2 ABSTRACT

3 We examined changes in large-scale functional connectivity and temporal dynamics and
4 their underlying mechanisms in schizophrenia (ScZ) through measurements of resting-state
5 functional magnetic resonance imaging (rs-fMRI) data and computational modelling. The rs-fMRI
6 measurements from patients with chronic ScZ (n=38) and matched healthy controls (n=43), were
7 obtained through the public schizConnect repository. Computational models were constructed
8 based on diffusion-weighted MRI scans and fit to the experimental rs-fMRI data. We found
9 decreased large-scale functional connectivity across sensory and association areas and for
10 all functional subnetworks for the ScZ group. Additionally global synchrony was reduced in
11 patients while metastability was unaltered. Perturbations of the computational model revealed
12 that decreased global coupling and increased background noise levels both explained the
13 experimentally found deficits better than local changes to the GABAergic or glutamatergic system.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

14 The current study suggests that large-scale alterations in ScZ are more likely the result of global
15 rather than local network changes.

16 **Keywords:** schizophrenia, resting-state fMRI, computational model, large-scale networks, functional connectivity, temporal dynamics

1 INTRODUCTION

17 ScZ is a severe mental disorder with a high burden of disease (Lopez and Murray (1998); Charlson et al.
18 (2018)). However, the underlying mechanisms remain elusive. While no single brain area accounting for
19 the heterogeneous symptom profiles has been identified, the notion that ScZ can be understood in terms
20 of a general dysconnectivity has emerged (Friston et al. (1995); Friston (1999); Bullmore et al. (1997);
21 Pettersson-Yeo et al. (2011)).

22 Experimental evidence for the dysconnection hypothesis comes from neuroimaging studies. Analyses of
23 resting-state fMRI connectivity have shown widespread changes of functional connectivity. However, there
24 is still a debate whether correlations of neural activity between regions are decreased (Liang et al. (2006);
25 Bluhm et al. (2007)) or increased in ScZ (Zhou et al. (2007)). There is also growing evidence for possible
26 longitudinal changes of functional connectivity over the course of the disorder. Anticevic et al. (2015)
27 demonstrated that prefrontal cortical connectivity is increased in early-course ScZ while the opposite
28 pattern was observed in chronic ScZ patients. Going beyond pairwise correlations between brain regions,
29 graph theoretic measurements have identified reductions in integration, hierarchy, clustering, efficiency and
30 small-worldness (Bassett et al. (2008); Liu et al. (2008); Bullmore and Sporns (2009); Lynall et al. (2010)).

31 Yet, the origin of functional dysconnectivity patterns in ScZ is still unclear. One hypothesis is that
32 cellular and synaptic changes associated with ScZ disrupt local processing and thus impact on large-scale
33 connectivity. Indeed changes at the microcircuit level have been identified in ScZ. Excitatory and inhibitory
34 neurotransmission is disturbed, for example a reduced excitatory drive onto GABAergic inhibitory neurons
35 (Chung et al. (2016, 2022)) and a decreased inhibitory output (Hashimoto et al. (2003); Morris et al. (2008);
36 Moyer et al. (2012)). Changes to the glutamatergic system, such as increased recurrent excitation, have
37 been suggested to lead to deficits in large-scale connectivity with a gradient along the cortical hierarchy
38 (Yang et al. (2016)).

39 Computational models of large-scale brain circuits can be used to investigate dynamical circuit
40 mechanisms linking local ScZ-associated alterations to global changes in the functional organisation
41 of the brain. Leveraging such computational models, studies have shown that decreases in global inter-
42 regional connectivity strengths can lead to wide-spread functional disruptions (Cabral et al. (2013)),
43 increased global signal variance (Yang et al. (2014)) and altered topological characteristics of functional
44 brain networks (Cabral et al. (2012b,a)) resembling ScZ. However, except for Yang et al. (2014), these
45 studies only investigated a global scaling of the inter-regional connectivity. Yang et al. (2014) manipulated
46 local and global neuronal coupling and demonstrated that both could increase signal variance as seen in
47 ScZ but did not explore their potentially differential effects on large-scale functional connectivity. Thus, so
48 far the effect of ScZ-associated local changes to glutamatergic and GABAergic neurotransmission and the
49 effect of increased background noise on large-scale functional connectivity has not been explored.

50 To address this question, we quantified functional connectivity differences in a data set of healthy controls
51 and chronic ScZ patients. We then implemented local microcircuit and global network parameter changes
52 in a computational model of large-scale cortical dynamics and compare the resulting connectivity changes
53 to the experimental data. Furthermore, we also explored the temporal dynamics of the resting-state brain

54 and characterised potential deficits in large-scale synchrony and metastability in ScZ patients and compared
55 them to the different computational models, thus identifying mechanistic links underlying these changes.

2 MATERIAL AND METHODS

56 2.1 Patient Sample

57 The study sample was collected through the Center for Biomedical Research Excellence (COBRE) led by
58 Dr. Vince Calhoun (more information here: http://fcon_1000.projects.nitrc.org/indi/retro/cobre.html) and
59 obtained from the SchizConnect database (<http://schizconnect.org>). This sample has previously been used
60 by our group to explore structural deficits in patients with ScZ (Dimulescu et al. (2021)). From the sample
61 of 43 patients and 43 healthy control participants, we excluded 5 patients due to missing resting-state
62 functional MRI (rs-fMRI) data or artefacts/excessive motion identified during the pre-processing. We
63 thus analyzed a final sample of 43 healthy control subjects and 38 patients with schizophrenia, which we
64 will refer to as the COBRE sample. All patients were receiving antipsychotic medication (see Table 1).
65 Symptom severity in patients was assessed using the Positive and Negative Syndrome Scale (PANSS) (Kay
66 et al. (1989)). Written informed consent was obtained from all participants, and the study was reviewed
67 and approved by the Institutional Review Board of the University of New Mexico.

68 2.2 Anatomical data

69 Data collection for the COBRE sample was performed using a Siemens Magnetom Trio 3T MR scanner.
70 Structural images (high resolution T1-weighted) were acquired using a five-echo MPRAGE sequence with
71 the following parameters: repetition time (TR) = 2530 ms; echo time (TE) = 1.64, 3.5, 5.36, 7.22, 9.08 ms;
72 inversion time (TI) = 1200 ms; flip angle (FA) = 7°; field of view (FOV) = 256 mm × 256 mm; matrix =
73 256 × 256; slice thickness = 1 mm; 192 sagittal slices. Diffusion tensor imaging (DTI) data were acquired
74 using a single-shot EPI sequence with TR/TE = 9000/84 ms; FA = 90°; FOV = 256 mm × 256 mm; matrix
75 = 128 × 128; slice thickness = 2 mm without gap; 72 axial slices; 30 non-collinear diffusion gradients (b
76 = 800 s/mm²) and 5 non-diffusion-weighted images ($b = 0$ s/mm²) equally interspersed between the 30
77 gradient directions. For more information see also Cetin et al. (2014).

78 For model validation we additionally used a subset of 156 healthy participants from the human
79 connectome project (HCP), which we will refer to as the HCP sample. The diffusion-weighted data
80 were collected with multiband diffusion sequence (HCP version available at
81 <http://www.cmrr.umn.edu/multiband>). Three different gradient tables are used, each with 90 diffusion
82 weighting directions and six $b = 0$ acquisitions. More information can be found at
83 <https://www.humanconnectome.org/study/hcp-young-adult/document/1200-subjects-data-release>.

