Abstract

Objective To analyze the current situation of reperfusion strategies of ST-segment elevation myocardial infarction (STEMI) in China and evaluate the efficacy and safety of different reperfusion strategies, especially pharmaco-invasive percutaneous coronary intervention (PI-PCI).

Methods The CCC-ACS (Improving Care for Cardiovascular Disease in China-Acute Coronary Syndrome) project is a joint study between the American Heart Association and Chinese Society of Cardiology (CSC). STEMI patients who were recruited to the CCC-ACS project between November 2014 and December 2019 and admitted within 48 hours after symptom onset and treated by thrombolysis or percutaneous coronary intervention (PCI) were included in this cohort study. The primary efficacy outcomes were major adverse cardiac cerebrovascular events (MACCEs) that occurred during hospitalization. The primary safety outcomes were Thrombolysis in Myocardial Infarction (TIMI) major or minor bleedings criteria during hospitalization. Univariate regression logistic analysis, multivariable logistic regression analysis, propensity score-matched analysis, and inverse probability of treatment weighting analysis were performed to evaluate the efficacy and safety of different reperfusion strategies.

Results Of 37733 STEMI patients, 35019 patients received primary percutaneous coronary intervention (PPCI), 999 patients received thrombolysis and 1715 patients received PI-PCI. Compared with PPCI, the thrombolysis group had higher incidence of all cause death (1.6% vs 2.8%, $P=0.003$), MACCEs (2.0% vs 3.6%, $P<0.001$), and TIMI major bleedings (1.2% vs 2.2%, $P=0.007$). In the PI-PCI group, the incidence of MACCEs (2.0% vs 0.8%, $P=0.001$), all cause death (1.6% vs 0.4%, $P=0.001$), and cardiac death (1.5% vs 0.4%, $P=0.001$) were significantly lower than PPCI group; and the same conclusion was found in the subgroup of in time from first medical contact(FMC) to reperfusion ≥ 3 h. However, the risk of TIMI minor bleedings (5.1% vs 6.7%, $P=0.008$) was higher in the PI-PCI group in the subgroup of in time from FMC to reperfusion ≥ 3 h. Compared with timely PPCI group, the incidence of all cause death was significantly lower and the incidence of heart failure was higher in the scheduled PCI group. Compared with late PPCI group, the incidence of all cause death, MACCEs were significantly lower in scheduled PCI group. Compared with timely PPCI, the ratio of heart failure was statistically significant higher in the rescue PCI group. There was no significant difference in all outcomes in all models between rescue PCI group and late PPCI group. Moreover, compared with

scheduled PCI \leq 24h group, the scheduled PCI during 24h to 7d group had lower risk of TIMI major or minor bleedings and the scheduled PCI $>$ 7d group had the similar risk of bleedings; the scheduled PCI $>$ 7d group had lower risk of heart failure.

Conclusions This study demonstrates that in STEMI patients who could not perform timely PPCI, PI-PCI is feasible, including rescue PCI, which can reduce the rate of MACCEs and mortality during hospitalization. But the increased risk of bleedings also should be noted. In scheduled PCI after successful thrombolysis, appropriate extension the time window of scheduled PCI can be considered under stable clinical conditions.

Key words: ST-segment elevation myocardial infarction, primary percutaneous coronary intervention, pharmaco-invasive percutaneous coronary intervention, thrombolysis

1. Introduction

ST-segment elevation myocardial infarction (STEMI) is a clinical syndrome defined by the presence of myocardial ischemic symptoms, electrocardiographic (ECG) findings of new ST-segment elevations in two continuous leads or new left bundle branch block, and subsequent detection of biomarkers indicative of myocardial injury.¹

