**Abstract**

Viral sequencing has been critical in the COVID-19 pandemic response, but sequencing and bioinformatics capacity remain inconsistent. To examine the utility of a cloud-based sequencing analysis platform for SARS-CoV-2 sequencing, we conducted a cross-sectional study incorporating seven countries in July 2022. Sites submitted sequential SARS-CoV-2 sequences over two weeks to the Global Pathogen Analysis Service (GPAS). The GPAS bioinformatics cloud platform performs sequence assembly plus lineage and related sample identification. Users can share information with collaborators while retaining data ownership. Seven sites contributed sequencing reads from 5,346 clinical samples, of which 4,799/5,346 (89.8%) had a lineage identified. Omicron lineages dominated, with the vast majority being BA.5, BA.4 and BA.2, commensurate with contemporary genomic epidemiological observations. Phylogenetic analysis demonstrated low within-lineage diversity, and highly similar sequences present in globally disparate sites. A cloud-based analysis platform like GPAS addresses bioinformatics bottlenecks and facilitates collaboration in pathogen surveillance, enhancing epidemic and pandemic preparedness.

## Introduction

Viral genomic sequencing has been pivotal in understanding and responding to SARS-CoV-2 viral evolution during the COVID-19 pandemic. Global sharing of data and comparison of samples has facilitated public health surveillance by tracking the emergence of variants globally,[1] demonstrating the impact of travel restrictions on viral dynamics across continents,[2] and of travel and quarantine on spread within countries,[3,4] as well as demonstrating transmission routes within hospitals.[5] As successive waves driven by new viral variants emerged, it became clear that rapidly detecting new lineages is critical both for understanding and predicting disease epidemiology as well as for guiding both public health measures and treatment of infection, including the use of neutralising antibodies.[6,7] However there remains marked global variability in sequencing costs and capacity.[8] Much SARS-CoV-2 sequencing has been undertaken at centralised reference laboratories, but the speed and power of this tool is greatly enhanced when researchers and clinicians at any location can contribute to the global view of viral evolution and surveillance.[9]

Several important challenges remain in expanding pathogen genomic surveillance, including access to sequencing technology, the availability of bioinformatic resources and the global interpretability of results generated using different bioinformatics approaches.[10,11,12] One solution to the relative shortage of bioinformatic expertise in many settings is web-accessible analysis infrastructure.[13] The Global Pathogen Analysis Service (GPAS) is a cloud-based globally web-accessible platform that provides secure and rapid access to comprehensive SARS-CoV-2 sequencing genome assembly and analysis software. GPAS supports multiple sequencing platforms and tiling PCR primer schemes, and has been validated against widely used methods. Users can opt to share their data on this platform, allowing those who opt in to view their own results in a wider context, facilitating comparisons for rapid and comprehensive assessments of viral data. The platform is designed for use by clinical and public health laboratory scientists and has been established and used for over a year in a tertiary hospital based clinical microbiology laboratory to ISO15189:2012 standards. Scaling

up this simple-to-use assembly, variant calling and analysis tool for SARS-CoV-2 empowers laboratories to control the analysis of their sequence data. It provides proof of principle that standard microbiology laboratories without bioinformatics expertise from across the world can generate outputs for local surveillance and automated submission to public databases. Such a service is an exemplar of how cloud-based services, accessible in all settings with internet access, offer great promise for overcoming an important barrier to effective genomic surveillance.

The primary aim of this project was to demonstrate that a globally broad snapshot of SARS-CoV-2 viral diversity can be simultaneously gathered, processed and shared through a cloud-based software, enabling aggregation for combined descriptive analysis.

## Methods

*Sample frame and sequencing:* Sequencing centres participated in a two-week pilot in July to August 2022. Centres were from seven countries: Senegal; Chile; South Africa; New South Wales (NSW), Australia; Vietnam; United Kingdom; Virginia, United States (USA). Centres were either accredited clinical microbiology or public health laboratories. All clinical samples in which SARS-CoV-2 was detected were eligible for inclusion and underwent in-house genomic sequencing at participating sites during the pilot were eligible for inclusion, with no more than one submission from an individual patient.

Sequencing was performed using either Illumina or Oxford Nanopore Technology (ONT) platforms. Multiple primer schemes were supported (ARCTIC V3, V4 or 4.1, and Midnight). Sequencing platform and primer schemes were chosen by participating sites, who followed their established sequencing protocols.

