6

7

8 **Abstract**

9 **Objective** Low socioeconomic status (SES) has been associated with an increased risk of
10 depression and psychiatric disorders in general. In this systematic review and meta-analysis,
11 we aim to provide an estimate of the risk of clinical depression associated with low SES
12 across cultures, age groups and study designs. Finally, we tested whether associations
13 between SES and depression differed by the income of the country in which the study was
14 conducted.

15

16 **Methods** A literature search across five databases returned 7,943 studies. Title, abstract and
17 full text screening resulted in 162 included studies of which 122 were meta-analysed, 22 were
18 included in a cross-sectional narrative review and 19 studies were included in a longitudinal
19 narrative review. Meta-analyses were divided into risk estimates for composite SES, income,
20 education, and employment. Sensitivity analyses based on differences in economic situation
21 in the country of study origin were performed to investigate a possible source of between
22 study heterogeneity.

23

24 **Results** Low SES was associated with an increased risk of depression across all measures of
25 SES. Low income was associated with the highest odds ratio for depression (OR = 1.96, 95%
26 CI = 1.53-2.52). Sensitivity analyses revealed no significant differences in between-study
27 heterogeneity or risk of depression between high- and low-income economy groups.

28

29 **Conclusions** Comparable risks of depression across economy groups suggest that income
30 relative to your peers, rather than absolute income, is a risk factor for depression.
31 Preventative measures and possible policy interventions are discussed.

32

33 **Strengths and limitations of this study**

- 34 • This systematic review provides the largest and most comprehensive review and
35 meta-analysis of the association between socioeconomic status and depression.
- 36 • The included studies span a broad range of ages, cultures, and country economies,
37 allowing for better generalisation of the results.
- 38 • The inclusion of component parts of socioeconomic status (income, education, and
39 employment) in the meta-analysis allows for comparisons of the different risk
40 estimates.
- 41 • The broad inclusion criteria are likely to allow for increased between-study
42 heterogeneity.
- 43 • Due to the observational nature of the studies included it is difficult to make
44 conclusions on the direction of causality between socioeconomic status and
45 depression. However, the inclusion of a longitudinal narrative review may give an
46 indication of a direction of causality.

47

48

49 **Introduction**

50

51 Depression is a leading cause of disability world-wide, affecting over 322 million people
52 (WHO 2017). Depression is associated with an elevated mortality risk (Gilman et al., 2017)
53 due, in part, to an increased risk of suicide in depressed people (Bachmann 2018), and to a
54 number of common life-shortening comorbidities (Walker et al 2018.). While there is a
55 significant genetic contribution to the risk of developing depression (Sullivan et al 2000)
56 there is evidence that environmental risk factors, amongst them poverty, deprivation, and low
57 socioeconomic status, are likely to confer an increased risk of depression.

58

59 Socioeconomic status (SES) refers to a composite level of income, education and
60 occupation, where lower SES reflects overall material and social deprivation. Lower SES has
61 previously been associated with an increased risk of developing depression (Lorant et al.,
62 2003) and is one of the strongest predictors of overall poor mental and physical health
63 (Everson et al., 2002). Low SES is also a risk factor for many of the chronic diseases
64 associated with or comorbid with depression (Hosseinpoor et al., 2012; Robbins et al., 2005).
65 This relationship may be bidirectional as chronic disease can lead to loss of income,
66 unemployment, or interrupted education.

67

68 Many studies of psychiatric disorders in general and depression in particular control
69 for SES when investigating the effects of other risk factors of interest. However, this
70 approach minimises the contribution of poverty itself, which may have larger effects on
71 depression than many of the factors being studied. For example, a recent meta-umbrella
72 systematic review (Arango et al. 2022) on modifiable risk factors common to major
73 psychiatric disorders failed to include analysis of any socioeconomic measures.

74

75 While a growing body of research links low SES with poor health, there is a global trend
76 for increasing life expectancy, rising levels of education and fewer people living in poverty
77 (Roser & Ortiz-Ospina, 2016; Roser et al., 2013). However, this trend is not uniform across
78 all countries (World Bank Group 2020; Marmot 2020).

79

80 Given the persistent nature of relationships between low SES and health outcomes, such as
81 increased risk of depression, there is a clear need to quantify the strength of this association.

82 It is also unclear whether the relationship of depression with SES depends upon an
83 individual's absolute socioeconomic position, or on their position relative to that of other
84 individuals in the same country. Previous research on the association between SES and
85 depression have shown evidence of an association in specific cultures and contexts
86 (Richardson et al. 2015), certain age groups (Reiss et al 2013), and sections of society (Lund
87 et al 2010).

88

89 In the present review, we systematically reviewed the existing literature measuring the
90 effects of low SES on risk of depression. We provide an synthesis of studies from countries
91 spanning the spectrum of income economies. We sought to test whether differences in SES
92 were associated with the absolute level of poverty in the nation from which participants were
93 recruited, or if differences in SES were consistent across income settings and therefore
94 indicative of an association with relative rather than absolute social position.

95

96

97 **Methods**

98 **Inclusion and exclusion criteria**

99 Peer-reviewed literature and published PhD theses that examined the association
100 between SES and clinically relevant depression were included. PhD theses were included to
101 mitigate publication bias.