84 2.3 Resting-state functional MRI data

85 COBRE data was acquired using single-shot full k-space echo-planar imaging (EPI) with ramp sampling
86 correction using the intercommissural line (AC-PC) as a reference (TR: 2 s, TE: 29 ms, matrix size: 64x64,
87 32 slices, voxel size: 3x3x4 mm³). The resting-state scans were acquired in the axial plane with with an
88 ascending slice order (multi slice method; interleaved). For more information see Aine et al. (2017). For the
89 COBRE data set, we preprocessed the rsfMRI data using the FSL FEAT toolbox (Woolrich et al. (2001)).
90 For each data set, we discarded the first five volumes. We corrected head motion using the FSL McFLIRT
91 algorithm and subsequently high-pass filtered the data with a filter cutoff of 100 s. We linearly registered
92 each functional image to the corresponding anatomical image of that subject using FLIRT. We then used

93 the mean volume of the data to create a brain mask using BET. Using the ICA FIX FSL toolbox (Griffanti
94 et al. (2014); Salimi-Khorshidi et al. (2014)), we conducted MELODIC ICA and removed artefactual
95 components (motion, non-neuronal physiological artefacts, scanner artefacts, and other nuisance sources).
96 Finally, we transformed the high-resolution mask volumes from MNI to individual subject functional space
97 and extracted the average BOLD time courses for each cortical region in the AAL2 parcellation scheme
98 using the `fslmeans` command from `Fslutils`.

99 Acquisition details for the functional MRI data from the HCP S1200 release can be found here:
100 <https://www.humanconnectome.org/study/hcp-young-adult/document/1200-subjects-data-release>. For the
101 HCP data set, we used the data preprocessed according to Glasser et al. (2013) and extracted the average
102 BOLD time courses for each cortical region as described above.

103 2.4 Measures of connectivity and temporal dynamics

104 We used the average global brain connectivity (GBC) measure (Cole et al. (2010, 2011)) to assess the
105 changes in connectivity strength. To assess alterations in temporal dynamics we used synchrony and
106 metastability (Deco et al. (2017)). Because of the computational model being restricted to cortical areas,
107 we also restricted our connectivity analysis to cortical areas. However, including subcortical regions did
108 not substantially change the findings (see Supplementary Material).

109 Specifically, we define the functional connectivity matrix (FC) as the matrix of Pearson correlations of
110 the BOLD signal between two brain areas over the whole time range of acquisition. From the FC matrices
111 we calculate the global brain connectivity (GBC) of a single brain region i as follows (see also Cole et al.
112 (2010, 2011)):

$$GBC(i) = \frac{1}{n} \left(\sum_j FC(i, j) \right),$$

113 where n is the number of regions. The average global GBC can then be defined as the average GBC over all
114 cortical regions i . To calculate the average GBC for a functional subnetwork or generally a set of regions,
115 one simply averages over the regional GBC values for the respective regions.

116 To assess the temporal dynamics of the functional networks, we used the Kuramoto order parameter as a
117 measure of synchrony and its standard deviation as a measure of metastability, i.e. the variability of the
118 states of phase configurations over time (see for example Deco et al. (2017)). Here the Kuramoto order
119 parameter $R(t)$ is defined as

$$R(t) = \frac{1}{n} \left| \sum_{k=1}^n e^{i\phi_k(t)} \right|,$$

120 where again n is the number of regions and $\phi_k(t)$ is the instantaneous phase of the BOLD signal in region
121 k . It measures the global level of synchronization of the BOLD signals from all regions, where a low level
122 close to 0 reflects an almost uniform distribution of the signal phases, and a high value close to 1 reflects
123 near equality of the signal phases. To calculate R , we band-pass filtered the signal in the narrowband
124 0.04-0.07 Hz (see Deco et al. (2017)) and then extracted the instantaneous phases of the signals at every
125 time step using the Hilbert transform.

126 2.5 Computational network model

127 We use a whole-brain network model, where the connectivity, connection strength and delay between
128 network nodes (i.e. brain regions) is derived from brain imaging data. As a model of single-node activity
129 dynamics we employ a mean-field description of a spiking neural network of an excitatory and an inhibitory
130 neural population, where the individual neurons are described by the adaptive exponential integrate-and-fire
131 model (AdEx model; Brette and Gerstner (2005)), developed in our group (Augustin et al. (2017); Cakan
132 and Obermayer (2020)). The following section describes the model in detail.

133 2.5.1 Single-Node model

134 A mean-field neural mass model based on a spiking network of coupled excitatory and inhibitory
135 populations, the so-called ALN model (Augustin et al. (2017)), was implemented. The mean-field
136 description offers a drastic speed-up of simulations on the order of about 4 orders of magnitude compared
137 to the spiking model while still retaining its dynamical states and its biophysical parameters. The model
138 has been extensively validated against simulations with the detailed spiking network and overall shows
139 very good agreement (Cakan and Obermayer (2020)).

140 The mean-field reduction of the spiking neural network utilises the Fokker-Planck approach, i.e. the fact
141 that in the limit of an infinite network size and under the assumption of a sparse, random connectivity,
142 the distribution $p(V)$ of the membrane potentials and the mean firing rate r_a of a population a , can be
143 described by a Fokker-Planck equation (Brunel (2000)). However, to calculate the potential distribution a
144 partial differential equation has to be solved, which is computationally costly. Therefore, the dynamics of
145 a population is captured by a low-dimensional linear-nonlinear cascade model, and can be described by
146 a set of ordinary differential equations (Fourcaud-Trocmé et al. (2003); Ostojic and Brunel (2011)). The
147 mathematical derivation and the underlying assumptions have been detailed in (Augustin et al. (2017)), and
148 we will only provide the final set of model equations in this manuscript.

149 A single network node in the whole-brain model is represented by the population activity of two
150 interconnected neural populations, an excitatory population E and an inhibitory population I . The dynamics
151 of the membrane currents of a population $a \in \{E, I\}$, are governed by the following equations:

$$152 \tau_a \frac{d\mu_a}{dt} = \mu_a^{syn}(t) + \mu_a^{ext}(t) + \mu_a^{ou}(t) - \mu_a(t) \quad (1)$$

$$153 \mu_a^{syn} = J_{aE} \bar{s}_{aE}(t) + J_{aI} \bar{s}_{aI}(t) \quad (2)$$

$$\sigma_a^2(t) = \sum_{b \in \{E, I\}} \frac{2J_{ab}^2 \sigma_{s,ab}^2(t) \tau_{s,b} \tau_m}{(1 + r_{ab}(t)) \tau_m + \tau_{s,b}} + \sigma_{ext,a}^2 \quad (3)$$

154 In the above equations μ_a describes the total mean membrane currents, μ_a^{syn} the currents from synaptic
155 activity, μ_a^{ext} the currents from any sources of external input, μ_a^{ou} the external noise input, τ_m the membrane
156 time constant (calculated from the membrane capacitance C and the leak conductance g_L), and $\tau_{s,b}$ the
157 synaptic time constant. Furthermore, σ_a^2 is the variance of the membrane currents, and J_{ab} represent the
158 maximum synaptic current when all synapses from population b to population a are active. The dynamics
159 of the synapses are described by

$$\frac{d\bar{s}_{ab}}{dt} = \tau_{s,b}^{-1} ((1 - \bar{s}_{ab}(t)) r_{ab}(t) - \bar{s}_{ab}(t)) \quad (4)$$

$$\frac{d\sigma_{s_{ab}}^2}{dt} = \tau_{s,b}^{-2}(1 - \bar{s}_{ab}(t))^2 \rho_{ab}(t) + (\rho_{ab}(t) + 2\tau_{s,b}(r_{ab}(t) + 1)\sigma_{s_{ab}}^2(t)) \quad (5)$$

160 where \bar{s}_{ab} represents the mean of the fraction of all active synapses, which lies in the range $[0, 1]$, with the
161 extreme cases being no active synapses and no inactive synapses, respectively. Furthermore, $\sigma_{s_{ab}}^2$ is the
162 variance of s_{ab} .