China is facing the dual pressure of aging population and continuous prevalence of metabolic risk factors, and the burden of cardiovascular diseases and the mortality of acute myocardial infarction is increasing.² Primary percutaneous coronary intervention (PPCI) has been the preferred reperfusion strategy for patients with STEMI. However, PPCI is not universally available, and delays in performing PPCI are common in real-world practice.³ Even in some large cities, patients have a high chance of presenting to hospitals not providing around-the-clock PPCI service. The outcome of STEMI is varied significantly in different hospitals. As the efficacy of PPCI is time-dependent, the no-reflow phenomenon in PPCI may lead to failure of myocardial reperfusion. Therefore, intravenous thrombolysis still remains a viable option for reperfusion, and plays an important role in modern STEMI management. However, the reoccurrence of myocardial ischemia after thrombolytic therapy is common. Pharmaco-invasive percutaneous coronary intervention (PI-PCI) strategy, an early reperfusion strategy encompassing initial prompt fibrinolysis with subsequent early catheterization, has been proposed as a therapeutic option for STEMI patients when timely PPCI is not available.^{4,5}

Current evidence on the efficacy and safety of the therapeutic strategies for PI-PCI in patients with STEMI remains limited. We aim to analyze the current situation of reperfusion strategies of STEMI in China and compare the efficacy and safety of different reperfusion strategies during hospitalization, especially PI-PCI.

2. Methods

2.1 Study design and patient selection

The CCC-ACS (Improving Care for Cardiovascular Disease in China-Acute Coronary Syndrome) project, a nationwide registry and quality improvement study focusing on quality of acute coronary syndrome (ACS) care, was launched in 2014 as a collaborative initiative of the American Heart Association and the Chinese Society of Cardiology across China. This study is registered at ClinicalTrials.gov (unique identifier: NCT02306616) and complies with the Declaration of

Helsinki. Detailed information on the design and methodology of the CCC-ACS project has been published previously.⁶ STEMI was defined in accordance with the Chinese Society of Cardiology guidelines for the diagnosis and management of patients with non-ST-segment elevation ACS and STEMI.^{7,8} From November 1, 2014 to December 30, 2019, a total of 113,651 patients with ACS were enrolled in the CCC-ACS project. Among them, 37,733 inpatients with STEMI admitted within 48 hours after symptom onset and treated by thrombolysis or PCI were selected for analysis. The inclusion and exclusion criteria are shown in Figure 1.

PCI=percutaneous coronary intervention; PPCI=Primary percutaneous coronary intervention; PI-PCI=Pharmaco-invasive percutaneous coronary intervention; STEMI=ST-segment elevation myocardial infarction; NSTEMI=non-ST-segment elevation acute coronary syndrome; CABG=coronary artery bypass graft; FMC=first medical contact

2.2 Definition of in-hospital outcomes

The primary efficacy outcomes were major adverse cardiac cerebrovascular events (MACCEs) that occurred during hospitalization. MACCEs were defined as cardiac death, non-fatal myocardial infarction, and acute stent thrombosis or ischemic stroke. The primary safety outcomes were defined as Thrombolysis in Myocardial Infarction (TIMI) major or minor bleeding during

hospitalization.⁹ The net clinical outcomes (NET) were defined as a composite of the primary efficacy outcomes and the primary safety outcomes. The cardiac net clinical outcomes (cNET) were defined as MACCEs, new onset heart failure or new onset heart shock during hospitalization.

2.3 Statistical analysis

Continuous variables were shown as mean \pm SD or median (interquartile range) according to different distributions and were compared using Student's t-tests or Mann-Whitney U test. Categorical variables were presented as the number (percentage) and compared using chi-square test or Fisher exact tests. A linear-by-linear association trend test (Mantel-Haenszel test for trend) was used to assess trends of the ratios of different reperfusion therapy strategies. In-hospital clinical events were evaluated using multivariable logistic regression and adjusted for confounding factors that have been reported more than once as having an effect on outcomes. Candidate adjustment variables included age, female, previous myocardial infarction (MI), hypertension history, diabetes mellitus (DM) history, renal failure history, heart failure (HF) history, stroke history, atrial fibrillation (AF) history, dyslipidemia history, peripheral artery disease (PAD) history, previous PCI, previous coronary artery bypass grafting (CABG), anemia at admission, heart rate, systolic blood pressure (SBP), diastolic blood pressure (DBP), Killip class, hospital grade, length of hospital stay, low-density lipoprotein cholesterol (LDL-C), estimated glomerular filtration rate (eGFR). To consolidate the findings, we also carried out propensity score (PS) method in the study. A logistic regression was performed to estimate PS, adjusting for the variables consistent with the multivariate analysis. We established PS-matched and inverse probability of treatment weighting (IPTW) cohort based on the PS score and evaluated the impact of different reperfusion strategies in STEMI. By this means we obtained a stabilized weight for each case of the study cohort, avoiding any extreme values that may result in unreliable outcomes.

