicated that sex and body
420 fat related to higher CRP serum levels, while higher BMI was borderline associated with
421 coherence of hypothalamic microstructure, represented in MD.

422

423 *Prebiotic fiber intake and peripheral markers of inflammation*

424 Considering blood-based inflammatory markers, we could not confirm that habitual fiber
425 intake related to lower fasting levels of CRP, TNF- α or IL-6, or that a high-fiber intervention
426 decreased these inflammatory markers in our sample. These null results thus question a
427 strong effect of fiber intake on markers of systemic inflammation. Causal evidence for
428 inflammation-lowering effects of high-fiber diets based on interventional studies is indeed
429 scarce: King et al. observed decreases in CRP after three weeks of two different high-fiber
430 diets. However, this observation applied only to a specific subgroup, i.e., the lean group of
431 the study population (17 participants) and not to participants living with obesity (18
432 participants). Further, there was no placebo control, so that test-retest effects could not be
433 ruled out (King et al. 2007). More recent controlled RCTs observed decreases in TNF- α and IL-
434 6, but not in CRP, in 52 women with type-2 diabetes (mean age 48 years) after 8 weeks of 10
435 g/d inulin (Dehghan, Pourghassem Gargari, and Asghari Jafar-abadi 2014), and in a group of

436 42 overweight and obese children after 16 weeks of inulin supplementation (Nicolucci et al.
437 2017). In general, dietary intervention studies such as ours are often difficult to monitor and
438 can therefore be limited by false reports of habitual dietary intake or insufficient supplement
439 intake. Of note, we did not observe significant effects when controlling for total energy intake
440 to control potential over- or under-reporting, and all participants reported regular
441 supplement intake according to self-report. The lacking effect of fiber intake on systemic
442 inflammation in our study might be also attributed to ceiling effects. For instance, room for
443 inflammatory improvement might have been limited in our study population of overweight
444 young adults as they showed only low-grade inflammation levels (indicated by floor-levels of
445 IL-6) and were metabolically healthy. Participants in our study also already showed an average
446 moderate, habitual dietary fiber intake of 16 g/day, outperforming previous study populations
447 (Dehghan, Pourghassem Gargari, and Asghari Jafar-abadi 2014). In addition, the timeframe of
448 the intervention might have been too short to induce significant effects (two weeks in
449 comparison to 8 (Dehghan, Pourghassem Gargari, and Asghari Jafar-abadi 2014) and 16 weeks
450 (Nicolucci et al. 2017). As CRP-levels were not altered by fiber supplementation in previous
451 studies, it might not be sensitive enough towards fiber diet-induced changes. However, IL-6
452 levels, which had been lowered in previous studies by fiber supplementation, were in most
453 cases already below detection threshold at baseline in our study population, so already at the
454 healthier end.

455 On the neural level, hypothalamic microstructure was not related to neither habitual nor
456 supplemental fiber intake. After two weeks of intervention, we observed that mean
457 hypothalamic MD tended to marginally decrease in the fiber intervention condition and
458 marginally increase after placebo intake, however, changes appeared negligible in size and
459 need to be interpreted with caution due to a lack of significance in the time-by-group

460 interaction ($p = 0.07$). Our results are in line with a previous systematic review reporting rather
461 non-significant effects or very small effect sizes across five RCTs investigating Mediterranean
462 dietary intervention effects on cognition and brain functions (Radd-Vagenas et al. 2018). In a
463 closely controlled environment, however, Song et al. could show that greater adherence to
464 Mediterranean diet, indicative of high-fiber intake, linked to less progression of white matter
465 lesions, probable of vascular and inflammatory pathology, in a prospective study over the
466 course of 5 years (Song et al. 2022). Further, a three-months Mediterranean-DASH
467 intervention led to an increase in surface area of the inferior frontal gyrus suggesting that such
468 a dietary intervention can reverse the potentially adverse effects of previous unhealthy diet
469 on brain structure (Arjmand, Abbas-Zadeh, and Eftekhari 2022). Notably, evidence of diet-
470 body/brain effects might be biased by inaccuracies in study conception and conduction, in
471 particular concerning dietary reporting, underpowered studies and short time-frames
472 (Duplantier and Gardner 2021).

473 The lack of a significant effect of fiber in our sample might also be explained by the overall
474 healthy condition of participants: hypothalamic MD was lower, indicative of healthier tissue,
475 compared to populations with a three decades-higher mean age (Thomas et al. 2019).
476 Additionally, our study was not powered for the detection of short-term intervention effects
477 on young adults' brain microstructure. As absence of evidence does not prove evidence of
478 absence, fiber-induced brain changes might be observable in larger or metabolically
479 conspicuous populations. We suggest that future studies should be designed with longer
480 intervention durations or with patient populations (e.g., including aging or metabolic disease).
481 Data pooling can additionally increase sample size to increase the probability of more definite
482 conclusions.