163 The timescale $\tau_a = \Phi_T(\mu_a, \sigma_a)$ of the input-dependent adaptation, the average membrane potential
164 $\bar{V}_E = \Phi_E(\mu_E, \sigma_E)$, and the instantaneous population spike rate $r_a = \Phi_r(\mu_a, \sigma_a)$ are computed every time
165 step by means of precomputed transfer functions. The mean r_{ab} and the variance ρ_{ab} of the effective input
166 rate from population b to population a can be described by

$$r_{ab} = \frac{c_{ab}}{J_{ab}} \tau_{s,b} (K_b \cdot r_b(t - d_{ab}) + \delta_{abE} \cdot K_{gl} \sum_{j=0}^N C_{ij}(r_b - D_{ij})) \quad (6)$$

167 and

$$\rho_{ab} = \frac{c_{ab}^2}{J_{ab}^2} \tau_{s,b}^2 (K_b \cdot r_b(t - d_{ab}) + \delta_{abE} \cdot K_{gl} \sum_{j=0}^N C_{ij}^2(r_b - D_{ij})) \quad (7)$$

168 given a certain delay for the spike transmission d_{ab} . Here c_{ab} represent the amplitude of the post-synaptic
169 current resulting from one individual spike (for $s_{ab} = 0$). Furthermore, K_{gl} scales the global coupling in
170 the network, and C_{ij} and D_{ij} define the connection strengths and the connection delays between regions,
171 estimated from the fibre count and fibre length matrices, respectively. Finally, $\delta_{abE} = 1$ for $a = b = E$ and
172 0 otherwise restricting coupling between regions to be exclusively from excitatory to excitatory populations.

173 The adaptive exponential integrate-and-fire model explicitly accounts for the evolution of a slow
174 adaptation currents that represents both subthreshold and spike-triggered adaptation currents. The
175 subthreshold adaptation current is described by the adaptation conductance α and the spike-triggered
176 adaptation current is denoted by β . In the limit of infinite population sizes, an adiabatic approximation can
177 be employed to describe the mean adaptation current in terms of the mean population firing rate. The mean
178 adaptation current \bar{I}_A can be understood as an inhibitory membrane current whose dynamics are governed
179 by

$$\frac{d\bar{I}_A}{dt} = \tau_A^{-1}(\alpha(\bar{V}_E(t) - E_A) - \bar{I}_A) - \beta r_E(t). \quad (8)$$

180 The individual populations a of a single region of the whole-brain network receive an external input
181 current with a given mean $\mu_a^{ext}(t)$ and a standard deviation $\sigma_a^{ext}(t)$. This background input current can be
182 thought to represent baseline input from extracortical areas in the brain. Additionally, the regions also
183 receive a noise input current $\mu_a^{ou}(t)$ modelled as an Ornstein-Uhlenbeck process with a mean of 0 described
184 by

$$\frac{d\mu_a^{ou}}{dt} = -\frac{\mu_a^{ou}}{\tau_{ou}} + \sigma_{ou}\xi(t). \quad (9)$$

185 Here $\xi(t)$ is a white noise process drawn from a normal distribution with a mean of 0 and a variance of 1.
186 σ_{ou} determines the fluctuation amplitude of the noise around its mean.

187 To determine the mean external input to the E (μ_{Eext}) and I (μ_{Iext}) populations, the noise strength σ_{ou} ,
188 the subthreshold adaptation conductance α and spike-triggered adaptation increment β parameters for the

189 model in the control condition, we used an evolutionary optimization procedure as described in Cakan et al.
190 (2022). We compared the simulated BOLD FC to the empirical rsfMRI data. We initialized the algorithm
191 with a random population of $N_{init} = 160$ individuals and repeated the evolutionary block with $N_{pop} = 80$
192 individuals for 100 generations. Initial parameter values were selected from a uniform distribution across
193 the following intervals for the model parameters: $\mu_{Ext} \in [0.0, 4.0] \text{ mV/ms}$, $\mu_{Int} \in [0.0, 4.0] \text{ mV/ms}$,
194 $\sigma_{ou} \in [0.0, 0.3]$, $a \in [0.0, 40.0] \text{ nS}$, and $b \in [0.0, 40.0] \text{ pA}$. The global coupling strength was set as in
195 Figure 2 of Cakan et al. (2022). All other model parameters were set as given in Table 1 in Cakan et al.
196 (2022) and they are summarised in Table 2.

197 2.5.2 BOLD model

198 In order to compare the model output, i.e. the neural activity of the regions, to the BOLD signal of the
199 rs-fMRI data, the firing rates of the excitatory population of each region had to be converted into model
200 BOLD signal timecourses. Here, we used the well-established Balloon-Windkessel model (Friston et al.
201 (2000); Deco et al. (2013)), for specific parameters see Friston et al. (2003).

202 2.5.3 Network connectivity

203 Structural images were preprocessed employing a semi-automatic pipeline implemented in the FSL
204 toolbox (www.fmrib.ox.ac.uk/fsl, FMRIB, Oxford). For the anatomical T1-weighted images we used the
205 brain extraction toolbox (BET) in FSL to remove non-brain tissue and to generate the brain masks. After
206 manual quality checks, 80 cortical regions were defined according to the automatic anatomical labelling
207 (AAL2) atlas (Rolls et al. (2015)). For the diffusion-weighted images, we performed a brain extraction as
208 well and corrected the images for head motion and eddy current distortions afterwards. Probabilistic fibre
209 tracking, using the Bayesian Estimation of Diffusion Parameters Obtained using Sampling Techniques
210 (BEDPOSTX) and the PROBTRACKX algorithms implemented in FSL (Behrens et al. (2007)), was then
211 used with 5,000 random seeds per voxel to extract individual connectomes. Since the tractography does not
212 yield directionality information and the connectome matrices are non-symmetric, we explicitly enforced
213 symmetry by averaging the entries from region i to region j and from region j to region i for all pairs of
214 regions. Furthermore, we normalised each connectome by dividing each matrix entry by the maximum
215 matrix entry, thus ensuring compatibility between participants. The resulting connectome then determines
216 the relative coupling strength between regions in the above described computational whole-brain model.
217 The fibre tracking also yielded matrix fibre lengths for each participant, which, when multiplied with the
218 signal speed, determines the delay of signal propagation between any two regions in the model.

219 2.5.4 Modelling ScZ-associated changes

220 We implemented four different sets of parameter changes that are thought to represent the following four
221 ScZ-associated alterations: 1) local GABAergic inhibition, 2) local glutamatergic excitation of inhibitory
222 cells, 3) global interregional coupling, and 4) global noise levels.