All tests were 2-sided, and a value of $P < 0.05$ was considered statistically significant. All statistical analyses were performed using Statistical Package for the Social Science (SPSS) 26.0 and R version 4.2.2.

3. Results

3.1 Situation of treatment strategies and clinical characteristics in STEMI

From November 2014 to December 2019, a total of 37733 patients were enrolled with a diagnosis of STEMI admitted within 48 hours after symptom onset and treated by thrombolysis or PCI.

Among them, 35019 patients received PPCI, 999 patients received thrombolysis and 1715 patients received PI-PCI. The ratios of different treatment strategies over the 5-year study period were shown in Figure 2. Between 2014 and 2019, The ratio of patients with STEMI received thrombolysis and PI-PCI increased over time while PPCI decreased.

Compared with the PPCI group, the thrombolysis group had a higher proportion of previous MI, previous CABG, previous ischemic stroke history, Killip class I, statins at admission, anti-coagulation therapy, higher levels of blood pressure, LVEF and hemoglobin, and longer length of hospital stay. In contrast, the thrombolysis group had a lower proportion of previous PCI, DM, dyslipidemia, family history of coronary heart disease, tertiary hospital, β -blockers, warfarin, heart rate, the implantation of mechanical assist devices and temporary cardiac pacemaker during hospitalization, and lower levels of CK-MB, troponin I, troponin T, BNP and glucose (Table 1). Compared with the PPCI group, the PI-PCI group was younger, had a higher proportion of statins, higher levels of CK-MB, Troponin T and BNP, and longer length of hospital stay, lower levels of SBP and glucose, a lower proportion of female, tertiary hospital, previous PCI, hypertension, DM, stroke history, β -blockers, and the implantation of temporary cardiac pacemaker (Table 1).

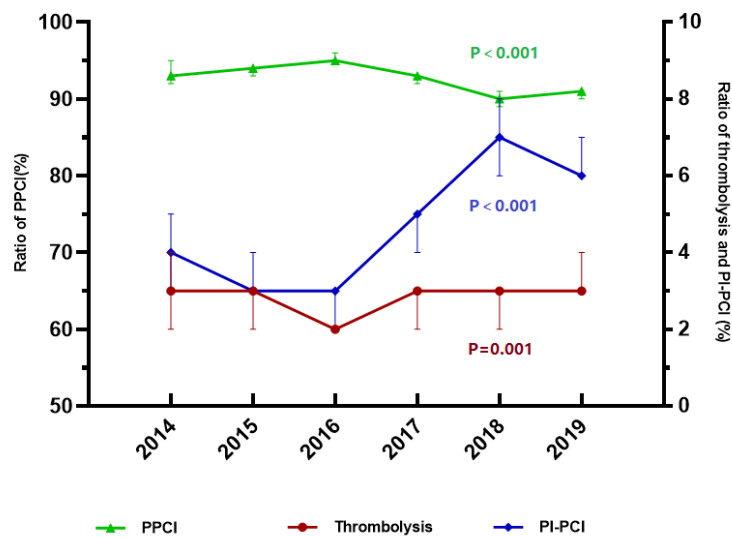

Figure 2. The ratios of PPCI, thrombolysis and PI-PCI from 2014 to 2019

3.2 In-hospital outcomes between PPCI group and thrombolysis group

After adjustment using the PS-matching method, baseline characteristics were well balanced ([Supplemental Table 1](#)). The incidence of all cause death (1.6% vs 2.8%, $P=0.003$), MACCEs (2.0% vs 3.6%, $P<0.001$), cardiac death, non-fatal MI, stroke, TIMI major bleedings (1.2% vs 2.2%, $P=0.007$), the net clinical outcomes, the cardiac net clinical outcomes, cardiac shock, cardiac arrest and new onset heart failure were significantly higher in the thrombolysis group than in the PPCI group, similar results were found after adjustment using the multivariate logistic analyses and PS-matching methods ([Table 2](#)). There was no significant difference in the incidence of TIMI minor bleedings between two groups ([Table 2](#)).