*Bioinformatic methods:* Unselected raw sequences were submitted to GPAS in FASTQ format with sequencing information (instrument platform, primer scheme) and limited

associated metadata (sample name, whether sequence data was a control or study sample, collection date, country of origin). At upload, a Universally Unique IDentifier (UUID) was randomly generated and assigned to each sample. The mapping between the centre's sample identifier and the GPAS UUID was held only by the submitting organisation, ensuring that no potentially personally identifiable information was transmitted to the GPAS platform. When results were returned to the submitter after analysis, they could hence be re-linked to the subject's record. At upload, only reads mapping to SARS-CoV-2 were kept,[14] guaranteeing that no human reads were retained and pushed to the cloud. Tight access control to data applied within GPAS. With the permission of all collaborators, data access controls were configured such that all submitters could access each other's sequences, metadata and analytical output data for the duration of the investigation.

Sequence data analysis was performed by the GPAS SARS-CoV-2 bioinformatics pipeline. Genome assembly was performed by an amplicon-aware *de novo* genome assembly tool Viridian v0.3.7.[15] Viridian applies quality control (QC) at both a read and amplicon level, to produce a consensus assembly. Each genomic position is called A,C,G or T only where 10 or more reads passing amplicon-aware QC provide at least 70% support, otherwise it is called ambiguously as N. After assembly, clade assignment and amino acid mutation calls were made using Nextclade,[16] and Pango lineages assigned with Pangolin.[17] Samples were further labelled according to the United Kingdom Health Security Agency (UKHSA) nomenclature to define and track variants of concern using aln2type.[18] The GPAS QC suite provided read-level QC output for each sample, reporting the number of mapped reads per sample, median read depth, reference coverage at read depths of 10 and 20, and the number of amplicons failing quality control. Consensus genome assemblies were aligned by Viridian to the Wuhan-Hu-1 reference genome (MN908947.3).[19] Aligned sequences were compared using findNeighbour4, which identifies sequences without conflicting variant calls (0 single nucleotide variants (SNVs)), as well as those differing by one, two and three SNVs.[20,21]

Submitting sites verified the run quality reports of each sequencing batch, including review of positive and negative controls, and outputs were passed or failed accordingly. All passed samples were tagged for aggregate analysis, and released to the GPAS shared data pool, which identifies other samples within three SNVs in the shared data pool. The GPAS platform recorded the total number of sequencing runs and total number of samples. Analysis duration was also monitored, along with descriptive reports of any unexpected issues with the platform.

*Phylogenetic analysis:* In Oxford, genome assemblies in the shared data pool were downloaded from the GPAS portal. A maximum likelihood phylogeny of aligned sequences was constructed for the three largest Pango lineages in the sample set (BA.5, BA.4 and BA.2) in using RAxML [22] (assuming a general time reversible (GTR) nucleotide substitution model).

## Results

All sites tagged their sequencing data and results granting access for aggregated analysis. 5,437 sequences were shared (Table 1, Table S1). As different sequencing centres worked with samples collected at different times, the date of collection of submitted sequences varied by centre, ranging from April to July 2022. Of submitted samples 91 (1.7%) were controls and 5,346 (98.3%) were clinical samples Among these, 4,797/5,346 (89.7%) were assembled with at least 70% coverage (at a depth of 10 reads), and 4,799/5,346 (89.8%) were assembled with sufficient coverage to be assigned a lineage (Table 2). 4,775/4,799 (99.5%) were Omicron variants, with BA.5, BA.4 and BA.2 being the most common. A small number of Delta variant sequences were identified (23/4,799 0.5%), all of which were collected prior to July 2022.

Table 1: Samples submitted by study centre, with date of collection and genome coverage (with minimum depth of 10 reads)

| Centre | Submitted | Controls | <50% coverage | 50-70% coverage | >70% coverage | Earliest sequence | Latest sequence |
|---|---|---|---|---|---|---|---|
| Senegal | 197 | 0 | 14 | 10 | 173 | 13th July 2022 | 20th July 2022 |
| Chile | 1205 | 20 | 4 | 7 | 1174 | 16th June 2022 | 21st July 2202 |
| South Africa | 202 | 0 | 9 | 4 | 189 | 17th May 2022 | 24th June 2022 |
| NSW, Australia | 1194 | 31 | 34 | 23 | 1106 | 21st June 2022 | 18th July 2022 |
| Vietnam | 316 | 3 | 20 | 5 | 288 | 1st April 2022 | 14th July 2022 |

| Virginia, USA | 500 | 0 | 0 | 0 | 500 | 7th June 2022 | 29th June 2022 |
| Total | 5437 | 91 | 400 | 149 | 4797 | 1st April 2022 | 26th July 2022 |