102 Studies involving participants with clinical depression were included if they used any
103 recognised structured diagnostic criteria, whether self-reported, obtained through data
104 linkage, or diagnosed using a diagnostic clinical interview or questionnaire with a clear
105 clinical cut-off. Studies focusing on symptoms and comparisons between subgroups of
106 depression were excluded. Studies with an unclear division between cases and controls i.e.
107 comparing sub groups of depressions, and those with insufficient results to be meta-analysed
108 were also excluded if study authors were not able to provide this information. There were no
109 restrictions on the age, sex, cultural heritage or comorbid diseases of the participants in the
110 present review.

111 Studies that grouped depression with other psychiatric disorders (often anxiety or
112 schizophrenia) in the “case” group and compared it to a “control” group without both the
113 psychiatric disorders present in the “cases” group were excluded. However, there were no
114 restrictions on comorbidities being included in the present systematic review. As a result,
115 studies with participants with more than one psychiatric disorder or health problem were
116 included, as long as the only difference between the cases-group and controls-group was the
117 presence or absence of depression.

118

119 **Search strategy**

120 Literature searches were performed in the following databases: PsycInfo, EMBASE,
121 Medline, Web of Science, ASSIA. The databases were chosen to cover as broad a range of
122 medical and sociological sources as possible.

123 In four out of five databases searches were conducted using subject headings. The
124 following search template was used in PsycInfo, EMBASE. Medline and ASSIA:

125 Depression AND (Socioeconomic status OR Income OR Occupation OR Education).

126 Web of Science does not facilitate subject heading searches. Instead, a keyword
127 search was conducted using the same key words that were used in the subject heading search
128 (Depression ADJACENT (Socioeconomic status OR Income OR Occupation OR Education))
129 ensuring the keywords were within 5 words of each other using the “adjacent” search
130 function.

131 In all databases, filters were applied to exclude reviews, conference abstracts and
132 animal research and to limit the search to English language papers. There were no restrictions
133 on publication date or country of origin of the search results. Studies on perinatal depression,
134 depression subtypes and depressive symptoms were not filtered out. This was done to
135 minimise automatic exclusion of studies meeting inclusion criteria. Instead, studies
136 investigating perinatal depression, depression subtypes and depressive symptoms were
137 excluded during the two screening processes.

138

139 The last date for all searches was 15th of March 2019.

140

141 A protocol for this systematic review and meta-analysis was published on the international
142 prospective register of systematic reviews (PROSPERO). The protocol can be found under
143 the ID: CRD42019129509. The protocol was followed except for a risk of bias assessment. To

144 date there is no universally recognised screening tool for risk of bias for observational studies
145 (Bero et al., 2018) and the most popular tools for observational research have been found to
146 be inconsistent (Losilla et al. 2018). The Newcastle-Ottawa Scale for case control and cohort
147 studies (mentioned in the protocol) has been argued to include invalid items, producing
148 highly arbitrary results (Stang 2010). As a consequence the authors of this review decided not
149 to conduct a formal risk of bias assessment.

150

151 **Data collection**

152 Abstracts and titles were initially screened by one author (AJ). Studies screened that met
153 inclusion criteria but could not be found through online databases were requested through the
154 University of Edinburgh's interlibrary loan services. Assessing interrater reliability is
155 important to ensure that the screening process does not miss any eligible studies and that the
156 screening method is replicable across different assessors. Selection bias can be introduced in
157 the screening processes if an assessor repeatedly includes or excludes studies based on factors
158 other than those listed in the inclusion and exclusion criteria. To assess interrater reliability
159 and selection bias a second author (RM) screened a 10% subsample (N = 795) of abstracts
160 and titles. There was an 89.7% agreement on the outcome of the screening by the two
161 authors. 521 studies were screened against their full text.

162

163 Data collection was done alongside full text screening, and a sample of the data
164 collection sheet can be found in Additional file 1.

165

166 **Analysis**

167 For the meta-analyses the studies were divided into four groups according to how they
168 measured SES: dichotomous, ordinal with three groups, continuous, and longitudinal. The

169 dichotomous study group was made up of all the studies reporting data in a
170 binary/dichotomous format and all the studies reporting results in an ordinal format with 4
171 socioeconomic groups. The latter type of study was dichotomised by merging the top two
172 socioeconomic groups together (high) and the bottom two socioeconomic groups together
173 (low). Dichotomous, studies were meta-analysed separately according to the type of SES
174 indicator used: a composite SES measure, income, education, and employment
175 (unemployment). As a result of meta-analysing each SES indicator separately, some studies
176 appeared in several meta-analyses, because they reported results for more than one indicator.

177 A pooled OR and 95% CI was calculated for each SES indicator using the package
178 ‘meta’ (Balduzzi et al., 2019) in R version 4.0.4. The effects were calculated using a random
179 effects model and the between studies variation was calculated using the Sidik-Jonkman
180 estimator (IntHout et al., 2014). RRs and ORs were meta-analysed together as they are
181 statistically comparable when the prevalence is low.

182

183 Data files and code can be accessed at:

184 https://osf.io/dqnp5/?view_only=ca92b1486ab842b4bbf8c20f9ea4e4c2.