223 First, we systematically reduced GABAergic inhibition in the model. Postmortem gene expression studies
224 have robustly demonstrated reduced levels of parvalbumine (PV) and somatostatin (SST) expression in PV
225 (Hashimoto et al. (2003)) and SST (Morris et al. (2008)) interneurons together with a reduction of GAD_{65}
226 and GAD_{67} (Hashimoto et al. (2003)), in cortical regions in ScZ. We implemented these changes as a
227 reduction of the inhibitory weights J_{EI} and J_{II} in the ALN model of the regional dynamics. We varied
228 the strength of the inhibition onto the excitatory population J_{EI} and onto the inhibitory population J_{II}
229 simultaneously in the range from 100% to 60% in steps of 5%.

230 Next, we systematically reduced the glutamatergic, excitatory drive onto inhibitory neurons in our model
231 of regional activity. These changes reflected the reduced and more varied colocalization of glutamatergic
232 pre- and postsynaptic markers on PV interneurons in dorsolateral prefrontal cortex (DLPFC) (Chung et al.
233 (2016, 2022)). Specifically, we reduced the excitatory weight onto inhibitory neurons J_{IE} in the ALN
234 model in a range from 100% to 60% in steps of 5%.

235 Global dysconnectivity might also be explained by a simple reduction of the global connectivity strength.
236 Therefore, to test whether the differences we found experimentally could alternatively be explained by an
237 overall network decoupling, we reduced the global coupling strength K_{gl} in the range from 100% to 60%
238 in steps of 5%.

239 Finally, the global alterations of functional connectivity might also be the result of an increase in
240 background noise disrupting functional connectivity in the network (Winterer et al. (2000); Winterer and
241 Weinberger (2004); Winterer et al. (2004)). Consequently, we increased the global background noise σ_{ou} in
242 a range from 100% to 140% in steps to 5%, to test whether a global increase in noise level can account for
243 the connectivity differences found in the experimental data.

244 2.5.5 Simulation details

245 Simulations were implemented using the neurolib Python framework (Cakan et al. (2021)). The
246 differential equations of the model were solved numerically using an Euler forward scheme with a time
247 step of 0.1 ms. For all described simulations the duration was 70 s and we discarded the transient response
248 in the first 5 s before calculating any of the above described measures. To assess the robustness of our
249 results, we created 40 virtual subjects by changing the seed for the random number generator underlying
250 the Ornstein-Uhlenbeck noise process. These 40 virtual subjects were then kept fixed for all implemented
251 changes allowing for a direct comparison to the default, 'healthy' condition.

3 RESULTS

252 3.1 Demographic and clinical characteristics

253 The control and the patient group did not differ significantly in terms of age and gender (see Table 1).
254 Patients also did not show a change in symptomatology or type/dose of antipsychotic medication during
255 the three months before the assessment (for more details see Aine et al. (2017)).

256 3.2 Global differences in connectivity strength and temporal dynamics between ScZ 257 patients and healthy controls

258 Global GBC was significantly reduced in patients with ScZ (effect size $g = -0.65$; see Figure 1 a) and
259 Table 3). Comparing both groups a substantial shift from high GBC towards medium to low GBC values
260 occurs in ScZ patients (Figure 1 b) and Table 3). Synchrony, as measured by the Kuramoto order parameter
261 was lower in the patient group (effect size $g = -0.44$; see Figures 1 c) and Table 3). However, variability
262 in synchrony, measured by metastability, did not significantly differ between groups (Figure 1 d) and Table
263 3).

264 Reductions of functional connectivity strengths affected all seven subnetworks (effect sizes ranging
265 from $g = -0.57$ to $g = -0.83$; see Table 3), with the dorsal-attention, the somato-motor and the visual
266 subnetworks showing the strongest effects (Figure 1 f)).

267 We further tested whether the GBC differences we found were specific to association areas as indicated
268 by a previous study (Yang et al. (2016)). We grouped the default mode subnetwork, the control subnetwork
269 and the ventral attention subnetwork together as the association areas and the somatomotor subnetwork, the
270 visual subnetwork and the dorsal attention subnetwork as the sensory areas. We found reduced GBC for
271 ScZ patients in both groupings, with the sensory areas showing an even stronger effect than the association
272 areas (effect sizes $g = -0.78$ for sensory areas versus $g = -0.61$ for association areas, see Figure 1 e) and
273 Table 3).

274 3.3 Mechanisms underlying connectivity and dynamics alterations

275 3.3.1 Control model

276 We derived a model of healthy large-scale cortical activity that matched the behaviour of the control
277 group data from the COBRE study well in terms of functional connectivity (Figures 2 b) and d)). The
278 correlation between simulated FC (simFC) and empirical FC (empFC) ($r = 0.33 \pm 0.09$; Figure 2 e)) was
279 higher than the correlation between empirical structural (empSC) and empFC ($r = 0.19 \pm 0.07$; Figure2
280 e)).

281 To further assert that the default model captures the resting-state functional connectivity of healthy
282 subjects well, we also validated the model behaviour against a set of 156 subjects from the HCP S1200
283 release. Here, we also found a good fit for functional connectivity (Figure 2 c) and d)).

284 Overall, the model functional connectivity correlated well with the empirical functional connectivity of
285 individual HCP subjects ($r = 0.43 \pm 0.08$; see Figure 2 e)). This correlation was again substantially higher
286 than the correlation of structural connectivity and empirical functional connectivity ($r = 0.20 \pm 0.08$; see
287 Figure 2 e)).

288 3.3.2 Modelling ScZ-associated alterations

289 We systematically performed perturbations to four key aspects of the model that have been associated
290 with schizophrenia: 1) local GABAergic inhibition, 2) local glutamatergic excitation of inhibitory cells, 3)
291 global interregional coupling, and 4) global noise levels.

292 We found that changing the inhibitory weights (model perturbation 1) did not alter the global GBC
293 and the GBCs for sensory and association areas significantly. Furthermore, the changes did not alter the
294 synchrony and the metastability (see Supplementary Table S3). As for the local changes to the inhibitory
295 system, changes to the glutamatergic excitatory drive to the inhibitory population (model perturbation 2)
296 did not result in significant changes in GBC on all levels, synchrony and metastability (see Supplementary
297 Table S4).

298 A reduction of global coupling (model perturbation 3) resulted in a strong decrease in global brain
299 connectivity as well as connectivity within the sensory and association systems (Table 4). Additionally,
300 synchrony decreased strongly and metastability increased for larger reductions (Table 4).

301 An increase in noise levels (model perturbation 4) yielded a strong decrease in global brain connectivity
302 as well as connectivity within the sensory and association systems, even stronger than for the global
303 coupling changes (Table 5). Additionally, synchrony decreased strongly and metastability increased for
304 larger noise strengths (Table 5).