3.3 In-hospital outcomes between PPCI group and PI-PCI group

After adjustment using the PS-matched method, baseline characteristics were well balanced ([Supplemental Table 2](#)). The incidence of MACCEs (2.0% vs 0.8%, $P=0.001$), all cause death and cardiac death were significantly lower in the PI-PCI group and similar results were found after adjustment using the multivariate logistic analyses and the PS-matching methods. The risk of new onset heart failure and the cardiac net clinical outcomes were higher in PI-PCI group and the difference were statistically significant after adjustment using the multivariate logistic analyses. There was no significant difference in the incidence of outcomes including stroke, cardiac arrest, cardiac shock, TIMI major or TIMI major bleedings and the net clinical outcomes between two groups. ([Table 3](#)).

Supplemental Table 2. Comparison of baseline characteristics between PPCI and PI-PCI groups in the whole, PS-matched and IPTW cohorts

3.4 Subgroup analysis

3.4.1 Comparison of outcomes between PPCI with PI-PCI groups in the time from onset to FMC

In the subgroup analyses, the time from onset to FMC \geq 3h, 22413 patients received PPCI and 1211 patients received PI-PCI. After adjustment using the PS-matching method, baseline characteristics were well balanced ([Supplemental Table 3](#)).

The incidence of all cause death (0.2% vs 1.6%, $P=0.001$) and cardiac death (0.2% vs 1.5%, $P=0.002$) were lower in the PI-PCI group than in the PPCI group in all models. The incidence of MACCEs (0.7% vs 1.9%, $P=0.003$) was lower in the PI-PCI group than in the PPCI group in unadjusted and adjusted models. The risk of TIMI major and minor bleedings was significantly higher in the PI-PCI group in all cohorts. The ratio of new onset heart failure, the net clinical outcomes and the cardiac net clinical outcomes were significantly higher in PI-PCI group in the multivariate logistic analyses cohort. There was no significant difference in outcomes including non-fatal MI, stent thrombosis, cardiac shock, cardiac arrest and stroke ([Table 4](#)).

3.4.2 Comparison of outcomes between PPCI with PI-PCI groups according to the reperfusion timing

Baseline characteristics are summarized in [Supplemental Table 4](#). Based on the reperfusion timing, we divided the PPCI group into the Timely PPCI (time from FMC to wire crossing of the infarction related artery ≤ 120 mins) and Late PPCI (time from FMC to wire crossing of the infarction related artery > 120 mins) groups; The PI-PCI is divided into scheduled PCI (PCI was scheduled within 24 hours after successful thrombolysis) and rescue PCI (PCI was performed immediately after thrombolysis failure) ([Supplemental Table 5](#)).

Compared with timely PPCI group, the incidence of all cause death was significantly lower in scheduled PCI group in all model. The incidence of MACCEs was statistically significant lower in the scheduled PCI group in the adjusted model. However, the incidence of heart failure was significantly higher in the scheduled PCI group in all models. The incidence of TIMI major or minor bleedings and the cardiac net clinical outcomes was statistically significant lower in scheduled PCI group in the unadjusted and adjusted models ([Figure 3 A](#)). Compared with late PPCI group, the incidence of all cause death, MACCEs were significantly lower in scheduled PCI group in all models and the incidence of heart failure was significantly higher in the scheduled PCI group in the unadjusted and adjusted models ([Figure 3 B](#)). Compared with timely PPCI, the ratio of heart failure was statistically significant higher in the rescue PCI group in the adjusted and PS-matched models and the ratio of the cardiac net clinical outcomes was higher in the rescue PCI group in the PS-matched model. ([Figure 3 C](#)). There was no significant difference in all outcomes in all models between rescue PCI group and late PPCI group ([Figure 3 D](#)).