185

186 A narrative approach was adopted for papers that could not be meta-analysed due to
187 the design of the study or insufficient reporting of results. Similarly, all longitudinal papers
188 were included in a longitudinal narrative review due to a combination of low number of
189 studies in each of the SES groups and variable follow-up time.

190

191 Significant heterogeneity between studies was anticipated given the large number of
192 studies included and the range of countries, age groups and diagnostic tools reported.

193 Between study heterogeneity was explored using Cochrane’s Q and quantified by an I^2

194 statistic. Both measures were calculated using the ‘meta’ package in R. To explore possible
195 reasons for between-study effect size heterogeneity, sensitivity analyses based on the
196 economic situation in the country of origin were performed. The World Bank country and
197 lending group classifications were used to divide countries into low- and high-income
198 economy subgroups. A sensitivity analysis was carried out for each measure-specific meta-
199 analysis on dichotomised data to compare ORs and CIs and heterogeneity measures between
200 high- and low-income economy subgroups. We hypothesised that estimates of depression risk
201 associated with SES indicators would be similar across low- to high-income economies,
202 consistent with the importance of relative position within a country, rather than absolute
203 differences.

204

205

206 **Results**

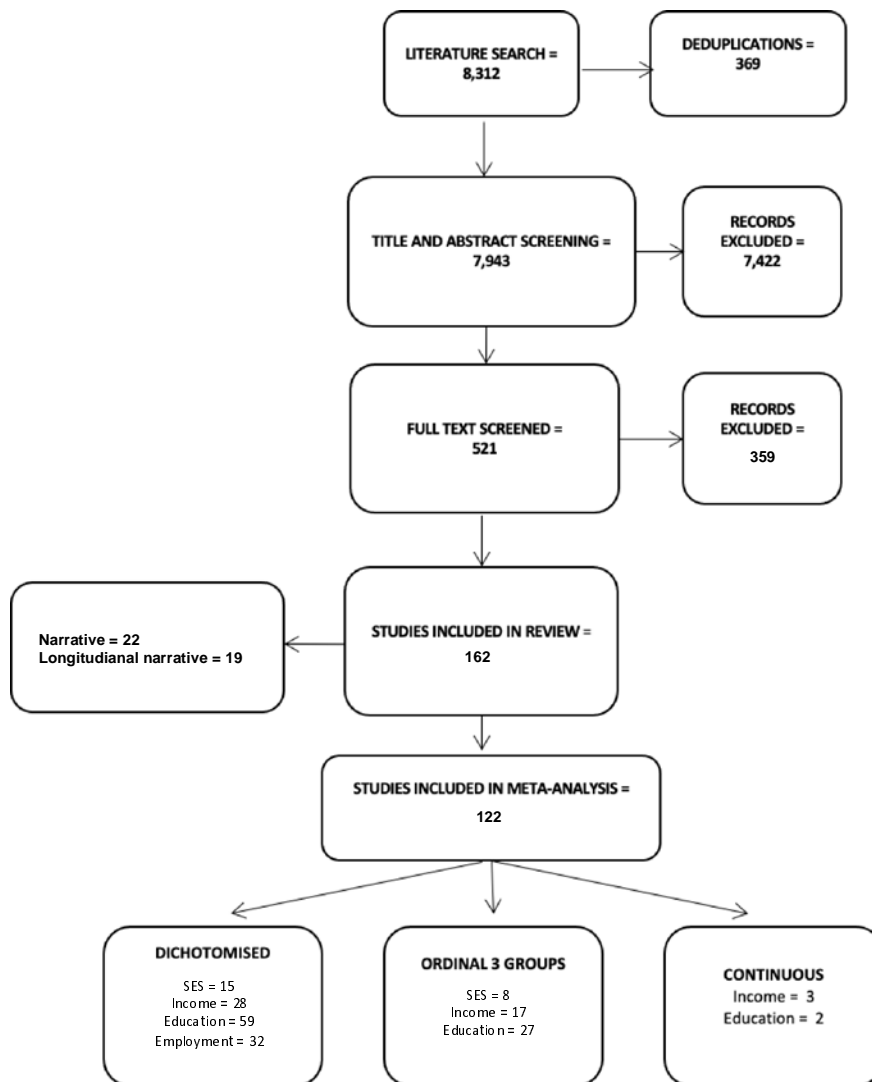

207

208 **Study inclusion**

209 The literature search returned 8,312 studies, 369 of which were duplications. During
210 title and abstract screening of the 7,943 remaining studies, 7,422 were excluded. The
211 remaining 521 studies were full text screened, leading to another 359 papers being excluded.
212 A breakdown of the reason for exclusions can be seen in Additional file 2.

213 As a result, 162 studies were included in the systematic review and meta-analysis.

214 Figure 1 shows a flow-chart with the number of studies excluded at each step and the number
215 of included studies in each of the meta-analyses.