483 Investigating the effect of confounding variables in exploratory analyses, we observed that
484 higher body fat mass was associated with higher CRP in blood. Detrimental effects of body fat
485 mass on inflammatory markers have been shown previously (Festa et al. 2001). A causal link
486 has been indicated by reversibility experiments in normal-weight, physically active individuals,
487 where weight loss was paralleled by decreased low-grade inflammation (Sarin et al. 2019).
488 In addition, men had lower levels of CRP similar to pre-midlife populations (Sarin et al. 2019),
489 and higher body fat related to higher CRP in males in our sample. This might have contributed
490 to the observation of lower inflammation values in males. Unfortunately, our sample
491 consisted of more males than females due to more strict exclusion criteria for women.
492 Underlying potential sex differences, the effects of higher BMI on promoting systemic
493 inflammation have previously been shown to be less pronounced in men compared to women
494 (Choi, Joseph, and Pilote 2013). We further found higher BMI to be borderline related to lower
495 hypothalamic MD. Previous results from our and other groups in on average older participants
496 rather indicated that higher BMI, as well as higher age, related to lower MD in the
497 hypothalamus (Birdsill et al. 2017; Dekkers, Jansen, and Lamb 2019; Kullmann et al. 2016;
498 Lampe et al. 2019; Thomas et al. 2019; Sewaybricker et al., 2023), however, one earlier study
499 reported higher values of the apparent diffusion coefficients correlating with higher BMI in
500 the hypothalamus in middle old adults (Alkan et al., 2008). Future studies are needed to
501 further disentangle putative divergent patterns of hypothalamus MD and weight status in
502 different age groups.

503 Taken together, sex and body composition across the lifespan likely affect peripheral
504 inflammatory markers and brain microstructure more strongly, while dietary habits or short-
505 term dietary interventions exert no strong effects. Indeed, self-reported dietary fiber
506 assessment might have been too coarse, and the two weeks of intervention might not have

507 been long enough to induce changes on markers of systemic inflammation and at the brain
508 microstructural level in this relatively healthy young and healthy population.

509

510 *Strengths and Limitations*

511 In sum, limitations of this study include the self-reported dietary measure and short
512 intervention timeframe of two weeks. The validity of self-reported dietary intake and
513 intervention compliance is a central concern of nutrition studies, questioning the overall
514 reliability of (null) findings (Ioannidis 2018). In the current study, we estimated habitual
515 dietary fiber intake from self-report using a validated quantitative food frequency
516 questionnaire (Haftenberger et al. 2010) and developed a detailed diet scoring on macro- and
517 micronutrient level (Thieleking et al. 2023). Our double-blinded interventional, cross-over
518 within-subject design providing >200 repeated measures can be rated as gold standard.
519 Supplementary fiber intake compliance during intervention was high according to daily diaries
520 (average missed intakes 1.25 ± 1.8 , min = 0, max = 9). Within our study, we also collected stool
521 samples which showed significant shifts in the gut microbiome after fiber intervention
522 (Medawar 2021, Medawar, in press) indicating high compliance with the supplementation. In
523 sum, quality of the dietary data and intervention compliance in the present analysis can be
524 considered reliable.

525 Regarding population characteristics, we selected intuitive, omnivorous dieters in an
526 overweight range. Therefore, the BMI range covered only a part of different body
527 constitutions, so that our results cannot be transferred to other weight categories.
528 Nonetheless, we deeply phenotyped all participants at each study time point collecting
529 various serum markers, questionnaire data and high-resolution brain microstructural and
530 structural data. Thereby, we reduced biases possibly interfering with effects of interest,

531 namely by adding confounding factors and random effects to our statistical models. For the
532 difficult extraction of hypothalamic volume and MD values due to proximity to the third
533 ventricle, we followed a state-of-art processing pipeline resulting in reliable measures of the
534 hypothalamus. We also controlled for known influences on brain microstructure. We
535 additionally want to emphasize that prior to completion of data acquisition and data analysis,
536 we preregistered a detailed analysis plan (<https://osf.io/uzbav>) and provided open code for
537 re-use.

538

539 **Conclusion**

540 In this study, we investigated whether a habitual high-fiber diet and a two-week prebiotic
541 high-fiber intervention would reduce inflammatory processes. More precisely, we
542 hypothesized a decrease in blood levels of CRP and TNF- α and in hypothalamic MD. Our
543 findings do not support evidence for habitual or supplemented dietary fiber acting in an anti-
544 inflammatory manner in this young, overweight population. Rather, sex and body composition
545 were of higher importance for prediction of peripheral inflammation. Future trials are needed
546 that implement more diverse age and weight status groups and a longer timeframe for
547 prebiotic fiber supplementation, to advance our understanding of diet-brain modifications.