For further analysis, according to the time to PCI after thrombolysis in scheduled PCI group, we divided the patients into 3 groups: scheduled PCI ≤ 24 h group, scheduled PCI during 24h to 7d group, and scheduled PCI > 7 d group. Compared with scheduled PCI ≤ 24 h group, the rate of TIMI major or minor bleedings and the net clinical outcomes were lower in scheduled PCI during 24h to 7d group in all models, and the rate of heart failure was also lower in scheduled PCI during 24h to 7d group in unadjusted model ([Figure 3 E](#)). In addition, compared with scheduled PCI ≤ 24 h group, the scheduled PCI > 7 d group had lower risk of heart failure in all models, and lower cardiac net clinical outcomes in IPTW model ([Figure 3 F](#)).

Figure 3. Main outcomes in subgroup analysis between PPCI with PI-PCI groups according to the reperfusion timing

Based on the reperfusion timing, we divided the PPCI group into the Timely PPCI (time from FMC to the wire crossing of the infarction related artery ≤ 120 min) and Late PPCI (time from FMC to the wire crossing of the infarction related artery > 120 min) groups; The PI-PCI is divided into scheduled PCI (PCI was scheduled within 24 hours after successful thrombolysis) and rescue PCI (PCI was performed immediately after thrombolysis failure); According to the time to PCI after thrombolysis in scheduled PCI group, we divided the patients into 3 groups: scheduled PCI ≤ 24 h group, scheduled PCI during 1d to 7d group and scheduled PCI > 7 d group.

(A) Comparing scheduled PCI with timely PPCI in main outcomes by unadjusted model, adjusted model and PS-matched model;

(B) Comparing scheduled PCI with late PPCI in main outcomes by unadjusted model, adjusted model and PS-matched model;

(C) Comparing rescue PCI with timely PPCI in main outcomes by unadjusted model, adjusted model and PS-matched model;

(D) Comparing rescue PCI with late PPCI in main outcomes by unadjusted model, adjusted model and PS-matched model;

(E) Compared scheduled PCI ≤ 24 h with scheduled PCI during 1~7d in main outcomes used by unadjusted model, adjusted model and IPTW model;

(F) Comparing scheduled PCI ≤ 24 h with scheduled PCI > 7 d in main outcomes by unadjusted model, adjusted model and IPTW model.

OR=odds ratio; CI=confidence interval; MACCEs=major adverse cardiac cerebrovascular events; TIMI=Thrombolysis in Myocardial Infarction; PCI=primary percutaneous coronary intervention; PS=propensity score; IPTW=inverse probability of treatment weighting; PPCI=primary percutaneous coronary; FMC=first medical contact; PI-PCI=Pharmaco-invasive percutaneous coronary intervention

4. Discussion

In our study, nearly 10% patients with STEMI received thrombolysis, in which 2.6% of the patients received thrombolysis alone. Consistent with the previous reports, our study showed that patients with STEMI were more male and had comorbidities, such as hypertension, DM and ischemic diseases (including previous coronary heart diseases, ischemic stroke, and PAD).¹⁰
¹¹Although PPCI is the reperfusion strategy of choice in STEMI patients when performed by an experienced team in a timely manner, thrombolysis therapy is still more feasible and often the only available, even the mainstay reperfusion strategy for STEMI in resource-poor settings without advanced technology or access to specialized care, especially in county-level hospitals.
^{10,12}

Thrombolytic therapy can improve the perfusion of the coronary artery and the microcirculation system. The following points should be noted in the thrombolysis. Firstly, the effect of thrombolysis has a clear time-dependence, both clinical guidelines and previous studies indicated that onset time ≤ 3 h was independent predictors of successful thrombolysis.^{7,11,13-17} However, the proportion of patients from the time of onset to thrombolysis ≤ 3 h in China was only 27.9%, while the proportion in the same period (2014) was as high as 54% in the United States of America, indicating that the pre-hospital delay of thrombolysis in STEMI patients in China is still serious problem.¹⁸ Secondly, the use of fibrin-specific thrombolytic agents was also a key factor in the success of thrombolysis therapy. In our study, the proportion of patients used non-fibrin-specific agents in thrombolysis group was 32.1%, which may lead to the poor efficacy of thrombolytic therapy. At last, hemorrhage is the most common complication of thrombolysis therapy, especially intracranial hemorrhage (0.9-1%). In our study, the rate of TIMI major bleedings was also significantly higher in thrombolysis group. The CAMI study showed that compared with urokinase, alteplase and reteplase had a higher rate of thrombolytic success, but more in-hospital bleeding events.¹⁵ Previous research found that prourokinase, as a novel and fibrin-specific anticoagulant, not only effectively recanalized blood vessels and improve the cardiac function of patients with STEMI, but also had very low rate of bleeding complications, which may provide an alternative and appropriate thrombolytic drug option for STEMI patients.^{19,20}