216

217

218 *Figure 1: Flowchart of the number of included and excluded studies. Studies in the “Dichotomised” bin reported data in 2*
219 *groups (e.g. high vs. low income), studies in the “ordinal 3 groups” bin reported data in 3 groups (e.g. low, medium, and*
220 *high educational attainment), and studies in the “continuous” bin reported continuous results (e.g. median income for*
221 *depressed people).*

222

223

224 **Missing data and contact with authors**

225 A total of 17 studies reported insufficient data (only worded or graphed results,
226 inconsistencies in reported numbers, no reporting of cut-off, etc.) to include the study in one
227 of the meta-analyses or one of the narrative reviews. Authors of 15 out of the 17 studies were
228 contacted for data or clarification. Author contact details for 1 study could not be found and
229 another had since deceased. Out of the 15 authors that were contacted, 7 replied, and 1
230 provided supplementary data enabling the study to be included in the meta-analysis.

231

232 **Study population**

233 The total number of participants in the 162 studies was 329,005 of which 48,158
234 presented with depression. The resulting overall prevalence is 14.6%. The participants were
235 recruited from 47 countries across 6 continents.

236 Of the studies included in the meta-analysis, 63 were from high income countries, 30
237 from higher middle-income economies, 11 from lower middle-income economies and finally
238 10 from low-income economies.

239 In 56 of the studies reporting statistics on their participants age, participants were over
240 18 and had a mean age below 50. Participants had a mean age of over 50 in 31 of the studies.
241 Children were included as participants in 10 of the studies.

242 Finally, of the studies included in the meta-analysis 72 of them recruited participants
243 from a community setting while 39 of them recruited from a clinical setting.

244

245

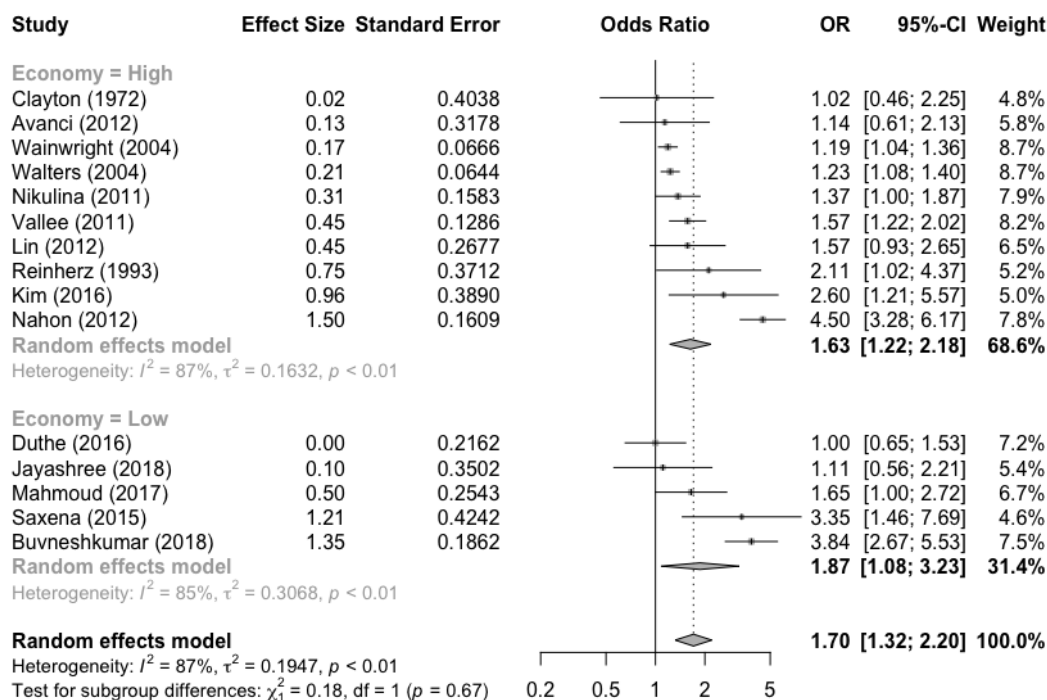

246 **Dichotomised meta-analyses**

247 **Socioeconomic status**

248 Results from the 15 studies included in the dichotomised meta-analysis of the
 249 association between composite SES measures and depression can be seen in Figure 2. The
 250 pooled OR for composite SES and depression was 1.70 (95% CI = 1.32-2.20), representing a
 251 70% increase in the odds of depression among individuals of low SES compared to high SES.
 252 A sensitivity analysis showed no significant differences in the estimates of risk between high-
 253 and low-income economy subgroups (df = 1, p = 0.67)

254 The between-study heterogeneity was estimated at $I^2 = 87%$ (with a variance of τ^2
 255 0.19). Cochran's Q was estimated at 105 (p < 0.001).

256

257

258 *Figure 2: Forrest plot of ORs and CIs of depression risk in people with low SES, from dichotomised data. (e.g. high vs. low*

259 *SES). Results are shown for each individual study, a pooled estimate for high- and low-income economy subgroups, and*

260 *pooled estimate for all included studies.*

261

262

263 **Income**

264 Results from the dichotomised meta-analysis of the association between income and

265 depression, including data from 28 studies, can be seen in figure 3. In the pooled estimate,

266 individuals on a low income had a 96% increase in odds of having depression compared to