4 DISCUSSION

4.0.1 Global changes in connectivity and temporal dynamics

Evidence for large-scale dysconnectivity in functional networks has been accumulated over the last years in ScZ (Liang et al. (2006); Bluhm et al. (2007); Bassett et al. (2008); Liu et al. (2008); Bullmore and Sporns (2009)). However, it is still unclear, how these changes relate to changes on the microscopic level. To address this gap, we analysed resting-state fMRI data from healthy participants and patients with chronic ScZ. We identified a global reduction in functional connectivity that affected both sensory and association areas equally and that was present for all functional subnetworks together with a moderate decrease of temporal synchrony. Using a biophysical network model, we found that a decrease in global coupling or an increase in global noise levels could explain the connectivity reduction and the increase in synchrony best, whereas local changes to the glutamatergic or GABAergic system did not produce changes matching our experimental findings. However, both changes also yielded an increase in metastability in our model, which we did not find in the experimental data.

Our findings of reduced global brain connectivity are in line with previous research. For example, Lynall et al. (2010) and Bassett et al. (2012) both found significantly reduced global integration in patients with schizophrenia. However, we did not find stronger connectivity disturbances in association areas compared to sensory areas, as previously reported (Yang et al. (2016)).

Our analysis of the temporal dynamics of the activity, i.e. synchrony and metastability, revealed a decrease in synchrony but no change in metastability. Our finding of unchanged metastability is in line with previous findings of Lee et al. (2018) on the same dataset but in contrast to very recent work from Hancock et al. (2023a), proposing metastability as a candidate biomarker for schizophrenia. However, we have to note that Hancock et al. (2023a) introduced a new measure of metastability with increased sensitivity to detect the differences between healthy controls and ScZ patients. This new measure of metastability did not rely on predefined brain parcellations but rather flexibly defined recurring spatio-temporal modes, so-called 'communities' where single brain regions may be grouped into more than one community. As this approach was not applicable to our computational network model we did not employ it in our analysis. Overall, several different metastability measures have been proposed and have been applied in different contexts in neuroscience (Hancock et al. (2023b)).

4.0.2 Mechanistic explanations of global changes in ScZ

Reduced global coupling and increased global noise levels are in line with earlier modelling studies. For example, several studies, using both simple phase oscillator models and dynamic mean-field models, have shown that a decrease of global coupling compared to the best model fit to human resting-state data led to a decrease in connectivity and a more random, less integrated graph structure (Cabral et al. (2012a, 2013, 2012b)). Similar to the model presented here, the operating point is chosen close to a bifurcation point from a silent down state to a limit-cycle which produces oscillating activity. In this regime, both functional connectivity and temporal dynamics best match empirical data. Therefore, the reduced coupling or the increased global noise disturbs this specific state and thus reduces global connectivity, synchrony and more complex network properties.

Previous work on the effects of changes to the glutamatergic and GABAergic system has demonstrated profound alterations on the cortical microcircuit level. For example, numerous computational studies have shown that ScZ-associated changes on the microcircuit level can lead to substantial reductions in gamma power in auditory steady-state response tasks (Metzner et al. (2016); Metzner and Steuber (2021); Metzner

346 et al. (2019); Vierling-Claassen et al. (2008)). Since local gamma oscillations have been hypothesized to at
347 least partially determine the large-scale functional connectivity and temporal dynamics of resting-state
348 activity (Cabral et al. (2014, 2022)), it seems surprising that changes to either of the systems did not
349 produce changes in global brain connectivity in our model. One reason for the lack of impact of the changes
350 might be that we applied them homogeneously. In the work presented here, we only varied glutamatergic or
351 GABAergic strength globally, i.e. without any spatial heterogeneity. Therefore, it seems plausible that these
352 changes disturbed the local, regional nodes all in a similar fashion and thereby did not substantially alter
353 their interrelation, thus not changing global brain connectivity. Indeed, several studies have demonstrated
354 that heterogeneous models of cortex, which explicitly incorporate regional differences in dynamics, match
355 experimental resting-state functional connectivity more accurately (Demirtaş et al. (2019); Kong et al.
356 (2021)). Importantly, these regional differences in dynamics covary with expression profiles for markers
357 of glutamatergic and GABAergic neurotransmission and E-I balance (Burt et al. (2018); Demirtaş et al.
358 (2019)). Therefore, a more detailed, heterogeneous model might be able to shed more light on the effect of
359 E-I balance changes associated with ScZ on large-scale functional networks.

360 4.0.3 Limitations

361 The computational model that we have employed in this study, while generally showing a very good fit to
362 the experimental data, is not fully biophysically realistic. Moreover, the model used an average connectome
363 and was not able to provide subject-specific, individual results for each participant. Furthermore, the
364 anatomic parcellation (AAL2 Rolls et al. (2015)) is relatively coarse-grained with a number of 80 cortical
365 regions.

366 The ALN model that was used to simulate regional activity has been demonstrated to approximate cortical
367 resting-state activity (Cakan and Obermayer (2020); Cakan et al. (2022)). However, it is restricted to the
368 cortex. Including subcortical regions such as the thalamus into whole-brain models is still in its infancy
369 and rarely goes beyond coupling a single cortical and thalamic region (e.g. Jajcay et al. (2022), but see
370 Griffiths et al. (2020)).

371 The ALN model also presents a simplification of the regional circuitry as it approximates and neglects
372 both the variability of cell types, especially the diversity of inhibitory interneurons, and the laminar structure
373 of the cortex. Therefore, the inclusion of more detailed models of regional activity, both in terms of cell
374 type diversity and of laminar structure and connectivity, seems likely to further our understanding of ScZ
375 dysconnectivity and its underlying mechanisms.

376 Lastly, the regional ALN model we used had the same parameters regardless of the cortical region
377 it represented, i.e. we implemented a homogeneous model in that respect. As already discussed above,
378 cortical regions are known to differ in various important aspects, whose incorporation are likely to provide
379 additional insight into the pathophysiology of schizophrenia.

380 4.0.4 Conclusion

381 The current study provides further evidence of large-scale changes in connectivity and temporal dynamics
382 in ScZ through the analysis of resting-state fMRI. Furthermore, through computational modelling, it
383 provides novel evidence that these changes are likely the result of global reductions in coupling or increases
384 noise levels and not of changes to local recurrent connectivity. These findings emphasize the effect of
385 global alterations in ScZ and have possible implications for the development of treatments.

CONFLICT OF INTEREST STATEMENT

386 The authors declare that the research was conducted in the absence of any commercial or financial
387 relationships that could be construed as a potential conflict of interest.