Table 2: SARS-CoV-2 lineage by study centre (where a lineage was assigned by Pangolin)

| | Omicron | | | | | | | Delta | Alpha | Other | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Centre | BA.5 | BA.4 | BA.2 | BE.1 | BF.1 | BA.1 | BG.2 | Delta | B.1.1.7 | B.28 | Total |
| Senegal | 69 | 47 | 34 | 5 | 18 | 0 | 0 | 0 | 0 | 0 | 173 |
| Chile | 397 | 607 | 145 | 20 | 4 | 0 | 0 | 0 | 0 | 0 | 1,173 |
| South Africa | 89 | 86 | 3 | 6 | 0 | 5 | 0 | 0 | 0 | 0 | 189 |
| NSW, Australia | 736 | 130 | 184 | 54 | 3 | 0 | 0 | 0 | 0 | 0 | 1,107 |
| Vietnam | 8 | 0 | 256 | 0 | 0 | 4 | 0 | 22 | 0 | 0 | 290 |
| United Kingdom | 974 | 169 | 57 | 140 | 23 | 2 | 0 | 0 | 1 | 1 | 1,367 |
| Virginia, USA | 95 | 94 | 296 | 11 | 1 | 1 | 1 | 1 | 0 | 0 | 500 |
| Total | 2,368 | 1,133 | 975 | 236 | 49 | 12 | 2 | 23 | 1 | 1 | 4,799 |

Comparing only clinical samples collected between 1st June 2022 and 31st July 2022, the proportion of samples assigned to the different Omicron sub-lineages varied substantially by study site (Figure 1). Each of BA.2, BA.4 or BA.5 dominated (constituted >50% of samples from) at least one site, while Senegal had no single dominant lineage. For each of the three most common lineages, a maximum likelihood phylogeny was constructed to compare diversity within and between sites (Figure 2).

Phylogenetic analysis revealed global mixing of Omicron lineages. There were no examples of sub-lineages being completely geographically restricted within this study. One sub-lineage in BA.4 was predominantly found in Chile (Figure 2), however examples of this sub-lineage were also identified in the United Kingdom. Similarly, a sub-lineage of BA.2 was mainly found in Vietnam (Figure 2) but again an example of this genotype was found in the United Kingdom.

Highly genetically similar samples were identified within lineages from globally distinct sites, with branch lengths corresponding to $\leq 0.01\%$ of the genome (approximately three nucleotides) separating many samples. This limited diversity was further explored by examining the relative likelihood of samples being from the same site with increasing genomic variation. By this measure, the greatest dispersal was seen within the BA.4 lineage

(Figure 3). In total 357/1,133 of BA.4 samples were genotypically identical to another sequenced sample. Among these, 244/357 (68.4%) were only identical to other samples from the same study centre. Allowing for just one single nucleotide variant (SNV) reduced the proportion of closely related samples to the same study centre (and country) to 302/634 (47.6%). The proportions reduced to 279/819 (34.1%) and to 201/923 (21.8%) when allowing for two and three SNVs respectively. Only 210/1,133 (18.5%) did not have a related sample allowing up to three SNVs. The other major lineages BA.2 and BA.5 likewise showed evidence of genotypically identical sequences identified at different study sites, with increasing evidence of dispersal as SNV threshold increased (Figure 3).

Cloud processing performance was measured by time elapsed from upload until completion of processing. The median sample processing time was 30.6 minutes (IQR 13.1-69.9 minutes). The distribution of processing times was much wider than expected, and processing delays occurred for several batches from Australia, United Kingdom and United States (Figure S1). Some of these coincided with data centre outages during an extreme heat event in the United Kingdom, while other delays occurred due to errors in a software update for the upload portal, which were resolved by improvements implemented in the user side command line interface software. Other data upload issues were identified and addressed in real time, including metadata file formatting errors, availability of upload clients for all required operating systems, and user interface display errors preventing batch release.

## Discussion

This pilot study reveals the potential for cloud-based synchronous global data processing and analysis for public health. The GPAS platform provides an example of unified assembly, variant calling and analysis of data from participating centres, which can facilitate both local and globally aggregated analysis. In this cross-sectional observational study, the aggregate analysis conforms to contemporary observations of SARS-CoV-2 genetic