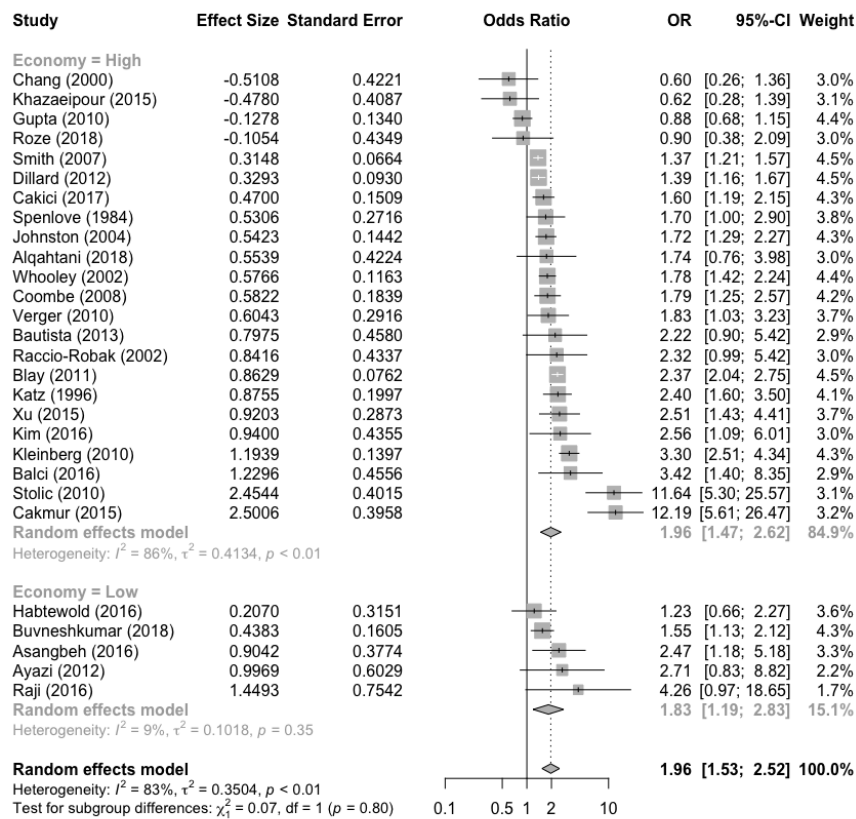

267 individuals on a high income (OR = 1.96, 95% CI = 1.52-2.53). A sensitivity analysis showed

268 no significant differences in the estimates of risk between high- and low-income economy

269 subgroups (df = 1, p = 0.80). The between-study heterogeneity was estimated at $I^2 = 83%$

270 (with a variance of $\tau^2 = 0.35$). Cochran's Q was estimated at 156 (p < 0.001).

271

272

273 *Figure 3: Forrest plot of ORs and CIs of depression risk in people with low vs high income, from dichotomised data. Results*
274 *are shown for each individual study, a pooled estimate for high- and low-income economy subgroups, and pooled estimate*
275 *for all included studies.*