Besides, this study showed that patients receiving thrombolysis alone had worse in-hospital ischemic outcomes. Previous studies have shown that plaque rupture and plaque erosion are the 2 most common underlying mechanisms for sudden cardiac death and acute coronary syndrome. It

has been well known that the necrotic core is 6 times more thrombogenic than all other plaque components.^{21,22,23} Confirmed by optical coherence tomography(OCT), residual thrombus burden 1 day after fibrinolysis was greater in a rupture compared with erosion in patients with successful fibrinolysis for STEMI.²⁴ The advantage of the thrombolytic therapy is to dissolve the large, medium, and microthrombus in coronary arteries, which can improve the perfusion of the coronary artery and the microcirculation system. However, the reoccurrence of myocardial ischemia after thrombolytic therapy is common. Therefore, thrombolysis therapy alone is not sufficient for patients with STEMI.

Previous studies showed that PI-PCI was not inferior to PPCI, and even better in follow-up in ischemic or mortality events. In the STREAM study, the composite end point of death, cardiac shock, congestive HF, and reinfarction was numerically but non-statistically significant lower in the pharmaco-invasive (PI) arm at 30 days.²⁵ The EARLY-MYO Trial indicated that a PI strategy with half-dose alteplase and timely PPCI offered more complete epicardial and myocardial reperfusion compared with PPCI in patients with STEMI presenting ≤ 6 hours after symptom onset but with an expected PCI-related delay in China.²⁶ The STREAM-2 study, enrolling in patients aged ≥ 60 years with STEMI, showed that there were no differences in lytic versus PPCI patients, either in symptom onset to start of reperfusion time, or in final TIMI 3 flow after PCI or last angiography, despite a higher baseline TIMI 0/1 flow prior to PCI in the intervention group.²⁷ The results of this study indicated that PI-PCI was superior to PPCI in mortality and MACCEs during hospitalization, also in the subgroup of the time from onset to FMC ≥ 3 h. However, PI-PCI had higher risk of TIMI major or minor bleedings than PPCI in the subgroup of the time from onset to FMC ≥ 3 h. A Norway Study showed similar results in patients who did not have PPCI performed within 120 mins.²⁸ An increased risk of bleeding may be caused by simultaneous application of thrombolytic and anticoagulant drugs in PI-PCI strategy. In our study, the incidence of heart failure was higher in the PI-PCI group. Movement of patients during transport increase the cardiac burden and more early reperfusion of PI-PCI increase the occurrence of malignant arrhythmia, which may increase the occurrence of in-hospital new onset HF in PI-PCI.

A meta-analysis compared pharmacoinvasive therapy (PIT, defined as administration of thrombolytic drugs followed by immediate PCI only in case of failed thrombolysis) with PPCI, showing that PIT significantly decreased short-term mortality [OR=1.46(1.08 to 1.96), I²=0%,

P=0.01] in those studies with a 200 mins of symptom-onset-to-device time.²⁹ Jamal *et al.* found that patients who underwent late PPCI had higher mortality rates than those underwent a PI strategy.³⁰ In our study, compared with timely PPCI and late PPCI, scheduled PCI group was better in in-hospital mortality and MACCEs, which indicated early thrombolytic therapy may further shorten the myocardial ischemia time and reduce the ischemic events. The rate of heart failure was higher in the scheduled PCI, which may be caused by the worse condition of the scheduled PCI group, especially in the ratio of Killip II-IV class.