FUNDING

388 CM and PJU were supported through the Einstein Stiftung Berlin (A-2020-613).

5 FIGURES

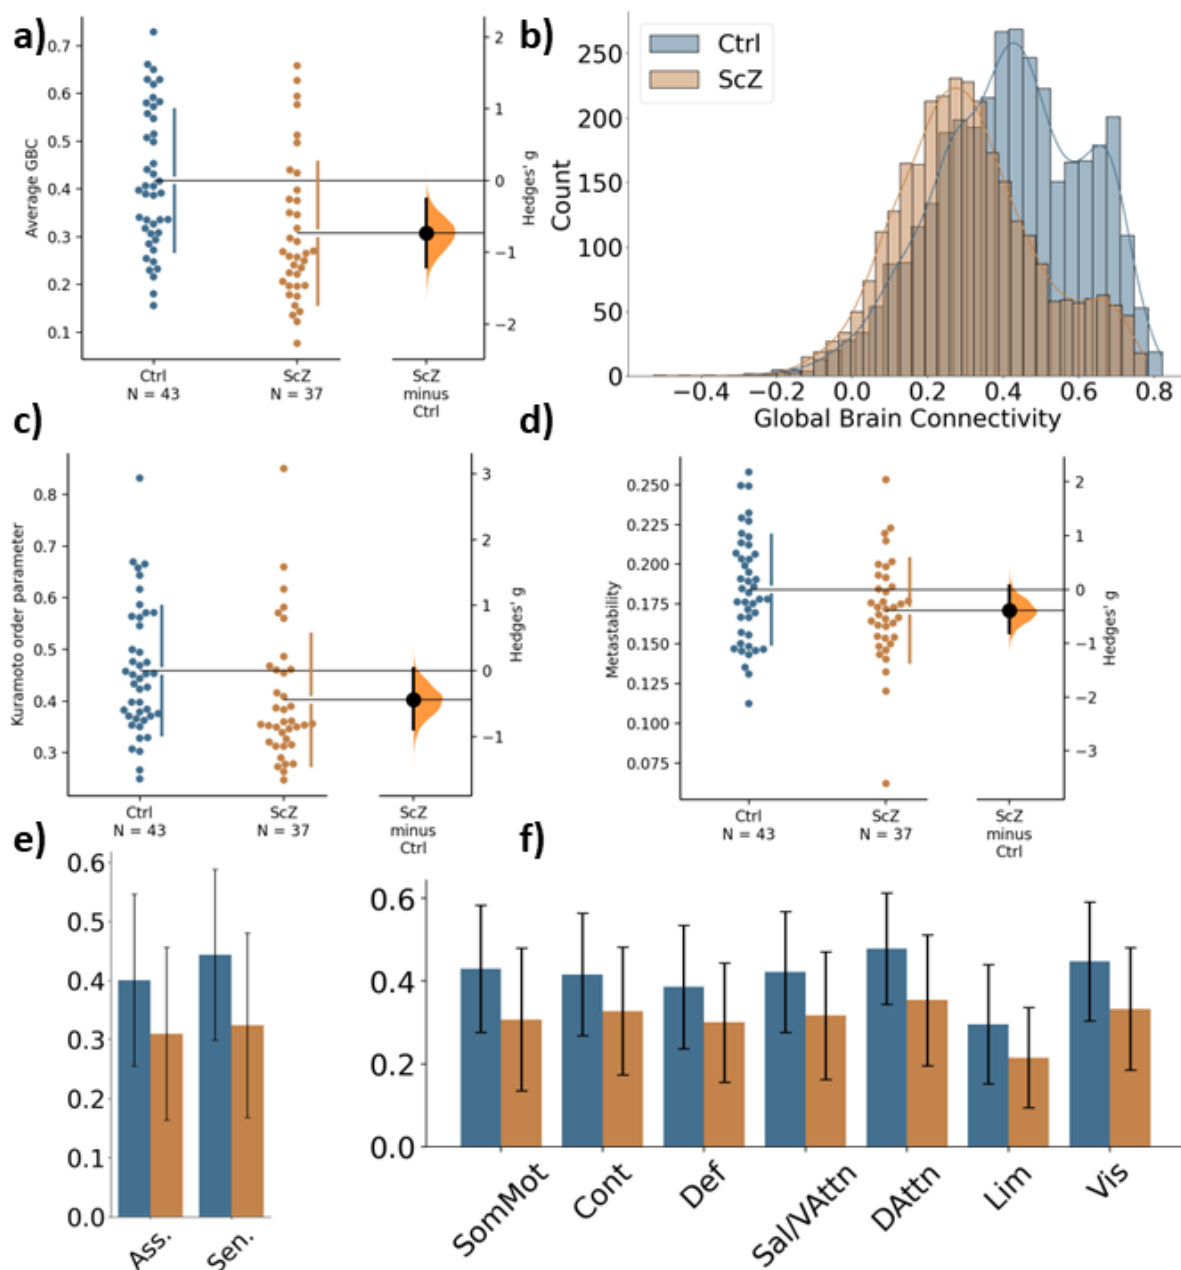

Figure 1. Global differences in functional connectivity and temporal dynamics between healthy controls and ScZ patients. a) Comparison of average GBC per participant for the two groups. Individual dots represent average GBC for one participant. The difference plot on the right shows the difference between the groups in terms of effect size. b) Histogram of region-wise GBC values for the two groups. The histogram displays the region-wise GBC data pooled for all participants in each group. c) Synchrony comparison between the two groups. Each dot represents the mean Kuramoto order parameter (a measure of synchrony) for one participant. The difference plot on the right shows the group difference in terms of effect size. d) Metastability comparison between the two groups. Each dot represents the metastability of one participant. The difference plot on the right shows the group difference in terms of effect size. e) Comparison of global brain connectivity for association areas (Asso. comprising: DMN, Cont, Sal/VAttn) and sensory areas (Sen. comprising: Sommot, Vis, DAttn). f) Comparison of global brain connectivity for the seven functional networks from Yeo et al. (2011): Somato-motor subnetwork (SomMot), Control subnetwork (Cont), Default mode subnetwork (Def), Saliency/Ventral attention subnetwork (Sal/VAttn), Dorsal attention subnetwork (DAttn), Limbic subnetwork (Lim), Visual subnetwork (Vis).