276

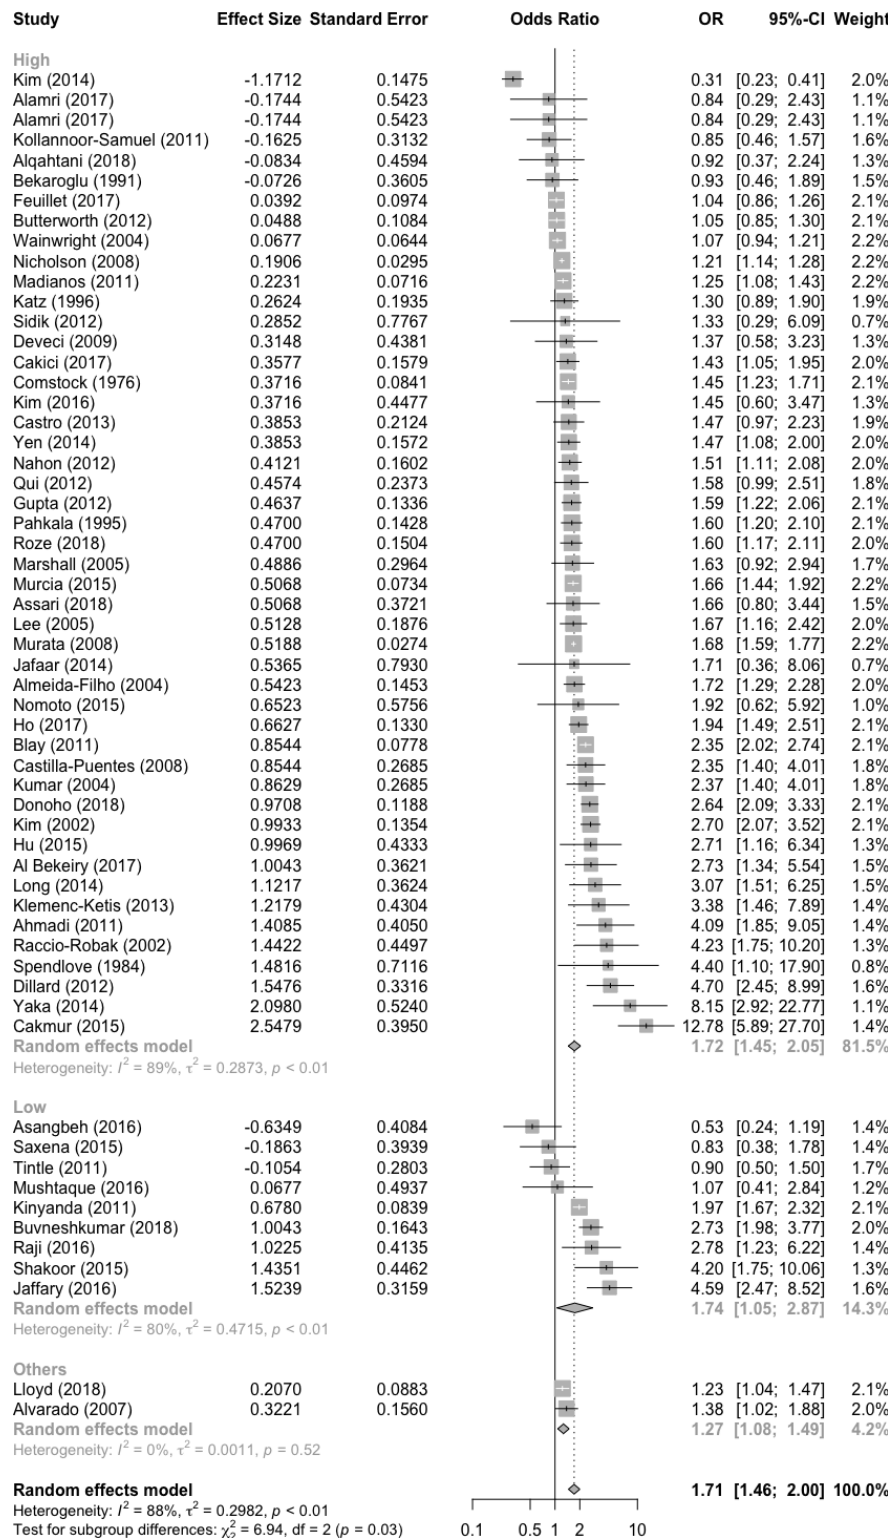

277

278 **Educational attainment**

279 The results from the dichotomised meta-analyses of association between educational
280 attainment and depression, including 59 studies, can be seen in figure 4.

281 In the pooled estimate, people with a lower educational attainment had a 69% higher
282 risk of depression compared to people with a higher educational attainment (OR = 1.71, 95%
283 CI = 1.46-2.00). The between-study heterogeneity was estimated at $I^2 = 88\%$ (with a variance
284 of τ^2 0.29). Cochrane's Q was estimated at 465 ($p < 0.001$). Note that two included studies
285 reported education-depression associations in multiple countries, including both high- and
286 low-income economy countries. When these studies were included as a separate subgroup,
287 there was a significant difference between risk estimates of the three economy subgroups (df
288 = 3, $p = 0.03$), with the pooled estimate for this third subgroup demonstrating relatively weak
289 associations between low educational attainment and increased depression risk. However,
290 without the third subgroup, there was no significant difference between risk estimates of the
291 high- and low-income economy subgroups ($df = 1$, $p = 0.90$).

292

293

294 *Figure 4: Forrest plot of ORs and CIs of depression risk in people with low educational attainment, from dichotomised data.*

295 *Results are shown for each individual study, a pooled estimate for high- and low-income economy subgroups, a pooled*

296 *estimate for studies that could not be placed in either high- and low-income economy subgroup (“others”), and pooled*
297 *estimate for all included studies.*