224 epidemiology[23,24,25,26,27], though these observations remain limited by global disparities
225 in sequencing volume.
226
227 The opportunistic sampling frame used means this study is likely to be geographically
228 incomplete, but even with this limitation we observed cosmopolitan global mixing of
229 Omicron lineages between study sites. Even a BA.4 sub-lineage which demonstrated
230 extensive replacement in one geographical location (Chile) was not completely restricted to
231 that site and could be identified in a geographically distant site (United Kingdom). During the
232 period of the study, the United Kingdom site performed genomic sequencing on all clinical
233 isolates which had tested positive for SARS-CoV-2 on PCR, and despite being dominated by
234 BA.5, was also able to identify examples of a BA.2 sub-lineage that was otherwise restricted
235 to Vietnam. Such mixing is likely the result of movement for travel and migration, as SARS-
236 CoV-2 related travel restrictions had been relaxed in the countries with participating sites.
237
238 Given evidence of global mixing and limited diversity between sites, viral genome
239 sequencing is limited in its ability to inform studies of local viral transmission in this
240 Omicron dominated era, where both rapid global mixing and transmission drives spread.[26]
241 Allowing for up to three different single nucleotide variants, the majority of isolates from the
242 dominant lineages BA.2, BA.4 and BA.5 had at least one closely related sample within each
243 countries' contemporaneously sequenced samples. Depending on lineage, between 10.0%
244 and 31.5% of genotypically identical sequences in this study were identified in different
245 countries and continents. The use of a shared bioinformatics analysis pipeline, as described
246 here, highlights how lineages can be simultaneously and confidently mapped across distant
247 sites. This captures the evidence of well described rapid global dispersal of Omicron lineages
248 with successive selective sweeps of these new Omicron variants over short time scales.[27]
249
250 These observations highlight the potential for deriving insights from viral sequencing at a few
251 globally distributed sites. While this study pertains to a specific point in the pandemic, it

raises the question of how to better design genomic surveillance balancing the public health need and available resources. It is recognised that a preponderance of sequence data came from high-income countries, who sequenced a proportion of cases ten-fold higher than that achieved in low- and middle-income counties during the first two years of the pandemic.[9] Nor was the data collected evenly over the course of pandemic. In retrospect this was not optimal. Better designed representative sampling would be immensely empowering and is likely possible through well-designed and suitably powered sampling frames. Ideally, this would be addressed through pandemic preparedness planning, enabling sequencing to be focussed at selected sentinel sites globally cognisant of national jurisdictions and the benefit of longitudinal data, as exemplified by a cohort design in the UK.[25]

Pathogen sequencing played a highly valuable role in the COVID-19 pandemic and remains a critical global and national capability. This is highlighted by studies of viral transmission that have yielded important insights into the modes of pathogen spread.[1-5] In addition, identification of emerging variants-of-concern guided public health and policy responses,[28] as well as informing assessments about the impact of emerging variants on the impact of therapeutics (such as monoclonal antibodies) and vaccines.[7,29] The present cross-sectional study has the limitation of lacking longitudinal data on how these findings changed over time. Nevertheless, this study demonstrates how simply structured sampling across the world is well placed to rapidly identify replacement by new lineages. The integration of genomic data with subject disease manifestation and severity data would enable the ready investigation of associations between genomic variation and severity of disease, as suggested by others [30] and predictive modelling for anticipating the course of future epidemics as described so effectively early in the SARS-CoV-2 pandemic [31].

The world is now better prepared to urgently initiate genomic pathogen surveillance. The available sequencing platform capacity is much improved, and the achievements of global data aggregation (illustrated by INSDC and GISAID databases) has alleviated a major

obstacle to effective genomic surveillance. A remaining obstacle is local turnkey bioinformatics to perform sequence assembly, variant calling and analysis. These are needed to deliver standardised and quality assured outputs – specifically the SARS-CoV-2 viral sequence FASTA file – for phylogenetic analysis either for global analysis by an international entity such as GISAID, or for local and national analyses. GPAS has developed an exemplar cloud-based, web-enabled service design that is optimised for operation by a laboratory scientist and removes dependence on in-laboratory bioinformatics expertise. Thus, this work reveals the benefit of establishing software for simply and automatically ingesting sequence data from a sequencer in a local lab and yielding data ready for local or international analysis. A software infrastructure such as the GPAS platform fills a gap in delivering global genomic surveillance. Flexible privacy protections allows users to control sharing of genomic data. GPAS is freely available to low- and middle-income countries, reducing some of the barriers to analysis services in low resource settings. Remaining challenges include high speed computer network access and local epidemiological tools, and expertise for detailed epidemiological analysis.

## Conclusions

The COVID-19 pandemic has demonstrated the multiple ways in which viral sequencing can inform pandemic responses, but resources and capabilities are not equitably distributed. A service like GPAS democratises SARS-CoV-2 genomics, enabling researchers and laboratories, regardless of their location or level of bioinformatics expertise, to participate actively in global surveillance efforts. By providing accessible and user-friendly tools for sequence assembly, lineage assignment, and data sharing, it fosters collaboration, harmonises data, and ultimately enhances pandemic preparedness.