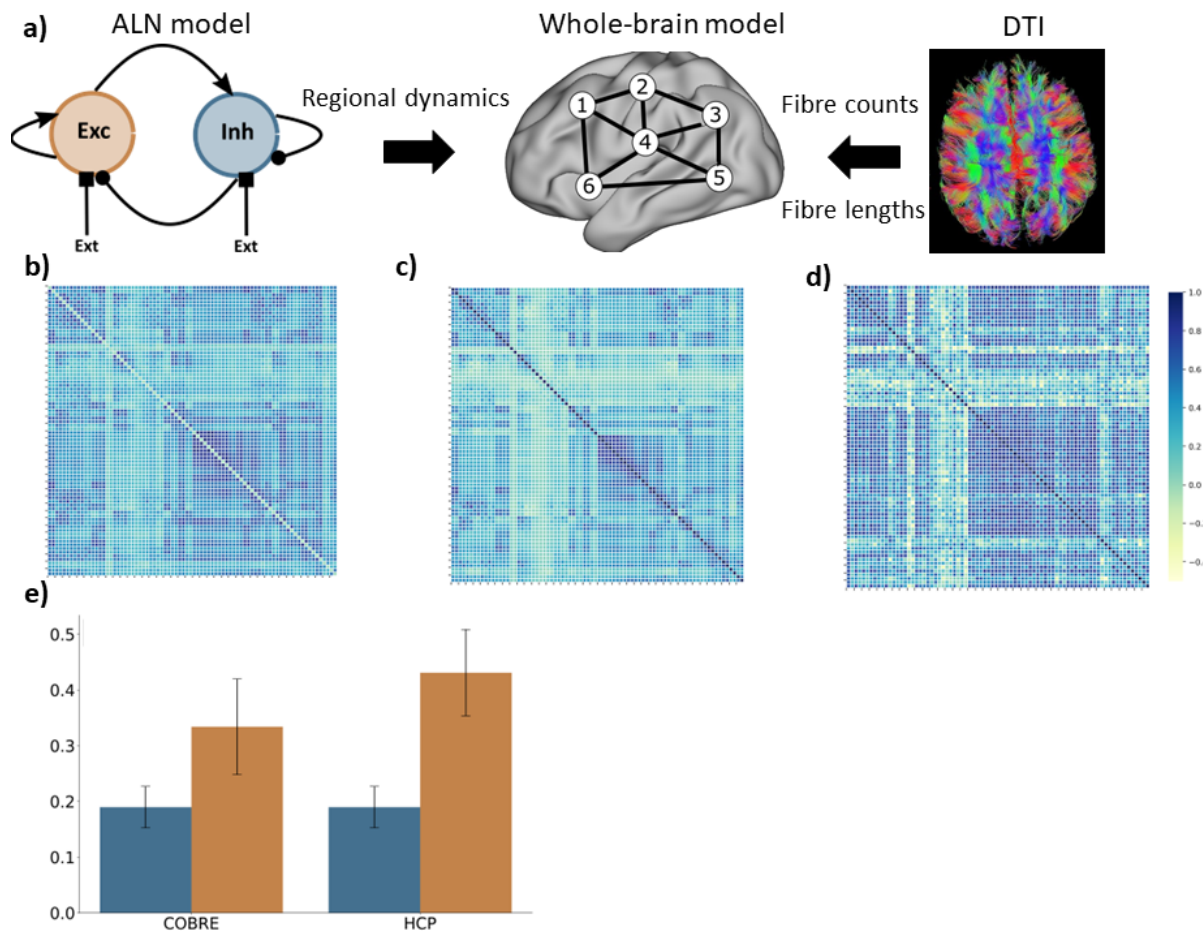

Figure 2. Computational model a) Modelling approach combining a model for the regional dynamics with anatomical input that defines the structural network. b) Average FC matrix for the COBRE sample c) Average FC matrix for the HCP sample d) Model FC matrix e) comparison of the correlation of empSC to empFC (blue) and the correlation of simFC and empFC (yellow) for the COBRE (left) and the for the HCP (right) data sets.

6 TABLES

	HC	ScZ	Statistics, <i>p</i> value
Group size	43	38	-
Age (y)	36.70(11.04)	38.97(13.67)	$t=0.82$, $p=0.41$
Gender	11F/32M	10F/27M	$\chi^2=0.02$, $p=0.88$
PANSS positive	-	14.92(5.04)	-
PANSS negative	-	14.81(5.31)	-
PANSS general	-	29.49(8.37)	-
PANSS total	-	59.22(78)	-
CPZ-equivalent dosage	-	396.26(330.91)	-
Illness duration (y)	-	17.19(12.61)	-

Table 1. Demographics and clinical characteristics. Data are shown as mean(standard deviation). Age differences between groups were compared using an independent samples t-test and differences in gender distribution using a chi-square test. Antipsychotic medication is reported as chlorpromazine (CPZ)-equivalent dosage.

Parameter	Value	Description
μ_E^{ext}	1.63 mV/ms	Mean external input to E
μ_I^{ext}	0.05 mV/ms	Mean external input to I
σ_{ou}	0.19	Noise strength
τ_{ou}	5.0 ms	Noise time constant
K_e	800	Number of excitatory inputs per neuron
K_i	200	Number of inhibitory inputs per neuron
C_{EE}, C_{IE}	0.3 mV/ms	Maximum AMPA PSC amplitude
C_{EI}, C_{II}	0.5 mV/ms	Maximum GABA PSC amplitude
J_{EE}	2.4 mV/ms	Maximum synaptic current from E to E
J_{IE}	2.6 mV/ms	Maximum synaptic current from E to I
J_{EI}	-3.3 mV/ms	Maximum synaptic current from I to E
J_{II}	-1.6 mV/ms	Maximum synaptic current from I to I
$\tau_{s,E}$	2 ms	Excitatory synaptic time constant
$\tau_{s,I}$	5 ms	Inhibitory synaptic time constant
d_E	4 ms	Synaptic delay to excitatory neurons
d_I	2 ms	Synaptic delay to inhibitory neurons
C	200 pF	Membrane capacitance
g_L	10 nS	Leak conductance
τ_m	C/g_L	Membrane time constant
E_L	-65 mV	Leak reversal potential of the AdEx model
Δ_T	1.5 mV	Threshold slope factor of the AdEx model
V_T	-50 mV	Threshold voltage of the AdEx model
V_s	-40 mV	Spike voltage threshold of the AdEx model
T_{net}	1.5 ms	Refractory time of the AdEx model
σ^{ext}	1.5 mV/ \sqrt{ms}	Standard deviation of external input
E_A	-80 mV	Adaptation reversal potential
α	28.26 nS	Subthreshold adaptation conductance
β	24.04 pA	Spike-triggered adaptation increment
τ_A	200 ms	Adaptation time constant
K_{gl}	250.0	Global coupling strength
v_{gl}	20.0 m/s	Global signal speed

Table 2. Network parameters. Overview of the different parameter values for the whole-brain model employed here.

	Mean difference	Hedges' g	95% CI	p value
Global cortical GBC	-0.11	-0.65	[-1.11 -0.18]	p=0.0056
Global cortical synchrony	-0.12	-0.44	[-0.89 0.04]	p=0.0488
Global cortical metastability	-0.005	-0.39	[-0.81 0.07]	p=0.0850
GBC Sensory areas	-0.12	-0.78	[-1.26 -0.29]	p=0.0004
GBC Association areas	-0.09	-0.61	[-1.07 -0.14]	p=0.0076
GBC Somato-motor (SomMot)	-0.12	-0.74	[-1.20 -0.26]	p=0.0008
GBC Control (Cont)	-0.09	-0.57	[-1.03 -0.10]	p=0.0110
GBC Default mode (Def)	-0.09	-0.57	[-1.03 -0.11]	p=0.0110
GBC Salience/Ventral attention (Sal/VAtn)	-0.11	-0.69	[-1.14 -0.21]	p=0.0024
GBC Dorsal attention (DAtn)	-0.12	-0.83	[-1.31 -0.33]	p=0.0001
GBC Limbic (Lim)	-0.08	-0.59	[-1.02 -0.13]	p=0.0102
GBC Visual (Vis)	-0.11	-0.77	[-1.26 -0.29]	p=0.0010

Table 3. Local and global group differences. Overview of the global and local differences in functional connectivity and temporal dynamics between the healthy control and the ScZ patient group.

	95%	90%	85%	80%
Avg. global GBC	-0.035 [-0.45]	-0.089 [-1.12]	-0.153 [-1.88]	-0.205 [-2.49]
Avg. GBC sen.	-0.039 [-0.47]	-0.097 [-1.16]	-0.169 [-1.99]	-0.231 [-2.68]
Avg. GBC ass.	-0.032 [-0.40]	-0.089 [-1.10]	-0.159 [-1.91]	-0.215 [-2.49]
Synchrony	-0.008 [-0.10]	-0.040 [-0.53]	-0.093 [-1.29]	-0.155 [-2.20]
Metastability	-0.001 [-0.05]	0.001 [0.03]	0.001 [0.04]	0.007 [0.26]
	75%	70%	65%	60%
Avg. global GBC	-0.238 [-3.16]	-0.258 [-3.63]	-0.265 [-3.89]	-0.264 [-4.02]
Avg. GBC sen.	-0.275 [-3.45]	-0.302 [-3.98]	-0.311 [-4.32]	-0.311 [-4.45]
Avg. GBC ass.	-0.250 [-3.15]	-0.273 [-3.66]	-0.282 [-3.94]	-0.282 [-4.13]
Synchrony	-0.215 [-3.01]	-0.266 [-4.00]	-0.298 [-4.76]	-0.313 [-5.23]
Metastability	0.018 [0.70]	0.026 [1.22]	0.032 [1.32]	0.035 [1.47]

Table 4. ScZ-associated changes of global coupling. Comparison of average global GBC, average GBC in sensory areas, average GBC in association areas, average synchrony and average metastability for reduced global coupling (from 95% to 60% in steps of 5%). Shown are the mean differences, i.e. the mean of the default condition minus the respective reduced global coupling condition and in brackets the effect size (Hedge's *g*). The mean in each condition is calculated over the 40 virtual subjects. Significant differences, i.e. a permutation *p* value of < 0.001, are highlighted in bold. Permutation tests were performed using 5,000 permutations of labels.