298

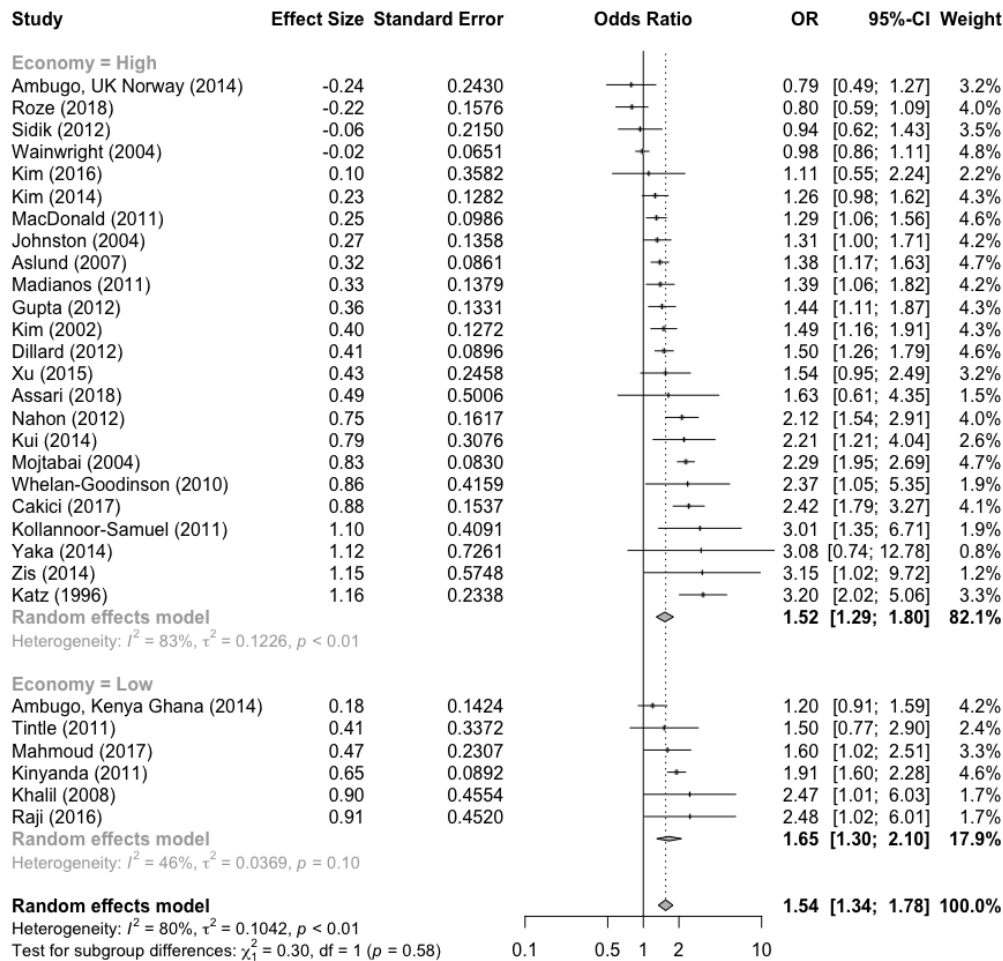

299

300 **Employment**

301 The dichotomised meta-analysis on the association between employment (or
302 unemployment) and depression, including results from 29 studies, can be seen in figure 5.

303 The pooled estimate indicated that people who were unemployed had a 57% higher
304 risk of experiencing depression. The between study heterogeneity was estimated at $I^2 = 81\%$
305 (with a variance of $\tau^2 = 0.09$). Cochranes Q was estimated at 138 ($p < 0.001$). There was no
306 significant difference between the risk estimates for low-income economies and high-income
307 economies ($df = 1, p = 0.58$).

308

309

310 *Figure 5: Forrest plot of ORs and CIs of depression risk in people with unemployment, from dichotomised data. Results are*
 311 *shown for each individual study, a pooled estimate for high- and low-income economy subgroups, and pooled estimate for*
 312 *all included studies.*

313 Forest plots of the ordinal and continuous meta-analyses can be found in Additional file 3,
 314 tables of narrative and longitudinal narrative reviews, can be found in Additional file 4.

315

316

317

318

319

320

321 **Discussion**

322 In all but one of the nine separate meta-analyses a consistent association was found
323 between low SES and increased risk of depression. These results were synthesised from 138
324 studies spanning almost five decades of research, 47 countries across six continents, covering
325 the whole human life span, and including 34 different comorbid diseases.

326

327 **Main findings**

328 Low composite SES, income, and educational attainment were all significantly
329 associated with an increased risk of depression in 8 out of 9 meta-analyses. Unemployment
330 was also associated with higher risk of depression. Of the 19 eligible longitudinal studies
331 identified, 15 reported a significant relationship between low SES and higher risk of
332 depression and 7 studies reported a null association. The majority of null associations were
333 reported between educational attainment and depression risk. None of the studies reported a
334 significant relationship between high SES and an increased risk of depression. Overall, the
335 findings from the longitudinal studies and the cross-sectional studies are congruent; most
336 studies report a significant association between low SES and increased risk of depression.
337 Among all 162 reviewed studies, only three (Kim et al. 2014; Kui et al. 2014; Bekaroglu et
338 al. 1991) found a reverse relationship, i.e. low SES being associated with a decreased risk of
339 depression.

340

341 The meta-analyses of dichotomised data revealed an increased risk of depression
342 associated with low SES in each of the measures (composite SES, income, education, and
343 unemployment). SES is a composite measure made up of components either directly or
344 indirectly related to income, education, and employment. It is perhaps not surprising that each
345 measure of SES showed a similar direction of association with depression, given these

346 measures are related. Income, education, and employment are, to varying degrees,
347 intercorrelated whilst also each accounting for a proportion of unique variance. For example,
348 having a high level of education makes it more likely to obtain a high income, whilst having a
349 high income makes it easier to retrain or pursue a higher level of education. Having any
350 income at all often relies on being employed, although this does differ from country to
351 country depending on the degree of economic support provided. However, these relationships
352 are far from fixed and many societal and individual factors influence the strength of the
353 relationships between components of SES. When partitioning the risk of depression
354 associated with SES into component risk factors it is important to remember that these
355 components are correlated with one another.

356 In the present systematic review low income showed the largest magnitude of
357 association with depression (OR = 1.96, 1.53-2.52) than other SES measures. The meta-
358 analyses of studies dividing SES into three groups further supported this finding.
359 Furthermore, there was evidence of a dose dependent pattern, with higher depression risk in
360 medium versus high income groups and low versus across medium income groups (see
361 Additional file 3). Sensitivity analysis showed no significant difference in the risk estimates
362 between high-income economies and low-income economies, suggesting a cross-culturally
363 stable association between low relative income and higher depression risk. A recent review
364 demonstrated an increased risk of depression in populations with higher income inequality
365 (Patel et al. 2018) which was not replicated in this review.