**Funding statement**

GPAS is free at the point of use for users in low- and middle-income countries. GPAS was developed specifically to minimise the need for bioinformatics staff (a scarce and expensive resource), to help bring genomic insights within reach for laboratories with limited resources.

GPAS operates as a non-profit organisation. All GPAS SARS-CoV-2 services were offered free of charge to all sites for the purposes of this study. Staff costs for the 5C analysis team were met by the University of Oxford.

The cloud infrastructure used in this study was donated by Oracle Corporation.

Sequencing activities for NICD are supported by a conditional grant from the South African National Department of Health as part of the emergency COVID-19 response; a cooperative agreement between the National Institute for Communicable Diseases of the National Health Laboratory Service and the United States Centers for Disease Control and Prevention (NU51IP000930); the South African Medical Research Council (SAMRC) with funds received from the South African Department of Science and Innovation; the African Society of Laboratory Medicine (ASLM) and Africa Centers for Disease Control and Prevention through a sub-award from the Bill and Melinda Gates Foundation grant number INV-018978; Africa PGI, the UK Foreign, Commonwealth and Development Office and Wellcome (Grant no 221003/Z/20/Z); and the Department of Health and Social Care's Fleming Fund using UK aid.. NICD sequencing was also supported by The Coronavirus Aid, Relief, and Economic Security Act (CARES ACT) through the Centers for Disease Control and Prevention (CDC) and the COVID International Task Force (ITF) funds through the CDC under the terms of a subcontract with the African Field Epidemiology Network (AFENET) AF-NICD-001/2021.

Genomic surveillance conducted in Vietnam was supported by the Wellcome Trust (222574/Z/21/Z). L.V.T. is supported by the Wellcome Trust of Great Britain (204904/Z/16/Z and 226120/Z/22/Z).

## Ethical statement

SARS-CoV-2 sequencing was performed for public health surveillance and ethical approval for secondary analysis was not required. This determination was reviewed by the University of Oxford Joint Research Office. No patient identifying information was shared as part of this study. Sample identifiers remain with the submitter, and are never kept on GPAS or shared with other users. GPAS generates identifiers for each sequence and writes a file linking anonymised ID to the submitted identifiers. Only the user submitting sequence data has access to these records. The GPAS upload client selects only SARS-CoV-2 sequence reads and discards non SARS-CoV-2 reads (including all human sequences).

## Data availability

Submitted sequencing reads (free from human reads) for all included samples are available from European Nucleotide Archive study accession PRJEB70597.

## Conflicts of interest

AvG and NW have received grant funding from Sanofi and The Bill and Melinda Gates Foundation.