	105%	110%	115%	120%
Avg. global GBC	-0.078 [-0.98]	-0.129 [-1.60]	-0.199 [-2.56]	-0.260 [-3.56]
Avg. GBC sen.	-0.082 [-0.98]	-0.139 [-1.64]	-0.215 [-2.59]	-0.285 [-3.64]
Avg. GBC ass.	-0.078 [-0.95]	-0.133 [-1.58]	-0.204 [-2.51]	-0.268 [-3.57]
Synchrony	-0.050 [-0.67]	-0.080 [-1.05]	-0.121 [-1.83]	-0.168 [-2.42]
Metastability	0.008 [0.26]	0.006 [0.21]	0.010 [0.37]	0.014 [0.52]
	125%	130%	135%	140%
Avg. global GBC	-0.313 [-4.58]	-0.362 [-5.71]	-0.383 [-6.07]	-0.394 [-6.08]
Avg. GBC sen.	-0.345 [-4.86]	-0.399 [-6.01]	-0.424 [-6.39]	-0.433 [-6.30]
Avg. GBC ass.	-0.323 [-4.56]	-0.373 [-5.62]	-0.396 [-6.15]	-0.408 [-6.22]
Synchrony	-0.202 [-2.97]	-0.230 [-3.62]	-0.244 [-3.95]	-0.261 [-4.17]
Metastability	0.018 [0.70]	0.019 [0.75]	0.026 [1.03]	0.027 [1.02]

Table 5. ScZ-associated changes of noise parameters. Comparison of average global GBC, average GBC in sensory areas, average GBC in association areas, average synchrony, and average metastability with increased noise (from 105% to 140% in steps of 5%). Shown are the mean differences, i.e. the mean of the default condition minus the respective increased noise condition and in brackets the effect size (Hedge's *g*). The mean in each condition is calculated over the 40 virtual subjects. Significant differences, i.e. a permutation *p* value of < 0.001, are highlighted in bold. Permutation tests were performed using 5,000 permutations of labels.

7 SUPPLEMENTARY TABLES AND FIGURES

551 7.1 Figures

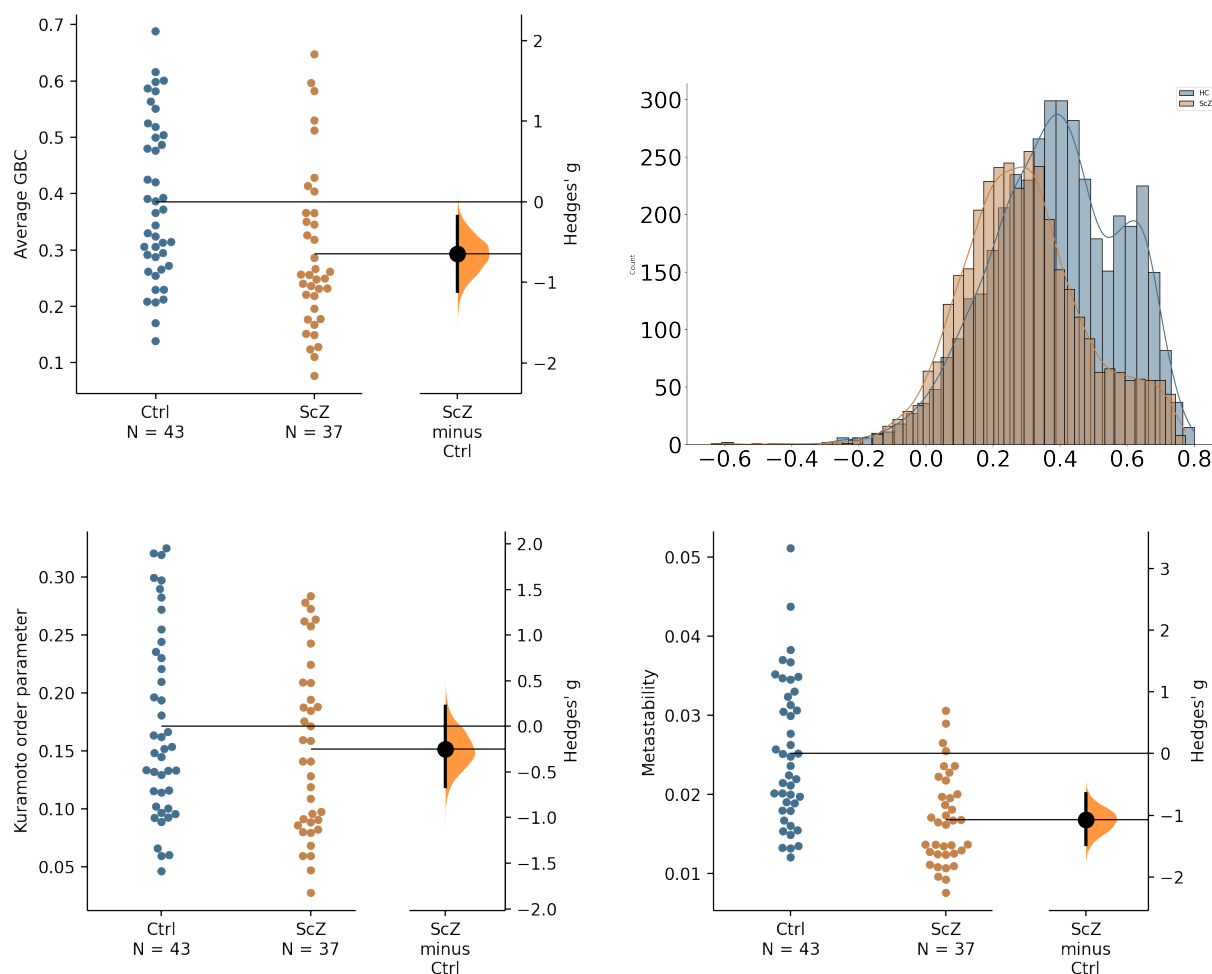

Figure 1. Global differences in functional connectivity and temporal dynamics. a) Comparison of average GBC per participant for the two groups. Individual dots represent average GBC for one participant. The difference plot on the right shows the difference between the groups in terms of effect size. b) Histogram of region-wise GBC values for the two groups. The histogram displays the region-wise GBC data pooled for all participants in each group. c) Synchrony comparison between the two groups. Each dot represents the mean Kuramoto order parameter (a measure of synchrony) for one participant. The difference plot on the right shows the group difference in terms of effect size. d) Metastability comparison between the two groups. Each dot represents the metastability of one participant. The difference plot on the right shows the group difference in terms of effect size.