European Society of Cardiology (ESC) and Chinese guidelines recommend a door-to-balloon time of ≤ 120 minutes.^{7,11} American College of Cardiology and American Heart Association (ACC/AHA) guidelines recommend a door-to-balloon time of < 90 minutes.¹⁴ There are various conditions, including occupancy of cardiac catheterization laboratory, will of patients and their families, and unsuitable clinical conditions of patient, inevitably increase the time to revascularization in the clinic and leading to increased risk of in-hospital mortality. At present, the total ischemic time rather than door-to-balloon time is the principal determinant of outcomes in STEMI. PI-PCI is a possible strategy better than PPCI in patients requiring transfer. PI-PCI can shorten the time of myocardial ischemia, significantly reduce the occurrence of no-reflow, markedly increase the proportion of TIMI 3 flow, expand the subsequent PCI time by early thrombolysis, and reduce the mortality rate.³¹ Therefore, for patients who cannot perform timely PCI, the reperfusion strategy of PI-PCI is relatively effective and safe. The factors needs to be considered including symptom-onset to first medical contact time, expected time of transfer to a PCI-capable hospital, and patients risk factors. However, it is notable that PI-PCI may increase the risk of bleeding during hospitalization. In suitable patients, PI-PCI should be evaluated in large clinical trials to assess its clinical and safety outcomes.

Our study also compared the in-hospital efficacy of performing PCI at different times after successful thrombolysis. Compared with scheduled PCI ≤ 24 h group, the scheduled PCI during 24h to 7d group had lower risk of TIMI major or minor bleedings, which may be caused by simultaneous application of thrombolytic drugs and anticoagulant drugs within a short time. However, the scheduled PCI > 7 d group had the similar risk of bleedings with scheduled PCI ≤ 24 h group, which may show that the prolonged using of anticoagulants achieved a high bleeding risk similar to the simultaneous application of anticoagulants and thrombolytic drugs. In addition,

the proportion of receiving anti-coagulation therapy in the scheduled PCI during 24h to 7d group was lower than both the scheduled PCI \leq 24h group and the scheduled PCI $>$ 7d group, which may be another reason for the low incidence of bleeding. Besides, compared with scheduled PCI \leq 24h group, the scheduled PCI $>$ 7d group has lower risk of heart failure. This study is a retrospective study, the treatment strategy of patients depends on the judgment of the doctor, and patients with serious clinical conditions are more inclined toward early revascularization. In the baseline data, the ratio of Killip II-IV class in scheduled PCI $>$ 7d group was the lowest (20.4%) among all the subgroups, which supported the above speculation. Therefore, it is feasible to appropriately prolong the scheduled PCI time in STEMI patients, accompanied by more stable clinical conditions, such as hemodynamic stability, stable symptoms, etc.

5. Limitation

First, this was a retrospective observational study, so we could not rule out unmeasured potential confounders. Second, because the participating hospitals were not randomly selected, which may not reflect the clinical situation of all hospitals in China. Finally, this study only analyzed in-hospital outcomes and did not include long-term follow-up.

6. Conclusions

In STEMI patients who could not perform timely PPCI, PI-PCI is feasible, including rescue PCI, which can reduce the rate of MACCEs and mortality during hospitalization. But the increased risk of bleedings also should be concerned. In scheduled PCI after successful thrombolysis, appropriate extension the time window of scheduled PCI can be considered under stable clinical conditions.

Declaration of competing interest

The authors declare that they do not possess any conflict of interest.

Acknowledgement

The authors thank Dr Jun Liu (Department of Epidemiology, Beijing Anzhen Hospital, Capital Medical University, Beijing Institute of Heart, Lung and Blood Vessel Diseases, Beijing, China) for her technical assistance. We acknowledge all participating hospitals for their contributions to CCC-ACS Project ([Supplemental Table 6](#)).

Funding

The CCC-AF project was supported by a collaborative project of the American Heart

Association and the Chinese Society of Cardiology. The American Heart Association received funding from Pfizer through an independent grant for learning and change and AstraZeneca as a quality improvement initiative.