## Figures

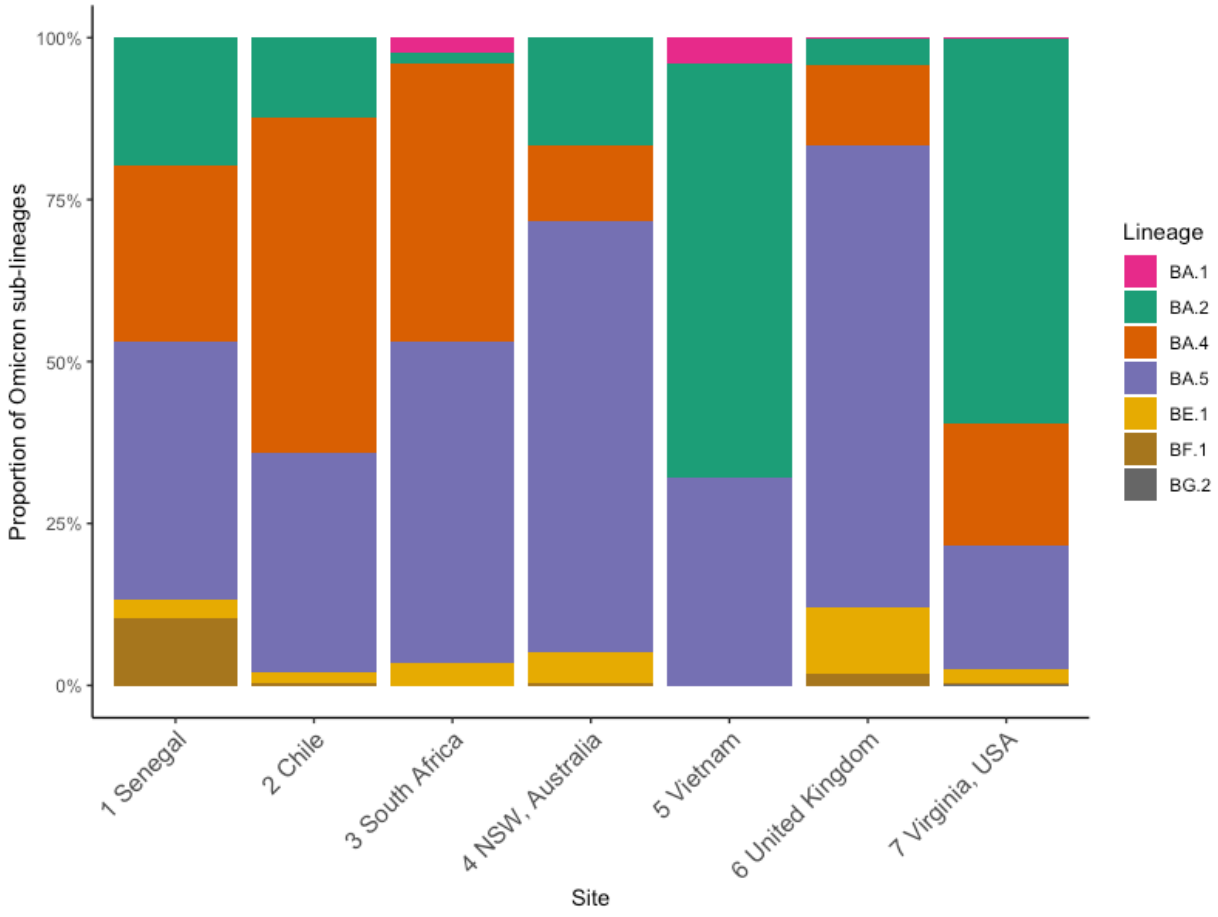

**Figure 1:** Omicron sub-lineages by study site. Proportion of samples assigned to Omicron sub-lineage within each study site, where collection date was in June or July 2022.