366 The direction of the effect is unclear from the reviewed studies. However, six out of
367 eight longitudinal studies reported an increased risk of depression following a period of low
368 income (two reported no significant association), suggesting the direction of causation may
369 be from low income to increased risk of depression. The reason behind the strength
370 difference in risk estimates between the SES measures, particularly the much stronger

371 association for low income, is also unclear. It is possible that low income, or poverty, is
372 particularly restrictive in terms of direct and indirect health promoting behaviours and
373 particularly impactful for psychological stress. It is also possible that income has a more
374 direct effect on depression risk as it is often the knock-on effect of other SES measures.

375 This finding could be important for informing policy intervention attempts. Of all the
376 SES measures, income may be the easiest immediate factor to change. Changing someone's
377 educational attainment or employment status takes a long time and is difficult, involving
378 changes to the structure of the education system and labour market through macro-economic
379 measures. Preparing an individual for higher educational attainment or a more favourable
380 position within an existing labour market may entail removing impediments based on poor
381 health and carer commitments.

382 An increasingly appealing intervention against poverty (and low SES) is universal
383 basic income (UBI) (Arnold, 2018). At its core UBI means giving a regular amount of money
384 to an individual without any obligations or commitments necessary. Smaller trials of this
385 intervention have had positive effects on health, wellbeing and SES (Enns et al., 2021;
386 Forget, 2011; Koistinen & Perkiö, 2014). Many of these interventions are relatively short-
387 lived, leaving conclusions on the long-term impact vague. However, larger, and longer
388 interventions are underway in Kenya and the United States, lasting up to 12 years.

389 Studies on the association between SES and depression are often of an observational
390 nature and as such are prone to biases. However, using these observational studies to inform
391 the design of interventional experimental studies could be a methodologically strong
392 approach. Given the present systematic review found the highest risk of depression to be
393 associated with low income, UBI may present a preventative opportunity in an intervention
394 based experimental set-up.

395

396

397 **Strengths and limitations**

398 The main limitation of the present systematic review is the high levels of
399 heterogeneity in the meta-analyses, which may in-turn reflect differences in study
400 populations, methods or other factors (e.g., cohort effects where the association effect size
401 changes over decades). The analyses involving dichotomous data all have heterogeneity
402 estimates (I^2) between 81% and 89%. Sensitivity analyses were performed on each of the
403 meta-analyses to investigate if differences in countries' economies could explain the high-
404 level of heterogeneity. None of the meta-analyses differed significantly in risk estimates
405 between low-income economies and high-income economies. The sensitivity analyses of
406 income and unemployment revealed that most of the heterogeneity were in studies from high-
407 income economies. However, for both meta-analyses there were four times as many studies
408 in the high-income economy group which may be behind the difference in between-study
409 heterogeneity.

410 A good example of why the heterogeneity may not stem from differences in cultures
411 can be found in one of the studies included in this review; Ambugo et al (2014). The study
412 compares SES and depression associations in four countries (Ghana, Kenya, UK, and
413 Norway) spanning low- and high-income economies, but crucially all with a similar design.
414 The risk estimates were similar and a meta-analysis of the effects reveals relatively little
415 heterogeneity ($I^2 = 50.9$, $Q = 6.11$).

416 The high levels of between study heterogeneity could instead be due to variation in
417 depression diagnosis screening tools, recruitment settings, and differences in covariate
418 inclusion across studies.

419 Finally, due to the observational nature of the data it is difficult to confidently infer
420 causality even when including longitudinal data. In the case of investigating the association

421 between a complex disease, such as depression, and a complex phenotype such as SES this is
422 even more pronounced.

423

424 The strengths of the present systematic review are its cross cultural, cross age-group,
425 and cross morbidity estimates of the association between SES and depression, as well as
426 providing risk estimates modelled on the largest evidence base to date.

427 Furthermore, the present meta-analyses are unlikely to be hindered by publication
428 bias, and as a consequence less likely to over-estimate the real risk of depression associated
429 with SES. For many of the included studies, the association between SES and depression
430 was not their primary outcome; this may also explain why a number of studies reported null
431 findings.

432 Finally, the inclusion of all measures of SES, whether composite or single indicator
433 measures, gives an opportunity to compare the risk of depression across subparts of SES.
434 This, in turn, lays the groundwork for future research to pinpoint which part of an
435 individual's SES confers the highest risk of depression.

436

437 **Future work**

438 Future research should strive to elucidate the direction of causality in the SES-
439 depression association. This could be obtained using cross generation longitudinal population
440 cohort studies, such as Avon Longitudinal Study of Parent and Children with data on several
441 generations of participants.

442 Another tool for examining causal directions is Mendelian Randomisation (MR),
443 which takes advantage of genetic variants as instrumental variables that are associated with
444 the independent variable (e.g., SES) but not directly with the dependent variable (e.g.,
445 depression risk). Previous MR studies into the association between low SES and depression

446 found a significant association between the two factors but did not find a robust indication of
447 causal direction (Harrison et al., 2020). Future MR studies would benefit from stronger
448 genetic instrumental variables and should investigate the possibility of a bidirectional
449 relationship between low SES and depression.

450 A better understanding of genetic risk of depression and the genetic make-up of SES,
451 will also provide the opportunity to tease apart the social or environmental part of SES that
452 confers risk of depression from the genetic part. This information could aid in pinpointing
453 areas of maximum impact for interventions or even help guide research into preventative
454 treatments of depression.