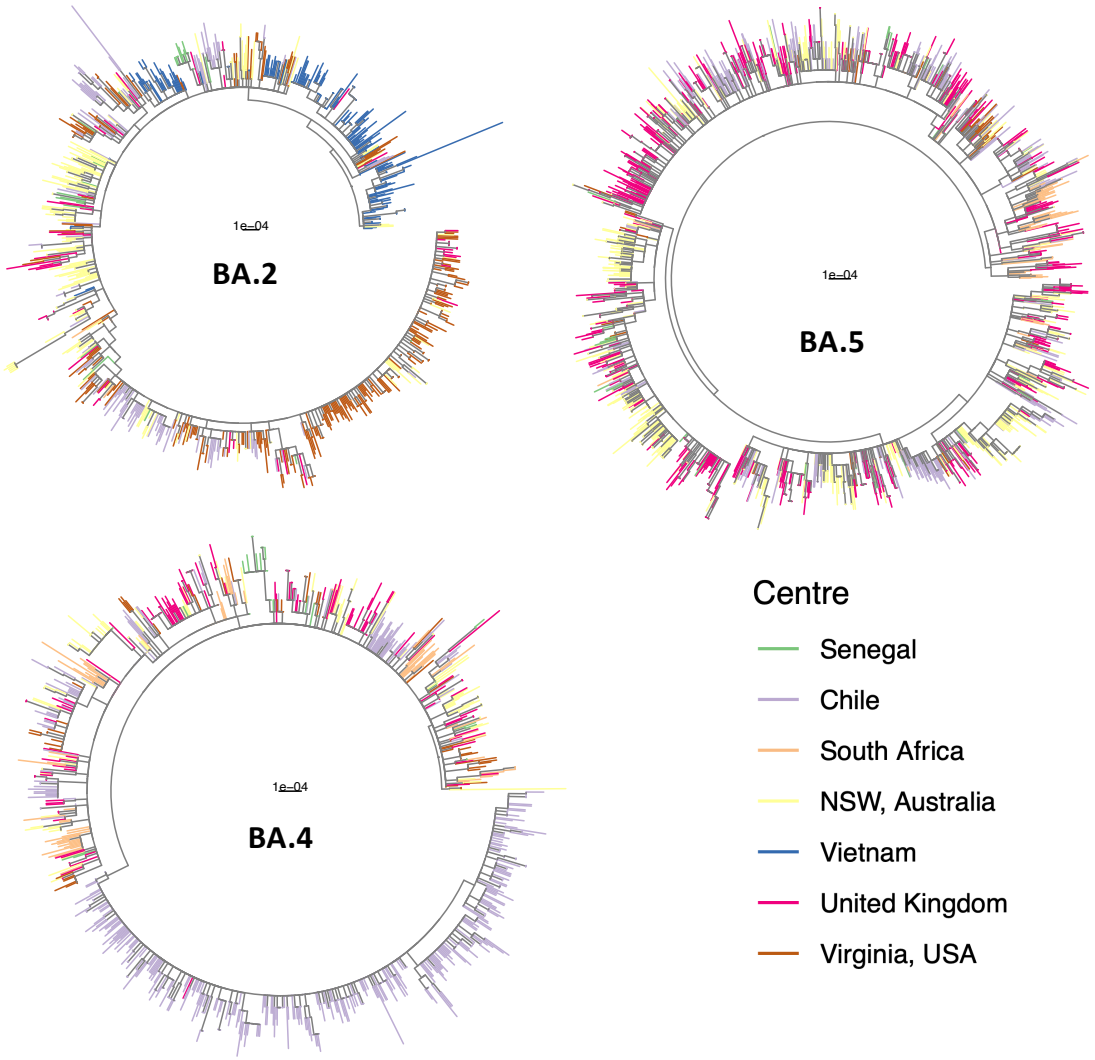

**Figure 2:** Maximum likelihood phylogeny of isolates from each major lineage (BA.2, BA.4, BA.5) found in seven centres. Final branches are coloured according the centre in which they were sequenced.

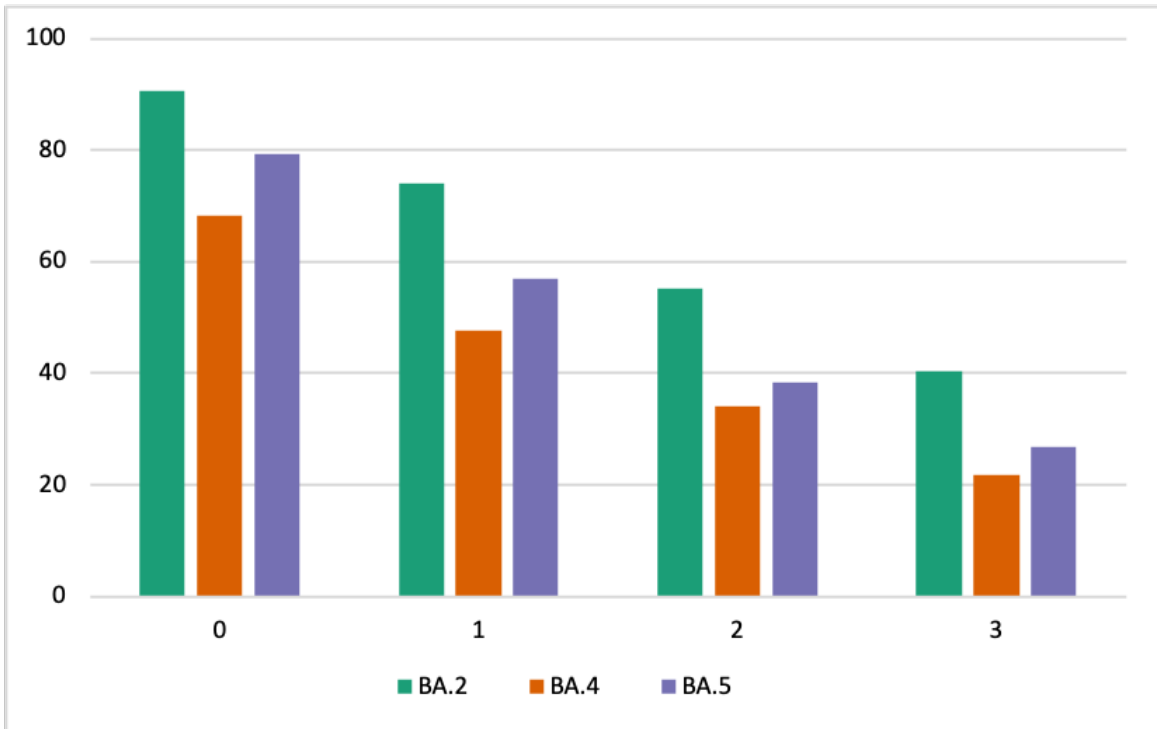

**Figure 3:** Percentage of related samples which are restricted to the same study site, allowing for 0, 1, 2 and 3 SNVS as the threshold for relatedness, for 3 major lineages (BA.2, BA.4 and BA.5).

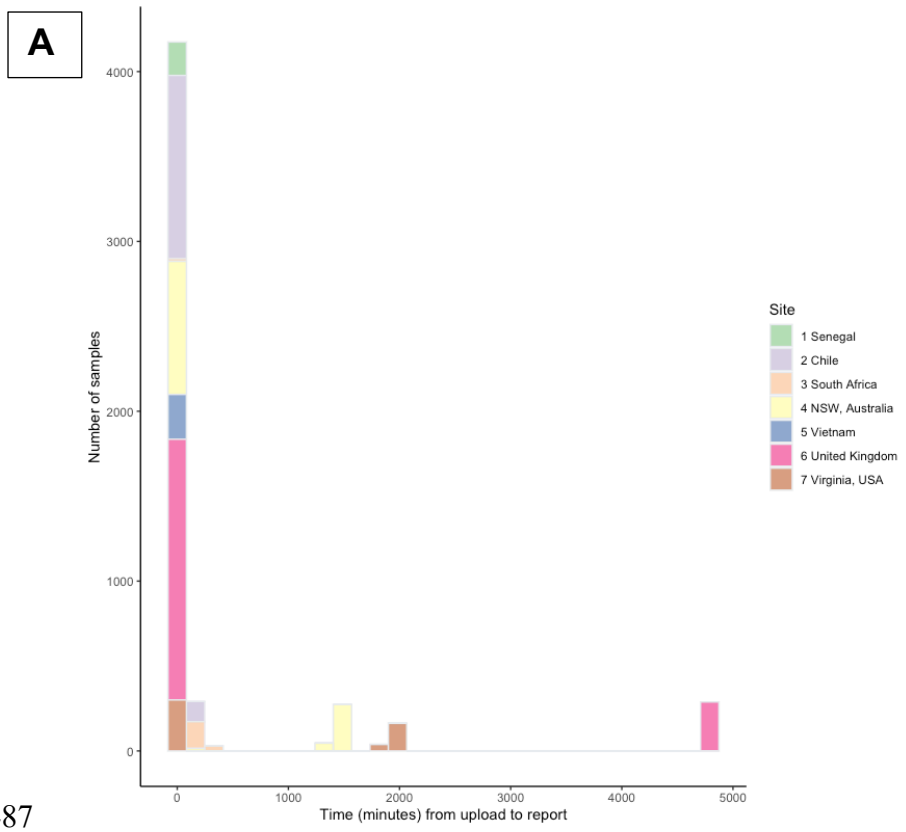

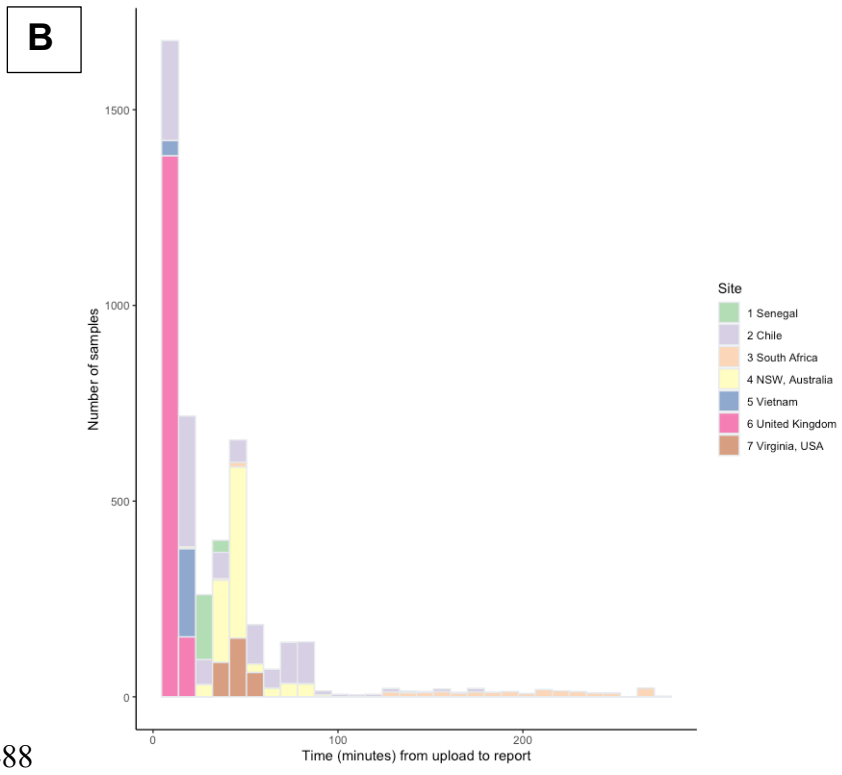

**Figure S1:** Distribution of processing time (in minutes) for each sample in GPAS pipeline according to submitting site (a) all samples and (b) samples processed in under 1000 minutes
